CHAMBERS'S

INFORMATION FOR THE PEOPLE

EDITED BY

WILLIAM AND ROBERT CHAMBERS

FIFTH EDITION

VOLUME I.

W. & R. CHAMBERS
LONDON AND EDINBURGH
1884

Edinburgh:
Printed by W. & R. Chambers.

PREFACE.

IT is now many years since CHAMBERS'S INFORMATION FOR THE PEOPLE first issued from the press. The cheapness of the work, its novelty, and the varied mass of useful knowledge which was embraced, rendered it a popular favourite. Without adventitious aid, its sale was immense. Since that time it has undergone numerous improvements both as regards matter and general appearance. Again, from the constant and rapid advance in every branch of science and art, it has been deemed necessary to recast the work in adaptation to the existing state of human knowledge. Hence the present, or FIFTH EDITION, which has been revised under the able Editorship of ANDREW FINDLATER, LL.D.

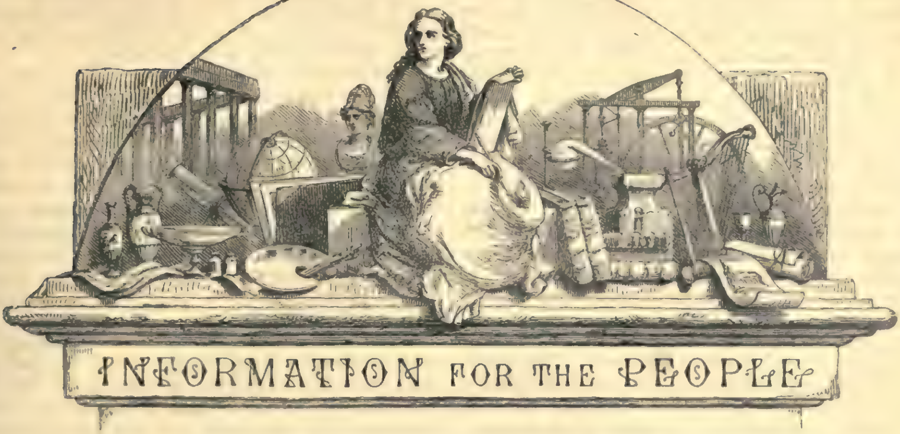
Designed in an especial manner for the People, though adapted for all classes, the work will be found to comprise those subjects on which information is of the most importance; such as the more interesting branches of science—physical, mathematical, and moral; natural history, political history, geography, and literature; together with a few miscellaneous papers, which seem to be called for by peculiar circumstances affecting the British people. Thus everything is given that is requisite for a *generally well informed man* in the less highly educated portions of society, and nothing omitted appertaining to intellectual cultivation, excepting subjects of professional or local interest. It will be understood, then, that the INFORMATION FOR THE PEOPLE is not an encyclopædia, in the comprehensive meaning of the word, but rather one embracing only the more important departments of general knowledge. The ruling object, indeed, has been to afford the means of *self-education*, and to introduce into the mind, thus liberated and expanded, a craving after still further advancement.

It may well be said of the present edition, as was said of the last, that the improvements are very considerable. The scientific treatises have, in general, been carefully remodelled, with due attention to recent discoveries. Subjects the interest of which is past have been omitted or greatly condensed, and others of a more enduring and important nature have taken their place. In the Indexes will be found a reference to almost every subject necessary in ordinary circumstances to be known.

In one important respect—that of the pictorial illustrations and embellishments—it must be obvious, to the most cursory observation, that a very great improvement has been effected.

W. & R. C.

CONTENTS.



ASTRONOMY.

ASTRONOMY teaches whatever is known of the heavenly bodies. The earth itself it regards only as one of them—viewing it as an entire body, such as it would appear were we to behold it from a sufficient distance.

The subject falls naturally under two general heads: 1*st*, A *description* of the heavenly bodies—the aspect of the heavens as a whole; the distances, shapes, and magnitudes of the several bodies; the figures they describe in their motions; the way in which they are grouped into systems, &c. 2*d*, Physical Astronomy, or the nature of the powers or forces that carry on the heavenly motions, and the laws that they observe. The processes of calculating the motions from a knowledge of the laws, with a view to turn them to the use of man, and the management of mathematical instruments for taking the necessary observations, form the art of the practical astronomer; into which we cannot enter.

GENERAL APPEARANCES OF THE HEAVENS.

When we raise our view to the sky over our heads, we find it occupied with the sun by day, and the moon and stars by night. The sun is evidently never at rest, but is either ascending upwards in the sky from the east, or else sinking towards the horizon or sky-line in the west, where his body goes out of sight. The same continual motion of rising and setting is observed in the moon and in the stars. If, at the beginning of a winter-night, we fix our attention on a conspicuous star near the east point of the horizon, and continue to observe it, we shall see it rising higher and higher for about six hours; it will then begin to descend to the west, and in about six hours more it will reach the west point of the horizon, and disappear. If we commence our watch again on the following night, we may discover the same star rising at the east point at about the same hour, and going through its course of mounting, crossing, and descending the sky as before.

If we turn to some point between east and north, and notice a star just rising, we find it gradually ascending in the heavens up to a certain point; then descending to the west, and going out of sight; and finally reappearing in the east in about twenty-four hours from the time of its previous rising: but these twenty-four hours, instead of being spent one half above and the other half below the horizon, as in the former case, will be unequally divided between the presence and the absence of the star; more than twelve hours will be taken to pass from the rising to the setting, and less than twelve hours will elapse between the setting and the next rising. The further *north* the point of rising, the longer the time spent in the upper course, and the shorter the time in the under and unseen course. If we go to the north point itself, and observe a star just a little above the horizon, we shall find that it will spend the first twelve hours in ascending to its highest point in the heavens, and the next twelve in descending to the neighbourhood of the horizon; and it will not go beneath at all, but commence again to rise and describe a circle in the heavens as before; such a star, therefore, will be always in sight. In like manner, all stars in the north quarter lying within the circle described by this never-setting star will perform their daily movement above the horizon.*

Poles, Axis.—In the inside of these circling motions we may observe a point in the sky which

* In the foregoing and in succeeding paragraphs, it is supposed that the stars may be seen day and night. By the naked eye no star can be seen while the sun is up, but they are all in their places nevertheless. The intense light of the sun generally makes other celestial objects invisible. With good telescopes, however, the stars may be seen in the daytime, in a clear day, except in the sun's immediate neighbourhood. From the bottom of deep wells and mines the stars in the sky overhead are seen through the day. When the moon is at a considerable distance from the sun, it may be seen when the sun is up.

seems to be their common centre. A star lying in it would be perfectly at rest, and stars near it describe very small circles, or move within narrow limits. This point of rest is situated in the north quarter of the heavens, more than half-way up from the sky-line, towards the summit. It is called the *north celestial pole*, or the *north pole of the heavens*, and is the most important point in the sky for astronomical references. No visible star is actually residing in it; but a very bright star lies near it, called for that reason the *pole-star*.

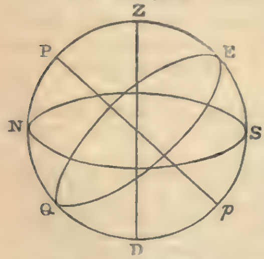
By observing the movements of stars that rise in the *south-east*, and seeing their visible paths becoming shorter and shorter, as they lie more southward, we cannot help inferring that there is a large region of stars describing circles wholly out of sight, and that there is a point beneath, which is the centre of these circles, corresponding to the centre of the northern heavens. This point is called the *south celestial pole*. An imaginary line drawn from pole to pole, or from the elevated north resting-point to the concealed south resting-point, is called the *axis of the heavens*, or the *axis of the world*. Owing to one pole being a considerable way up in the sky, and the other far down out of sight, it is evident that the great whirl of the starry sphere goes on in a *slanting* direction.

Besides the poles and axis of the heavens, there are many other imaginary points, lines, and circles, which it is convenient to suppose drawn among the stars, and which of course we can actually draw in all figures and sketches of the starry heavens. The most important of these may be here explained.

Equator, *Horizon*, *Zenith*, *Meridian*.—The celestial *equator*, so called because it cuts the starry sphere into two equal halves, is an imaginary circle passing round the heavens midway between the two poles. The two halves into which it divides the sphere of stars form the *northern and southern hemispheres*.

The *horizon*, or the line where the earth seems to meet the sky, makes another division of the starry sphere, into the visible hemisphere, or stars *above the horizon;* and the invisible, or stars *below the horizon*. The point of the heavens directly over our heads, or the very summit of our sky, is called the *zenith*. The point that we should see directly beneath our feet, if the earth could be seen through, is called the *nadir*.

Another artificial circle supposed to be drawn in the heavens, is the *meridian*. Like the equator and the horizon, it divides the starry sphere into two equal half-spheres, but in a different direction from either of those circles. In fact, it is so drawn as to be perpendicular to both. It passes through the north point of the horizon, then upward through the north celestial pole, through the zenith, down through the south point of the horizon, through the south celestial pole beneath, and finally through the nadir: so that, in the first place, it lies north and south; and in the second place, it stands upright. Thus, if in the figure, P*p* be the great axis of the heavens terminating in the north and south celestial poles, EQ the celestial equator, NS the horizon, and N and S the north and south points of it, Z the zenith, and D the nadir; then the enclosing circle of the figure NPZES*p*DQ is the meridian.



It is evident from this description, that when the sun or the moon passes the meridian, or lies due south, it has reached its greatest height, and will immediately commence to descend. Hence, also, we can determine the meridian line in the heavens, by observing where a star is when it ceases to ascend and begins to descend; which of course gives us the direction of the north and south points, and serves the same end as the mariner's compass. It is evident, also, that the middle point between a body's rising and setting is its meridian passage.

Fixed Stars and Wanderers.—Although the general starry sphere turns round in one great mass, so that each star is always in the same place among the other stars, it was early observed that there were exceptions to the common movement; and that a small number, besides going round the sky daily, shift about among the others. In opposition to these erratic or *wandering* bodies, the general multitude that kept their places were called *fixed stars*.

The moon, for example, is soon observed to be an erratic body. One night we see it near one star, and the next night it is at a considerable distance to the east of it; even in a few hours there is a visible change of position. In the course of a month, we find it has gone through a complete circle from west to east among the stars, and come back nearly to the same place.

The sun has a similar motion, though it is slower, and also less easily marked, because his light prevents the stars from being seen at the same time. If we could see a star any night setting at the same instant as the sun, we should find that the next night it would set four minutes *before* the sun, the sun having in the meantime moved backward a short distance.

Ecliptic, *Latitude*, *Longitude*, *Declination*, &c.—When this motion of the sun among the stars is observed for a length of time, it is found that it forms a circuit, bringing him back, in the course of a year, to the same position. The path, however, which he travels, is not exactly east and west, or parallel to the equator. If this were the case, the sun would rise and set always in the same points of the horizon. But we see that on the 21st of March, for instance, he rises exactly in the east; for the next three months the point of his rising is more and more north of east, till the 21st of June, when it begins to recede, and again reaches the east point on the 21st of September; and during the winter months it makes a similar approach to and retreat from the south. The amount of divergence either way is about a fourth of the distance between the east point and the north or south point. From this, and other appearances, it is evident that the annual path described by the sun among the stars runs slanting across the equator. This is an important circle in astronomy, and is called the *Ecliptic;* the angle which it makes with the equator is called its *obliquity*, and on this depends the variety of the seasons. Its amount is about a fourth of a quarter circle (23° 28′).

The points where the celestial equator and the

ecliptic cross one another are called the equinoctial points, because the sun is in them at the equinoxes. The vernal equinoctial point, called Aries, is used as a fixed mark from which to measure distances on the heavens east and west, just as we measure distances east and west on the earth, or terrestrial longitude, from Greenwich.

The terms *latitude* and *longitude* have different meanings in astronomy and in geography. The latitude of a place on the earth's surface is its distance north or south of the equator; the latitude of a planet or star is its distance from the ecliptic, while its distance from the celestial equator is called *declination*. The longitude of a place is its distance east or west from the first meridian counted along the earth's equator; longitude in the heavens is distance eastward from the point Aries, measured in the direction of the ecliptic, and not in that of the equator. The distance of a heavenly body from Aries, measured in the direction of the celestial equator, is called its *right ascension*. The reason why the ecliptic is chosen to refer the latitudes and longitudes of the heavenly bodies to, is, that it is the only circle in the heavens that approaches to the permanency of the earth's equator; it maintains almost a fixed position among the stars, while the celestial equator shifts its position in the course of ages, and thus divides the starry sphere differently at different periods.

Besides the sun and moon, there are a good many other wandering stars. The ancients discovered five of these, and gave them the name of *planets*, from the Greek word 'to wander.' The rest have been discovered since the invention of the telescope.

Copernican and Ptolemaic Systems.—We have hitherto spoken of the *appearances* of the heavenly bodies and their motions, without inquiring whether they are as they seem. These apparent motions were long considered to be real motions. The earth was believed to be—what it seems to be—a fixed station, the centre of the universe; the starry sphere was a solid shell, revolving daily with its thousand fixed fires round the central earth; while within it were a succession of crystal spheres, carrying the sun, moon, and planets, and, while partaking of the common motion from east to west, having also each a motion of its own. But as observations of the planetary motions were multiplied, it became more and more difficult to account for all the appearances in this way. At last it was found necessary altogether to change the point of view—to give up the earth as the centre of all the heavenly motions, and admit that it itself, along with the other planets, is in motion round the sun as a centre. This view, called the Copernican system, from Copernicus, its author, or rather reviver—for it had been held by more than one ancient philosopher—is now universally prevalent; the earlier is known as the Ptolemaic system, from Ptolemy, the chief ancient writer on the subject whose works we possess.

Instead of attempting to state the arguments by which the old opinions are refuted, we will proceed at once to give an outline of what is now believed to be the arrangement and constitution of the heavenly bodies. The simple way in which the Copernican system accounts for all the appearances, is the best argument in its favour.

THE SOLAR SYSTEM.

Of the heavenly bodies, those spoken of above as wanderers compose a group altogether apart, the earth being one of them. The sun, which is vastly greater than all the rest put together, forms the centre of the group; which is hence called the *solar* system (from *sol*, the Latin word for 'sun'). Though the distances of the bodies of this group, from the central sun and from one another, are enormous when measured by ordinary terrestrial standards, they become as nothing when compared with the space that separates the whole of them from the nearest of the fixed stars. The solar system forms thus a compact inner world, cut off by an almost immeasurable chasm from the outer universe. It is with this inner world that the astronomer has chiefly to do; what is known of the fixed stars will be spoken of apart, under the head of Sidereal Astronomy.

Around the sun as a centre, the smaller bodies or *planets* wheel at different distances in paths or *orbits* of a round form, being what are called ellipses; these orbits lie pretty nearly in the same plane, a plane passing through the sun's centre; and the motions of the planets are, as a general rule, all in one direction—from west to east.

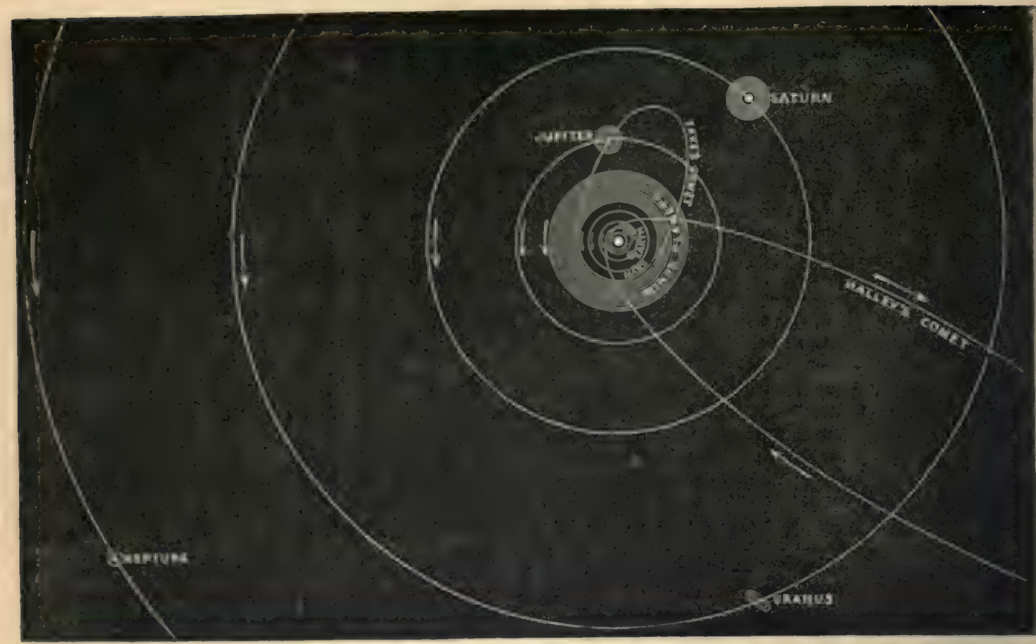
Some of the planets have other planets moving round them as centres—the moon, for instance, round the earth. These are called *secondary* planets, *moons*, or *satellites;* while those that move round the sun are called *primary* planets. The primary planets now known consist—*1st*, of eight larger planets, including the Earth; their names, in the order of their nearness to the sun, are—Mercury, Venus, the Earth, Mars, Jupiter, Saturn, Herschel or Uranus, and Neptune. *2d*, A group of small planets, called sometimes also asteroids, of which more than two hundred are now known. They are situated between Mars and Jupiter.

The satellites or moons, as yet discovered, number eighteen; of which the Earth has one, Mars two, Jupiter four, Saturn eight, Uranus four, and Neptune one. In addition to its moons, Saturn is attended by a luminous ring.

Those singular bodies called *comets* (Lat. *coma*, a lock or brush of hair) also belong, many of them at least, to the solar system. And in addition to the above luminous members of the system, it is now becoming apparent that there are multitudes of dark bodies, of various sizes, circling in the spaces between the known planets, some of which become visible to us when they accidentally enter our atmosphere as *shooting-stars* and other forms of *meteors*. See METEOROLOGY.

Such is a brief inventory, as it were, of the furniture of this inner world to which we belong. The figure on the following page represents the relative positions of the chief planetary orbits. Appended are tables of the diameters, distances, and other numerical particulars of the several bodies.

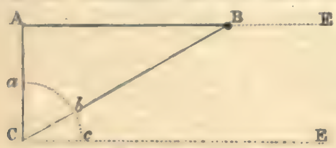
Astronomical Mensuration.—Though it would be inconsistent with the scope of the present sketch to describe minutely the processes by which these numbers are found, it is necessary to give a general idea of the methods followed, that the reader may be able to conceive the possibility of measuring and weighing objects so completely beyond our reach.



The Solar System, to the orbit of Neptune.

	Diameter in Miles.	Density, Earth's being = 1.	Mass, Sun's being = 1.	Distance from Sun in Millions of Miles.	Period of Revolution in Days.	Velocity in Orbit—Miles per Hour.	Velocity of Rotation at Equator—Miles per Hour.
MERCURY	2,962	1·24	$\frac{1}{4865751}$	35	88	105,330	386
VENUS	7,510	0·92	$\frac{1}{401211}$	66	225	77,050	1,010
EARTH	7,912	1·00	$\frac{1}{314760}$	$92\frac{1}{2}$	$365\frac{1}{4}$	65,533	1,040
MARS	4,920	0·52	$\frac{1}{2546247}$	139	687	53,090	628
MINOR PLANETS.							
JUPITER	88,390	0·22	$\frac{1}{1046}$	476	4,332	28,744	27,985
SATURN	71,904	0·12	$\frac{1}{3496}$	872	10,759	21,221	21,538
URANUS	33,024	0·18	$\frac{1}{24899}$	1754	30,687	14,963	10,921
NEPTUNE	36,620	0·17	$\frac{1}{18780}$	2746	60,127	11,958	?
SUN	852,584	0·25	1	*	*	*	4,407
MOON	2,153	0·63	$\frac{1}{24490744}$	*	*	2,273	10

The astronomer finds the distance between objects, not by measuring lines, but by measuring *angles*. Even distances on the earth are most

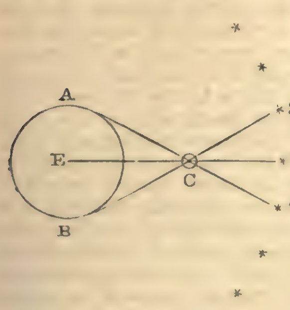


accurately measured in this way, as in trigonometrical surveying. Suppose that an observer at A wishes to ascertain the distance of an inaccessible object at B; it could never be found by looking at it from A alone. He chooses another station, C, to which he has access, in a direction perpendicular, we shall say, to the direction of B, and at a convenient distance, say 100 yards. If the object looked at from A lay directly east, it will no longer be east when looked at from C; its direction is now CB, not CE, and the difference of direction is seen in the greater or less wideness of the opening between those two lines, or in the *angle* BCE, as it is called. The size of such an angle is ascertained by describing a circle from the point C, and measuring how many degrees (that is, 360th parts of the circle) the arc *bc* contains.

By considering the figure, it will be seen that the more distant B is, the smaller must be the angle BCE, and also ABC, which is evidently equal to BCE. For every size of the angle ABC, there is a certain fixed length of AB (the length of AC remaining the same); and trigonometry teaches, from knowing the *base* AC and the angle opposite, to find the length of AB. Everything depends on measuring the angles of direction, or the angular distances, accurately. Degrees are divided each into 60 parts, called *minutes*, and these again into 60 parts, called *seconds*; and astronomical instruments are now so delicate that a difference of direction of one second can be measured.

The difference of direction in which a body is seen when viewed from two places at a distance from one another, is called by astronomers

parallax, or displacement. The annexed figure represents the effect of parallax on a heavenly body C. V is its *true* place, or place in the sky as seen from the earth's centre; T is its place as seen from the surface at A, and the arc TV, or the angle ACE, is the amount of the horizontal parallax.



The distances of the heavenly bodies, even the nearest of them, are so great, that even when the two stations are taken as wide apart as possible—that is, from the opposite sides of the earth, where the distance between them is equal to the earth's diameter, or nearly 8000 miles—the angle of parallax ACB, or the displacement on the sky TS, is very small. In the case of the moon, the nearest of the heavenly bodies, it is nearly two degrees; and by means of it the distance of the moon is found to be about 239,000 miles, or about sixty times the half-diameter or radius of the earth. When the sun is observed from opposite sides of the earth, he suffers a displacement of only seventeen seconds of a degree. On so small an angle, a slight error of observation materially affects the result; and therefore other expedients were had recourse to, to determine the sun's distance with greater certainty and exactness, which may be stated in round numbers as 92,500,000 miles. When the distance of the earth from the sun was once known, a new and vastly extended base was obtained for the trigonometrical survey of the heavens. As the earth travels in its annual circuit round the sun at the distance of 92,500,000 miles, by observing a heavenly body at two different times, at an interval of six months, we in effect observe it from two stations removed from each other by the whole breadth of the earth's orbit, or nearly 185,000,000 miles. The displacement produced in this way is called *annual parallax*. Even this enormous base becomes as nothing when applied to measure the distances of the fixed stars; by far the greater number shewing no sensible parallax.

Knowing the distances, we can find the real sizes of bodies from their apparent size, or from their dimensions, taken by an angular instrument. If an object be a mile off, and if its breadth make an angle of 1° at that distance, its lineal breadth is determined by these two quantities. Thus the *moon*, being about 239,000 miles from the earth, and having an angular breadth in the sky of somewhat more than half a degree, its actual breadth must be about 2000 miles. The accurate estimate is 2153 miles. The *sun* has almost the same apparent size in the sky as the moon; but being at nearly 400 times the distance of the moon, it must have nearly 400 times the breadth of the moon to appear equally large. The diameters of the planets are determined in the same way.

The solid contents or *volumes* of the several bodies are found from their diameters, by a simple rule of geometry. To state the number of cubic miles that each contains, gives little real information, the important thing being their relative magnitudes. Now, it is important to bear in mind that the magnitudes or bulks are not in the simple proportion of the diameters, but as the *cubes* of the diameters. Thus, the diameter of the sun being about 107 times that of the earth, his volume or bulk will be 1,200,000 (107 cubed) times greater.

To speak of *weighing* such stupendous masses as the sun, moon, and stars, seems at first sight extravagant; yet it is by no means one of the most difficult problems, as will be explained under Physical Astronomy.

Diameter of the Earth.—In measuring the distances of the heavenly bodies, the diameter of the earth is taken as a known base to start from; but how is this got at? If at any place we observe the height of a star on the meridian—say the pole-star—and after travelling directly north for a considerable distance, observe the height of the same star, it will be found to be greater. This arises from the round form of the earth; and it is easily shewn that, if the star has risen one degree higher in the heavens, the observer must have moved north one degree. We are thus enabled to fix two stations on a meridian, the distance between which shall be exactly one degree, or the $\frac{1}{360}$th part of the whole circle or circumference of the earth. When the length of such a line is measured, it is found to be a little less than seventy English miles. This, multiplied by 360, gives the whole circumference in round numbers at 25,000 miles, and the diameter at 8000.

SEPARATE MEMBERS OF THE SYSTEM.

The Sun (☉).—The apparent or angular breadth of the sun, at the mean distance of the earth, is slightly more than 32′. The real diameter of the sun is 853,380 miles, which, as already stated, is 107 times that of the earth, so that in volume or bulk the sun is equal to 1,200,000 earths.

That the sun is a ball or globe is evident from its always appearing round, while we know, at the same time, that it turns or rotates on an axis. The fact of its rotation, and the time it occupies, are inferred from observing the motion of the dark *spots* which are seen at times on its surface: the period of rotation is ascertained to be a little over 25 days.

A solar spot presents the appearance of a black irregular patch, called the *umbra*, surrounded by a less dark fringe, called the *penumbra*. Spots appear and disappear very irregularly, some lasting only a day, others for weeks and even months. Sometimes few or no spots are to be seen, at other times they appear in profusion; and these alternations are observed to come regularly round in periods of about *ten years*. Individual spots have been seen to attain the enormous breadth of 50,000 miles, covering an area of five times the surface of the earth. They are inferred, with almost certainty, to be hollows.

Around the spots, and on other places, there are often masses brighter than the general surface, which are called *faculæ*, or torches. The general surface itself is not uniform, but appears to be coarsely mottled, and to be made up of bright roundish patches, with soft edges, sprinkled irregularly on a less luminous background. The move-

ments and changes, of almost incredible velocity and magnitude, constantly going on in the spots and bright patches lead irresistibly to the conclusion that the luminous surface of the sun—his *photosphere*, as it is termed—is of a cloudy nature.

But during a total eclipse of the sun, when his shining disk is covered by the dark body of the moon, there is readily seen a white halo, called the *corona*, surrounding the moon; within this there were first observed fantastically shaped masses of a red colour, projecting considerably here and there beyond the moon's edge, and variously called red flames and red prominences; and closer observation has shewn that these larger prominences are connected by a continuous belt of similar colour at a lower level. This less brilliant envelope is known as the *chromosphere*.

By bringing that new and marvellous instrument of investigation, the *spectroscope*, to bear on those appearances, a good many points have of late been established regarding the physical constitution of the sun—that is, what substances it is composed of, and the condition in which those substances exist. To explain the action of the spectroscope belongs to Optics; it is sufficient here to say, that it tells whether a distant luminous body is in a solid or liquid state, or whether it is in the state of vapour; and can discriminate between the light proceeding from incandescent hydrogen, for instance, and that from the vapour of sodium or of iron. The chief results arrived at may be thus summed up: The sun is composed of substances identical, in part at least, with those composing our earth; hydrogen, sodium, iron, magnesium, and several other metals have already been fairly ascertained. The matter of the sun is so intensely hot as to be to a great extent in the state of vapour; at all events, it is so to a considerable depth at the surface. The outer envelope, or cromosphere of the sun, consists mainly of hydrogen. Below this, we have the photosphere, or region containing metallic vapours, along, probably, with numerous deposited cloud-particles of these vapours, which particles are the chief source of the light and heat of the sun. The photosphere is in a state of constant agitation, like that of boiling, caused, apparently, by the portions on the surface cooling by radiation and rushing down at one place, while hotter matter from the interior is heaved up at another. When these 'convection-currents' are exceptionally violent, they become visible as faculæ and spots, the blackness of the latter being caused by a great down-rush of the comparatively cold matter from above into a hollow of the photosphere. This agitation of the photosphere causes a corresponding commotion in the chromosphere; where the photosphere is upheaved, masses of the red-hot hydrogen envelope are projected far above the general level, sometimes to the height of tens of thousands of miles, and form prominences. The velocity of these uprushes, and still more of the whirling motions going on in the hydrogen, is astonishing, being sometimes not less than 120 miles a second. The nature of the *corona* is yet not fully ascertained.

As to the sun's *heat*, it has been calculated that the amount given out by one yard of his surface is as great as that which would be produced by burning six tons of coals on it each hour. The amount received by the earth in one year would be sufficient to melt a layer of ice 100 feet thick all over the earth's surface. But the sun's heat is given out equally all round, so that the portion intercepted by the earth at its distance of 92,500,000 miles must be an inconceivably small fraction of the whole that is lost by the sun.

Is the sun becoming cooler with all this loss? It must be so, unless the loss is in some way made up. The most probable theory of the origin of the existing store of solar heat is, that the matter composing the sun was originally diffused in a nebulous form throughout space, and that this matter, falling together by gravity, had its motion converted into heat, just as two stones are heated by clashing together. But we know of no source from which the continual dissipation is replenished; and without fresh fuel, the fire, however big, must in the end go out. 'There will come a time when the sun, with all its planets welded into one mass, will roll, a cold black ball, through infinite space.'—*Lockyer's Astronomy.*

Mercury (☿) and *Venus* (♀), the two members of the system next to the central body, are called *inferior* planets, from their orbits being within that of the earth. Owing to their position, they can never appear at any great distance or *elongation* from the sun. Mercury, in fact, even at its greatest elongation, sets long before the end of twilight, or if west of the sun, does not rise till the dawn has begun; so that in our latitude and cloudy climate, it is rarely seen with the naked eye. Venus attains more than twice the elongation of Mercury, and is seen long after night has fairly set in, or before the morning twilight. Both inferior planets go through *phases* like the moon, and when seen through a telescope, have a crescent or a gibbous shape. They are never seen when full, or when new, being then near the sun. Venus is the most conspicuous of the heavenly bodies, next to the sun and moon; when it rises before the sun, it is called the *Morning Star*—the Lucifer of the ancients; and when it sets after the sun, it is the *Evening Star* or Hesperus.

Telescopic observations of Mercury and Venus are very difficult, owing to the intense brilliancy of the surface; hence nothing has been ascertained as to their physical constitution. Even the times of their rotation on their axes cannot be held as accurately determined.

The *Earth* (⊕) is the third planet in order from the sun, and closely resembles Venus. The earth is not a perfect sphere; it does not measure the same in all directions, but has its axis, or the diameter on which it rotates, shorter than its diameter at the equator. This is a general law in all planets, the cause of which will be explained afterwards. The earth, then, is flattened at the poles, and its shape is called by astronomers an oblate spheroid. If it were cut in two, by a plane passing through the two poles, the section would be, not a circle, but an oval, or *ellipse;* and the excess of the *equatorial* diameter over the *polar* diameter is called the *ellipticity* of the spheroid. The ellipticity of the earth is found to be $\frac{1}{300}$, or the equatorial diameter exceeds the polar by $\frac{1}{300}$th of its length. This was determined in two ways: by measuring degrees of the meridian at different latitudes; and by measuring the variation in the force of gravity, between the equator and the poles. The polar diameter, omitting fractions, is 7899 miles, the equatorial 7925;

the difference is thus 26 miles, and the mean diameter 7912 miles.

To ascertain the density of the earth, is a delicate problem, to be more particularly described under the head of Mechanical Astronomy. It is found to be from $5\frac{1}{2}$ to 6 times that of water. The densities of the other heavenly bodies are always given as compared with that of the earth, which is stated as 1. The motions of the earth, and the appearances caused by them, as well as the motions of its accompanying satellite, the moon, will be described under separate heads (see also PHYSICAL GEOGRAPHY).

Mars (♂), the fourth in order, is the nearest to us of the *superior* planets. In many respects it resembles our earth. It is distinctly ascertained to turn on its axis in 24 hours 37 minutes, the axis being inclined to the plane of its orbit at an angle of 28° 27′. Its days, then, are nearly the same as ours; and its year, which contains 668 Martial days, is varied by seasons like the terrestrial year. Mars has a reddish aspect. Around each pole is a region of dazzling white, conjectured to be snow. In 1877 it was discovered to be attended by two satellites.

The *asteroids* or *small planets* circulate in a region lying between the orbits of Mars and Jupiter, but on the whole nearer to the former. They form a distinct group of themselves. It is only recently that the existence of the small planets has become known, the first, Ceres, having been discovered in 1801. From observing, however, that the distances at which the planets generally succeed one another, form a kind of progression, that of each orbit, counting from Mercury, being nearly double of the one preceding, it had long been conjectured that a planet or planets might yet be discovered in the interval between Mars and Jupiter, which formed a break, as it were, in the regularity of the progression. The discovery of Ceres by Piazzi at Palermo in Sicily (Jan. 1, 1801), was speedily followed by that of Pallas, Vesta, and Juno; and up to the present time more than 200 have been catalogued and named.

In addition to their comparative smallness, the planets of this group are distinguished by their orbits being much more elliptical or elongated than those of the others, and also having a greater inclination—that is, rising and sinking much farther from the plane of the ecliptic. The inclination of Pallas is as much as 34° 37′. The diameter of the largest of the minor planets is only 228 miles, and many of the smaller ones are less than 50. They are invisible to the naked eye, except occasionally Ceres and Vesta.

From various observed facts, cosmogonists presume that the matter which in other cases has gone to form one planet of the first rank, has in their case been separated into several parts, assuming various but connected orbits.

Jupiter (♃).—The largest of all the planets is Jupiter. The diameter of Jupiter being upwards of eleven times that of the earth, his volume is 1400 times the volume of the earth. To the inhabitants of Jupiter the sun must appear less than one-fifth of the breadth he presents to us. By means of permanent marks, it is ascertained that the planet rotates on an axis inclined to its orbit at the small angle of 3° 4′, and in the short space of 9 hours 55 minutes. This makes the rotary velocity of Jupiter's surface twenty-seven times greater than that of the earth. Viewed through a telescope, Jupiter appears traversed by dusky streaks parallel to the planet's equator. Both Jupiter and Saturn have atmospheres so densely laden with clouds that the surfaces of the planets are, it is believed, never seen; and the parallel streaks, which both exhibit, are supposed to arise from the rapid rotation of those planets disposing the clouds in belts, on the principle of our trade-winds and calm-belts. The density of Jupiter, taking his bulk as we see it, is little more than that of water; but if he is surrounded by a thick envelope of cloudy atmosphere, the kernel of the planet may approach that of the earth. The same may be said of Saturn, whose density as a whole is about half that of water.

Jupiter is attended by four satellites, which revolve round it as the moon revolves round the earth, but in much shorter periods—the nearest requiring only forty-two hours. One of these satellites is of the same size as our moon; the others, larger. Their density is very small; so that the mass of the whole is only a 6000th part of that of Jupiter itself. The satellites of Jupiter were discovered by Galileo, being among the first results of the invention of the telescope.

Saturn (♄) with its ring, or rather rings, and eight moons, is the most remarkable member of the solar system. It turns on its axis in 10 hours 29 minutes.

The ring of Saturn, which surrounds the planet in the plane of its equator, is found, on closer examination, to consist of a series of rings one within the other, the two outer being bright, and the innermost dark and transparent. The distance from the body of the planet to the dark ring is 9760 miles. The whole ring system, inclusive of the interval between the two bright rings, is 37,570 miles broad, while its thickness appears not to exceed 100 miles. In certain positions of the planet, we can see its surface at a considerable angle, and the openings or loops which it forms at the sides of the planet. At other times, we see its dark side, or only its edge. It is now generally believed that these rings are composed of innumerable small satellites, moving each in its own orbit round the planet, and presenting a bright appearance where they are densely packed, but a dim appearance when scattered.

The eight satellites of Saturn revolve around it, on the exterior of the ring, and almost all of them in nearly the same plane. They are so small as not to be visible without a powerful telescope.

Uranus (♅) is invisible to the naked eye, and was discovered by Sir William Herschel in 1781. Owing to its enormous distance, little is known regarding it.

Uranus is attended by at least four satellites. In two respects, these satellites are quite singular: their orbits are nearly perpendicular to the plane of the ecliptic; and their motions in the orbits are *retrograde*—that is, from east to west, instead of being from west to east, like those of all other planets both primary and secondary.

The discovery of *Neptune* (♆) is one of the greatest triumphs of scientific astronomy. From irregularities observed in the motion of the planet Uranus, it had been conjectured that some disturbing cause, not yet discovered, was acting upon

it. Two astronomers, M. Le Verrier, in Paris, and Mr J. C. Adams of Cambridge, independently of one another, calculated where this disturbing cause must be situated. The results of Le Verrier were first made public; and Dr Galle of Berlin detected the new planet at the first search, September 23, 1846, within two diameters of the moon's disk from the place assigned for it by both astronomers.

UNIFORMITIES OR LAWS IN THE SOLAR SYSTEM.

These details of the movements, magnitudes, distances, &c. of the separate members of the solar system, are apt at first sight to appear a mass of unconnected facts, without any discernible plan; but more attentively considered, they display in several respects order and law.

The first important uniformity to be noticed among the planets is, that their orbits lie all nearly in one plane. If we take the plane of the earth's orbit, which is the same as that of the ecliptic, as a standard of reference, and suppose it represented by a ring held horizontally with the sun in its centre, then the other orbits will be represented by other rings, two within, and the others without, held so as also to have the sun in the centre, and (with the exception of a few of the planetoids) never rising above or sinking below the level of the earth's ring more than a very few degrees. In consequence of this arrangement, the motions of the planets, as seen from the earth, are confined to a narrow zone of the heavens, extending 9° on each side of the ecliptic. This circular belt, called the *Zodiac*, was from the earliest times divided into twelve equal parts, called *signs*, containing, of course, 30° each. These signs received each a particular name, from the groups of stars or constellations in them having a fancied resemblance to certain figures, chiefly of animals. The names of the signs, with the symbols by which they are usually represented, are as follows:

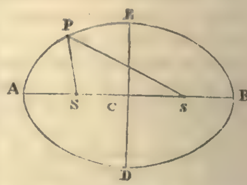
♈ Aries, the Ram.	♎ Libra, the Balance.
♉ Taurus, the Bull.	♏ Scorpio, the Scorpion.
♊ Gemini, the Twins.	♐ Sagittarius, the Archer.
♋ Cancer, the Crab.	♑ Capricornus, the Goat.
♌ Leo, the Lion.	♒ Aquarius, the Water-bearer.
♍ Virgo, the Virgin.	♓ Pisces, the Fishes.

This division of the zodiac affords a ready means of pointing out the place of a planet, or of the sun or moon, at any particular time, by telling in what sign it is.

Besides moving nearly in one plane, the planets move all in one direction—namely, from west to east. The same law prevails among the satellites, with the remarkable exception of those of Uranus, which have a *retrograde* movement, or from east to west.

But the grand uniformities of the solar system are those discovered by the celebrated astronomer Kepler, and known as 'Kepler's Laws.' Kepler merely deduced them as matters of fact from the observations of himself and others; it remained for Newton to discover their cause. One of these laws respects the exact form of the paths in which the planets move. The ancients, from some imaginary perfection which they attributed to the circle, had taken it for granted that all celestial movements must be circular; Kepler made the important discovery that this is an error, and that the planetary orbits are *ellipses*.

The ellipse is an important figure in astronomy; for not only are the planetary orbits ellipses, but the planets themselves have an elliptical shape, as we saw when speaking of the form of the earth. There is a ready practical way of describing an ellipse, which at the same time gives a good sensible notion of its nature. If the ends of a thread are fastened by pins to two points S and *s*, at a distance apart less than the length of the thread, and if the point of a pencil P, is put into the loop of the thread, and moved round so as to keep it stretched, the pencil will trace an ellipse.



The two points S and *s* are called the *foci* of the ellipse; AB is the major or transverse axis, C the centre; and SC, the distance of the focus from the centre, is the *eccentricity*. With the same length of thread, a variety of ellipses may be described, by altering the distance between the points S and *s*. The nearer they are brought to each other, the rounder does the figure become; and when they come together, it forms a perfect circle. In the planetary orbits, the sun is always in the focus S, and therefore the planet is at different distances from the sun in different parts of its orbit. When it is at A, the nearest point, it is said to be in *perihelion;* and when at B, in *aphelion.* SE is the mean distance, and is equal to AC. The planetary orbits differ very little from circles, or have very little eccentricity.

Another of Kepler's laws connects the change of a planet's distance from the sun with the speed of its motion: when the distance *increases*, the speed *diminishes;* and at the least distance we find the greatest speed. The exact nature of the relation is expressed by saying that the areas swept over by the line joining the sun and planet, which line is called the *Radius Vector*, are equal in equal times. This is known as the law of *Equal Areas.*

The two laws already noticed refer to the motions of a single planet; the third law shews a relation between the motions of all the planets, or all the bodies that revolve round the same centre. It is, that *the squares of the periodic times of any two planets are to each other as the cubes of their mean distances from the sun;* that is, if there be two planets, and one farther off than the other, the near planet will perform its revolution quicker than the other, in the proportion above expressed. The same three laws apply to the revolutions of satellites about their primaries.

DIURNAL AND ANNUAL MOTIONS OF THE EARTH.

The earth, like all the other planets, has two motions: it whirls round its axis once a day; and while doing so, it is all the while travelling bodily through space in a wide circuit round the sun, which it accomplishes in a year. The first is called a motion of *rotation*, the second of *translation.* The two combined give rise to the vicissitudes of day and night, and of the seasons.

The circumference of the earth being 25,000 miles, any spot at the equator, in order to go round in twenty-four hours, must move upwards of 1000 miles an hour. This velocity decreases

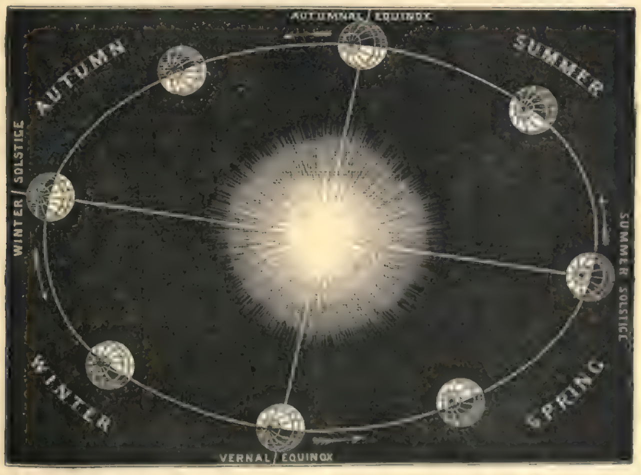
towards the poles, because the circles to be described become less; but in Great Britain it is still nearly 600 miles an hour. We are not sensible of this motion, because we and all our surroundings are carried along with it. It is in this way that the swift, but smooth and noiseless whirl which carries the earth's surface and its inhabitants eastward, makes the starry vault seem to flit past the eyes of these inhabitants towards the west.

It is the earth's rotation that causes the vicissitude of day and night. The earth being a globe, only one-half of it can be in the sun's light at once; to that half it is day, while the other half is in its own shadow, or in night. But by the earth's rotation, the several portions of the surface have each their turn of light and of darkness.

Length of a Day.—One complete rotation of the earth does not make a day, in the usual sense. If the time is noted when a particular fixed star is exactly south or on the meridian, when the same star comes again to the meridian the next day, the earth has made exactly one rotation, and the time that has elapsed is called a *sidereal day*. This portion of time is always of the same length. Sidereal time, or star-time, from its unvarying uniformity, is much used by astronomers. But the passage of a star across the meridian is not a conspicuous enough event for regulating the movements of men in general. It is not a complete rotation of the earth, but a complete alternation of light and darkness that constitutes their day. This, which is called the *natural* or the *solar* day, is measured between two meridian passages of the sun, and is about four minutes longer than the sidereal day. The cause of the greater length is this: When the earth has made one complete turn, so as to bring the meridian of the place to the same position among the fixed stars as when it was noon the day before, the sun has in the meantime moved eastward nearly one degree among the stars, and it takes the earth about four minutes more to move round so as to overtake him. If this eastward motion of the sun were uniform, the length of the solar day would be as simple and as easily determined as that of the sidereal. But the ecliptic or sun's path crosses the earth's equator, and is therefore more oblique to the direction of the earth's rotation at one time than another; and besides, as the earth moves in her orbit with varying speed, the rate of the sun's apparent motion in the ecliptic, which is caused by that of the earth, must also vary. The consequence is, that the length of the solar day is constantly fluctuating; and to get a fixed measure of solar time, astronomers have to imagine a sun moving uniformly in the celestial equator, and completing its circuit in the same time as the real sun. The time marked by this imaginary sun is called *mean solar time;* when the imaginary sun is on the meridian, it is *mean noon;* when the real sun is on the meridian, it is *apparent* noon. It is obvious that a sun-dial must shew apparent time, while clocks and watches keep mean time. Only in four days of the year do these two kinds of time coincide. In the intervals, the sun is always either too fast or too slow; and the difference is called *the equation of time*, because, when added to or subtracted from apparent time, it makes it equal to mean time. The mean solar or *civil* day is divided into twenty-four hours, the hours into minutes and seconds. A sidereal day, we have seen, is shorter; its exact length is 23 hours, 56 minutes, 4 seconds of mean solar or common time. Astronomers divide the sidereal day also into twenty-four hours, which are, of course, shorter than common hours. In the course of a civil year of 365 days, the earth turns on its axis 366 times, or there are 366 sidereal days.

The earth, then, gliding noiselessly and steadily round on its axis, is the great time-keeper, and the heavenly bodies are the pointers or indices by which we note its progress. The art of reading off the hour of the day from the heavenly bodies is necessary in the important problem of *finding the longitude* at sea.

The Seasons.—The way in which the earth's annual motion round the sun produces the alternations of the seasons will be understood from the accompanying sketch, which represents a bird's-eye view of the earth's orbit as it would be seen from the north side. At the left of the figure, the earth is seen in the position it has at the winter solstice (21st December), the upper end of the axis, or north pole, leaning directly away from the sun at an angle of 23½° from the perpendicular to the plane. Thus, the sun's rays, which can only



fall on half the surface at once, reach only to the arctic circle; and the turning of the earth on its axis has no effect to bring any part of the space within that circle into the light. On the north temperate zone, the sun's rays fall slanting and with little effect; and the part within the light at any one time is small compared with the part in darkness, which causes short days and long nights. As the earth moves round in the direction of the arrows, keeping its axis parallel to its original position—which it does on the principle of a spinning-top—more and more of the northern hemisphere comes within the light, until, at a quarter of the circuit, when the axis is at right angles to a line drawn from the sun, the rays fall direct on the equator, and reach to both poles, so that every part of the whole surface is twelve hours in light and twelve in darkness. This is the *vernal* equinox (22d March). In the continued progress of the earth, the effect of the inclination of the axis is to turn the north pole towards the sun, instead of from it, and bring more and more of the northern hemisphere into the hemisphere of light; and when the globe comes to the opposite point from where it started, the inclination is directly towards the sun, and its rays reach 23½° beyond the pole, so that the whole of the arctic circle turns round in continual day, and the temperate zone is longer in light than in darkness—it is midsummer (21st June). The earth's progress through the remaining half of its orbit has just the reverse effect on the position of the northern hemisphere with regard to the sun's rays; at the middle of it there is another equality of day and night—the *autumnal* equinox (22d September)—and at the end, things are in the position from which they started. It is evident at a glance that the hemisphere around the lower or south pole must undergo the same vicissitudes as the northern, only in reverse order, the summer in the one corresponding to the winter of the other.

The earth is in perihelion on the 1st of January; it is then about 3,000,000 miles nearer to the sun than on the 1st of July; the sun's disk is slightly broader, and we might expect this circumstance to mitigate the severity of our winter, and to add to the heat of summer in southern latitudes. But owing to the action of the law already given, by which the velocity of a planet increases with its nearness to the sun, the earth passes over the perihelion half of its orbit in less time than over the other half, and thus the effects of greater proximity are counteracted.

It is this real motion of the earth in its orbit that causes the apparent motion of the sun in the ecliptic already described. If we conceive a wide circle, described outside the orbit, to represent the sphere of the fixed stars, when the earth is in its position marked 'winter,' the sun will appear to be at a point in this circle beyond the earth's 'summer' position; and as the earth moves towards the vernal equinox, the sun will seem to travel along the outer circle in the direction of the autumnal. It is to this plane that the orbits of all the other planets are referred; they cross it at small angles, and the points of crossing are called *nodes*.

A year, in the usual sense of the term, is the time that the sun takes to move from either equinox back to the same equinox, or from either tropic back to the same tropic. This embraces a complete circle of the seasons, and brings the earth into the same position with respect to the sun; hence it is called a solar, equinoctial, or *tropical* year. If the equinoctial points remained fixed, this period would coincide with a complete revolution of the sun in the ecliptic, or—which is the same thing—of the earth in its orbit. But, owing to a cause which it belongs to physical astronomy to explain, the equinoctial points have a slow backward motion on the ecliptic of 50″ annually; when the sun, therefore, leaving the equinoctial point Aries one spring, arrives at that point next spring, he has yet 50″ to travel before he has completed a circuit among the stars, which makes a *sidereal year*. The return of the sun to the same equinoctial point thus *precedes* its return to the same point in the ecliptic; and this fact is known as the *precession of the equinoxes*. The length of the equinoctial or tropical year is 365 days, 5 hours, 48 minutes, 50·4 seconds; of the sidereal year, 365 days, 6 hours, 9 minutes, 10·4 seconds.

The equinoxes thus retrograde 1° in 71·6 years; and in 25,868 years they will make a complete revolution of the ecliptic. Celestial longitudes being counted from the point Aries, are slowly increasing: since the first catalogues were formed, the longitudes of the fixed stars are all greater by 30°.

The Calendar.—How the civil year, which must contain an exact number of *whole* days, is adjusted to the natural year, which contains fractions of a day, is explained in CHRONOLOGY.

THE MOON.

Next to the sun, the moon is to us the most striking of all the heavenly bodies. Its disk is almost equal to that of the sun, the mean apparent diameter being 31′ 7″. The real diameter is 2153 miles.

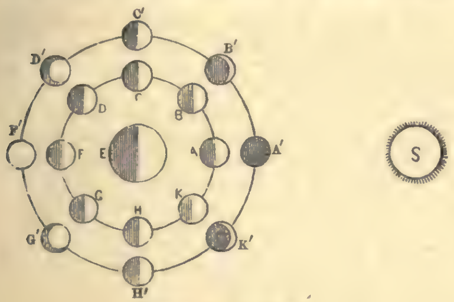
The moon's orbit being elliptical, and the earth in one of the foci, its distance varies to the extent of 26,228 miles; and this causes a corresponding variation in its apparent diameter. The moon's disk is thus sometimes larger than that of the sun, so as to cause a total eclipse of the latter, when it passes over it. The moon's path in the heavens does not coincide with the sun's path or ecliptic, but crosses it at two opposite points, at an angle of 5° 9′. These two points are called the *moon's nodes*. These points change their position, so as to make a complete revolution of the ecliptic, in a retrograde direction, in 18·6 years. When the moon is nearest to the earth, it is in *perigee;* and when at its greatest distance, it is in *apogee*.

A month.—The moon goes round the earth in her orbit in about 27⅓ days; and this motion makes her seem to us to move eastward among the stars at the rate of a little more than the length of her own apparent diameter in an hour. The time that the moon takes to make one complete revolution round the earth—that is, to return to the same place among the stars—is called a *sidereal* month or lunation. But while the moon is performing this journey, the sun has also advanced, though at a slower pace, in the same direction; and it takes the moon upwards of two days more to overtake the sun, as it were, and get again into the same situation with respect to that luminary and the earth. When it has done so, it has

completed a *synodic* revolution. The synodic period or lunation, then, is the period between two new moons, or two conjunctions of the sun and moon; it is the lunar month, and its mean length is 29 days, 12 hours, 44 minutes. The sidereal month is 27 days, 7 hours, 43 minutes.

The moon, besides revolving round the earth, also turns on its own axis, and, by a remarkable coincidence, the rotation on the axis is completed in exactly the same time as the revolution in the orbit; which is probably the case with all other secondary planets. In consequence of this coincidence, the same side of the moon is always turned towards the earth, as is evident from her surface presenting constantly the same easily recognised marks in the same positions.

Phases of the Moon.—The light of the sun, falling upon the moon, is partly absorbed into its body; but a small portion is reflected or thrown back, and becomes what we call *moonlight.* The illuminated part, from which we derive moonlight, is at all times increasing or diminishing to our eyes, as the moon proceeds in her revolution round our globe. When the satellite is on the opposite



Phases of the Moon:

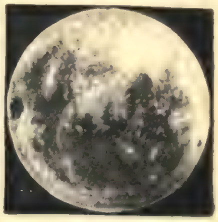
A, B, C, D, F, G, H, K, appearances presented by the moon to an observer situated at the pole of her orbit; A', B', C', D', F', G', H', K', 'phases' of the moon at the end of each eighth part of her course; S, position of sun; E, position of earth.

side of the earth from the sun, or in *opposition*, we, being nearly between the two, see the whole of the illuminated surface, which we accordingly term *full-moon.* As the moon advances in her course, the luminous side is gradually averted from us, and the moon is said to wane. At length, when the satellite has got between the earth and the sun, or into *conjunction*, the luminous side is entirely lost sight of; the moon is then said to *change.* Proceeding in her revolution, she soon turns a bright edge towards us, which we call the *new-moon.* This gradually increases in breadth, till she is one quarter of her circuit from the sun, or in *quadrature*, when half the disk is illuminated, and it is then said to be *half-moon.* The luminary, when on the increase from *new* to *half*, is termed *crescent* (increasing); when between half and full, it is *gibbous* (hump-backed).

In the early days of the new-moon, we usually see the dark part of the body faintly illuminated, an appearance termed the *old-moon in the new-moon's arms.* This faint illumination is produced by the reflection of the sun's light from the earth, or what the inhabitants of the moon, if there were any, might call *earth-light.*

It is estimated that it would take 547,513 full-moons to give as much light as the sun; which is twice as many as would find room in the whole half-sky. The moon's rays were till recently believed to be without heat; but by concentrating them in a lens of three feet diameter, the Italian philosopher Melloni obtained a sensible elevation of temperature.

The *physical condition of the moon* is in many respects remarkable. As a powerful telescope shews an object as if it were a thousand times nearer than it is, we can view the moon as if it were only 240 miles off, and thus the geography of its surface is pretty accurately known. The darker patches, which used to be considered seas, are found to be smooth planes, and have all the appearance of having once been sea-bottoms. The brighter parts are mountainous.



The Moon, photographed.*

'The mountains of the moon are not mountains, in the common acceptation of the term; they are circular pits, hollowed out into the lunar substance, and surrounded by a ring-shaped elevated border, more or less abrupt and broken. There are some that are not more than 300 or 400 yards across; others exceed 100 miles.'

These circular mountains are denominated, according to their magnitudes, *Walled Plains, Ring-mountains, Craters*, and *Holes.* The most remarkable of the ring-mountains is that called Tycho, after the illustrious Danish astronomer. The enclosure is a circle forty-seven miles in diameter, and the inner side of the ridge is as steep as a wall, and 16,000 feet high, while the height above the surrounding surface outside is only 12,000 feet. On the floor of the enclosed hollow stand a few isolated hills, one of them nearly a mile in height.

The heights of the lunar mountains are measured by means of the shadows they cast during the phases. More than a thousand have been thus determined, several of which reach a height of 23,000 feet. One peak named Dörfel is 26,691 feet high. Considering that the moon's diameter is little more than one-fourth that of the earth, the lunar mountains are thus on a much grander scale than the terrestrial. The mountains of the moon have in many respects a volcanic character; but no trace of an *active* volcano has yet been discovered. In addition to these ring-shaped hollows, there are long trenches with raised sides, called *rilles*, and bright *rays*, proceeding from a centre, like cracks, the nature of which is a mystery.

The moon is ascertained to be without any atmosphere; nor is there the least appearance of liquid of any kind, although the surface would seem to have been at one time partly covered with water. The direct rays of the sun will thus shine for fourteen days with a fierceness far beyond anything experienced on the earth; but there can be no accumulation of heat, and on the unilluminated side the cold must be for other fourteen days more rigorous than on the summits of our loftiest mountains. The present cold and dead appearance of the moon's surface, compared with what it must once have been, is accounted for by supposing that the original heat of the moon,

* Copied by permission of Messrs Smith, Beck, and Beck, from Warren De la Rue's photograph.

owing to its small size, has been dissipated into space.

The Moon and the Weather.—It is an almost universal belief that the changes of the moon influence the weather; but when put to the test of accurate observation, this opinion is found to be completely groundless: there is, in fact, no correspondence whatever between the changes of the moon and those of the weather. See METEOROLOGY.

ECLIPSES.

Eclipses are caused by the positions of the earth and moon with respect to each other and to the sun. An eclipse of the sun takes place when the moon is between the sun and earth; and an eclipse of the moon is the result of the earth being between the sun and moon.

The accompanying figure represents two positions of the moon: in the one she is in the earth's shadow, and totally eclipsed; in the other, her shadow is falling upon a part of the earth's surface, and eclipsing the sun to that part. Within the limited circle on which the moon's shadow, or *umbra*, falls, no part of the sun is seen, or he is in *total* eclipse; within a larger space round that spot, the moon seems to cover only part of the sun's disk, making a *partial* eclipse; and this space is within the *penumbra*, as it is called. When the moon happens to be so far distant from the earth that the cone of the shadow falls short of the earth, then a spectator standing immediately under the apex, or point, sees the moon covering

the middle part of the sun's disk, and leaving a ring of it visible. This is an *annular* eclipse.

It is only when the moon is in one of her nodes, or within a limited distance from it, that there can be an eclipse either of sun or moon. Now, the motions of the two orbs are such that there *must* be annually *two* solar eclipses, and there *may* be *four*. The limits for a lunar eclipse are shorter, and a whole year *may* elapse without one occurring. There are thus more solar eclipses than lunar, though the general impression is to the contrary. This arises from the circumstance that, whenever an eclipse of the moon occurs, it is seen at all places where the moon is above the horizon, and the atmosphere unclouded; whereas an eclipse of the sun is confined to a limited tract.

These eclipses, like all other things about the heavens, can be predicted with almost perfect accuracy. It is also possible to calculate backwards, so as to find the probable date of remarkable eclipses recorded to have happened in antiquity.

The inferior planets, Mercury and Venus, sometimes cross the sun's face, on which occasion they may be traced by a telescope as a dark speck moving from one edge over to another, and then disappearing. These are *transits*, and are of importance in ascertaining the sun's parallax and distance.

In times when people's fates and fortunes were predicted from the positions of the planets at the hour of their birth, much stress was put upon *conjunctions* and *oppositions*. When two bodies are in the same quarter of the heavens, so as to be near one another, or have the same *longitude*, they are said to be in *conjunction;* when they are half a circle apart in longitude, they are in *opposition*. Astronomers use the sign ☌ to indicate conjunction; and ☍ to indicate opposition.

COMETS.

'Comets,' says Humboldt, 'at the same time possess the smallest mass, and occupy the largest space of any bodies in the solar regions; in their number, also, they exceed all other planetary bodies, except, perhaps, aërolites, amounting to many thousands at least.' Comets have usually two parts—a body or head, and a tail. The head has the appearance of a round nebulous mass of light, with usually a brighter part in the centre called the nucleus, but so far from containing anything solid, that the smallest stars are seen through the densest part of the substance. The tail is a still lighter luminous vapour, surrounding the body, and streaming far from it in a direction generally opposite to that in which the sun is situated, as if repelled by that luminary, and often curved. A vacant space has been observed between the body and the enveloping matter of the tail, which also appears sometimes less bright along the middle, immediately behind the head, as if it were a stream which the head had parted in two.

Unlike planets, comets shine partly, at least, by their own light, and are believed by some to be masses of white-hot gas. Others suggest a connection between comets and the rings of small bodies that produce meteoric showers (see METEOROLOGY). The tail is by no means essential to a comet; by far the greater number have no such appendage, appearing merely as a nebulous disk.

With regard to the motions of the comets, instead of revolving, like the planets, nearly in the plane of the sun's equator, it is found that they approach his body from all parts of surrounding space. At first, they are seen slowly advancing, with a comparatively faint appearance. As they approach the sun, the motion becomes quicker, and at length they pass round him with very great rapidity, and at a comparatively small distance from his body. The comet of 1843 approached within one-seventh of his radius. When near the sun, their brilliancy is greatly increased.

In moving round the sun, comets obey the same general laws that regulate the planets. They do not, however, all describe ellipses; some pass through our system in parabolas, open curves, which never return into themselves. Now, the comets that move in shut orbits, or ellipses, must return to the sun again and again, and may

therefore be considered as members of the solar system. The others are only casual visitors; unless they meet with something to alter their orbits, they can never return, but must run off into the immensity of space.

The most remarkable of the comets ascertained to return is one usually denominated Halley's Comet, from the astronomer who first calculated its period. It revolves round the sun in about seventy-seven years, its last appearance being at the close of 1835. The annexed cut represents some of the various appearances it presented on that occasion in different parts of its orbit—*a*, *b*, *c*, in approaching the sun; *d*, *e*, in retreating.

Another, called Encke's Comet, from Professor Encke of Berlin, has been found to revolve once in 3¼ years; but in this case the revolving body is found, at each successive approach to the sun, to be a little earlier than on the previous occasion, owing probably to a cause to be afterwards described. A third, named Biela's Comet, revolves round the sun in 6½ years. It is very small, and

has no tail. During its visit in 1846, this comet was seen to separate into two distinct comets, which kept moving side by side, till they disappeared. On the return of the comet in the autumn of 1852, the distance between the two nuclei had much increased. In 1770, a comet got entangled amidst the satellites of Jupiter, and was thereby thrown out of its usual course, while the motions of the satellites were not in the least affected by its proximity. This proves the extreme lightness of the matter composing comets.

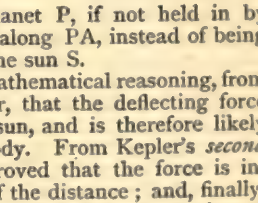
The comet now called Halley's, at its appearance in 1456, covered a sixth part of the visible extent of the heavens, and was likened to a Turkish scimitar. That of 1680, which was observed by Sir Isaac Newton, had a tail calculated to be 60,000,000 miles in length—a space two-thirds of the distance of the earth from the sun. There was a comet in 1744 which had six tails, spread out like a fan across a large space in the heavens.

PHYSICAL ASTRONOMY.

Not long after Kepler had made those remarkable discoveries which completed the view of the regular courses and periods of the celestial motions, the *causes* of the motions, or the forces whereby they are sustained, were also discovered by Sir Isaac Newton. He was the first to shew that the vast planetary balls whirl about their own centres, and fly through the celestial spaces, on exactly the same principles as a cannon-ball or a stone moves when thrown into the air. The principles of celestial mechanics, therefore, are the principles of motion discovered from the observation of bodies on the earth; they are the three Laws of Motion and the doctrines of the Composition of Forces, as illustrated under MATTER AND MOTION, and the doctrine of Universal Gravitation.

The fall of unsupported bodies to the earth is the most familiar action in nature; but it is not two centuries since Newton discovered that this action extends to the moon, the sun, and the planets. He proved that the moon is constantly falling towards the earth, and would fall into it, but for another motion she has, which is always carrying her off, and would of itself shoot her far away into space in a straight course; so that her actual circuit is the balance of two forces—one her weight, or gravity, towards the earth (*centripetal* force), the other an undying impulse to fly off at a tangent, like a whirled stone when the sling is let go (*centrifugal* force).

It was through the application partly of the laws of motion, and partly of Kepler's laws, that Newton established the universal prevalence of gravity. It being once found that the planetary motions could be kept up by a combination of forces; that is, by a force that projected the body once for all into free space with a great velocity, which, by the first law of motion, would be always kept up, whether it went off straight through space, or were compelled to go round a circle—and some second force to hold it in that circle; the great question arose: What is the *central* force—what power is it that causes the moon to fall towards the earth, instead of running off; and in like manner obliges the planets, with their immense speed, to keep constantly falling towards the sun? A planet P, if not held in by some tie, would fly off along PA, instead of being always carried round the sun S.



Newton proved by mathematical reasoning, from the *first* law of Kepler, that the deflecting force points exactly to the sun, and is therefore likely to be lodged in his body. From Kepler's *second* and *third* laws, he proved that the force is inversely as the square of the distance; and, finally, he shewed that the deflection of the moon from a straight line is exactly equal to the fall of a stone, if it were at the distance of the moon. The moon being sixty times farther off from the earth's centre than we are, gravity is there 3600 times weaker; so that the speed acquired by a stone falling one second near the earth's surface, would

be acquired only by falling an hour at the height of the moon. And it can be easily proved by calculation that the falling action of the moon is, in an hour, exactly that of a stone in a second. It being thus shewn that the moon is deflected by gravity, it was then concluded that the planets are deflected to the sun by the same cause; or that gravity is the great *central* force throughout the solar system.

After thus identifying the mechanical causes of the planetary motions, Newton deduced all the laws of Kepler from the combination of the two great forces of Gravitation and Straight Impulse. In this way he found that these laws are not strictly true, as given by Kepler, and that therefore the prediction of the places from them could not be perfectly accurate. Not only was the sun's centre not the true focus of the ellipse, that being the common centre of gravity of the sun and the planet, but he shewed that not one of the paths is an exact ellipse. If there were only one planet to the sun, that planet would describe a perfect ellipse; but if a second planet is introduced, this planet is not only attracted by the sun (and the sun attracted by it), but there is an attraction between it and the first planet which disturbs the motion of both.

In like manner, if the moon and the earth were alone in the universe, the moon would go round the common centre of gravity of the two in a perfect ellipse; but as both move round the sun, and he acts upon both, very great deviations take place from the elliptic orbit; in fact, the application of Kepler's two first laws to the moon could never predict her place with anything like accuracy.

Perturbations.—But the same discoveries that shew the defects of Kepler's laws, give the means of correcting those defects, or of calculating the disturbing influences, so as to predict what the real motions will be under those disturbances. The special disturbances are known as *perturbations* or *inequalities.* In calculating them, astronomers first suppose the case of one body revolving about a second, and disturbed in its regular orbit by a third; this is what is called the *problem of the three bodies;* the disturbing effect of each separate cause being thus found, the whole are then combined.

Masses of the Heavenly Bodies.—The theory of universal gravitation gives us the means of comparing the weights of the heavenly bodies, as if they were weighed on a steelyard. Thus the fall of the earth towards the sun in an hour can be compared with the fall of the moon to the earth in an hour; and the two quantities, multiplied by the squares of the two distances, will give the proportion between the mass of the sun and the mass of the earth, which is about 314,760 to 1. When we remember that the *bulk* of the sun exceeds that of the earth more than a million of times, we see that the matter of the sun is much lighter than the material of the earth. In the same way, Jupiter's mass is found to be 301 times that of the earth.

To find the actual density or specific gravity of the different bodies of the solar system, and compare it with a fixed standard, such as water, it is necessary to know the average density of the whole earth. This has been sought by comparing the attraction of some known body with the attraction of the globe. Thus, Dr Maskelyne attempted to calculate the attraction of a mountain in Perthshire, by finding how far it made a plumb-line to deviate from the perpendicular. In this experiment the plumb-ball was supposed to be attracted downwards by the general mass of the earth, and sideways by the mountain; and it could thus be seen how many times the whole earth surpassed the mountain in gravitating force. If the mountain itself then were measured, and its composition ascertained, so as to give the density of its rocky material, the entire mass of the mountain would be obtained, and from that the entire mass of the earth. The result of this experiment was, that the earth is, on an average, 5½ times denser than water, or more than twice the density of granite or sandstone rock. Other experiments, of a different kind, have given much the same determination. From this we can estimate the densities of the sun, moon, planets, and satellites.

The Figures of the Heavenly Bodies, how caused.—It has already been seen that the sun and planets are, in general, round masses, with a slight flattening, which seems to be connected with the rapidity of their whirl. Now, both the general roundness and the flattening can be shewn to arise from ordinary mechanical laws, such as we see operating on the earth, provided we suppose that the planets were at one time soft, fluid masses. If a fluid mass of attracting particles be left to itself—that is, if there be no external compulsion, either attraction or pressure—it will always assume the *round* shape.

But if such a body is whirled, the matter at the surface acquires a tendency to fly off, so as to oppose the general attraction towards the centre. If the whirled body is soft or liquid, it cannot remain at rest, or in equilibrium, in its round form, inasmuch as the matter at the equator, having a greater velocity than elsewhere, is rendered lighter by its centrifugal tendency, and is not a sufficient balance for the matter at the poles. To restore the balance, there must be a greater depth from the equator to the centre than from the poles to the centre; in other words, the equatorial width must exceed the polar width, which is what we actually find in all the revolving bodies. The planets also that revolve the most rapidly, as Jupiter and Saturn, are found to be the most elliptical.

Precession of the Equinoxes.—It has been already explained in what this consists. The cause is to be found in the combined action of the sun and moon on the protuberant mass of matter accumulated at the earth's equator. The exact nature of this action is too complex for description here; but combined with the rotation of the earth on its axis, the result is the regression of the equinoctial points above mentioned; while, as a necessary consequence, the celestial pole describes, at the same rate, a circle among the stars round the pole of the ecliptic at a distance equal to the obliquity of the ecliptic. Its motion, however, is not quite uniform or straight, but in a waving line, alternately approaching and receding from the pole of the ecliptic. This secondary disturbance, which is caused by the fluctuating position of the moon's nodes, is known as the *nutation* of the earth's axis.

The poles of the earth do not, then, point always to the same places among the stars. The present position of the north pole is within a degree and

a half of a bright star in the constellation of the Lesser Bear. Its motion will bring it gradually nearer until it is within half a degree of that star, after which it will recede from it. Its course may be traced by drawing a circle on a celestial globe round the north pole of the ecliptic, at the distance of 23½°. The celestial pole describes this circle in 25,868 years. Twelve thousand years hence, it will be near one of the brightest stars in the heavens, called α Lyræ, which will then be the pole-star.

Stability of the System.—It is natural to inquire whether the numerous perturbations which all the bodies are subject to, are such as in the long-run to overthrow the present arrangements of the system. Now, so far as has yet been positively ascertained, the total effect of all the mutual disturbances has no such tendency. Though there are secular variations that may go on increasing for thousands of years, it has been shewn that they will decrease continually for periods of like duration, and the limits within which this secular oscillation is confined are in all cases extremely narrow.

Two causes are pointed to as likely to produce permanent changes in the planetary motions. 1. It is generally held by philosophers, that space, instead of being perfectly empty, is everywhere filled with an exceedingly thin medium, which they call *ether*. Now, however slight the resistance this may offer to bodies moving in it, yet, if it exist at all, it must tell in the end, and will have the effect of contracting the orbits of the planets, and bringing them nearer and nearer to the sun. Such an effect would be most powerful in the case of light bodies like comets; and, accordingly, some of the short-period comets have been observed to return to the sun in a shorter period each successive revolution. In the case of the planets, no such effect has yet been appreciable, owing to their much greater mass. 2. The tidal wave moves westward on the earth's surface, contrary to the direction of the earth's daily motion; it is thus believed to act like a friction-break on a wheel, rendering the daily rotation slower, although by a quantity so small, that it has not yet been ascertained with certainty.

SIDEREAL ASTRONOMY—THE FIXED STARS.

The first thing that strikes us about the stars is their difference as to brightness. They can be classified according to this feature. The most brilliant are said to be of the first *magnitude;* the next of the second; and so on. The smallest stars visible to the naked eye are of the sixth or seventh magnitude. The number of stars visible in one hemisphere may be about 2000, making in all 4000. About twenty-four are reckoned of the first magnitude. By using telescopes, a vast mass of new stars come into view, which are reckoned as far as the seventeenth magnitude; the numbers and closeness increasing with every increase of the telescope's power.

From the earliest times, the stars have been divided into groups called *constellations*, which were named from fancied resemblances to animals or other figures. Thus, a group in the northern part of the sky is called *Ursa Major*, or the Greater Bear. From the figure of the seven more conspicuous stars, it is sometimes called *the Plough*. Another well-marked group is called after the mythical personage *Orion*. Individual stars are indicated by the letters of the Greek alphabet or by numbers, as η *Ursæ Majoris* (in the tip of the tail of the Greater Bear), 24 *Comæ*. Some remarkable stars have names, as Aldebaran (α *Tauri*), Sirius (in the nose of Canis Major). By means of a celestial globe, or a set of star-maps, the more conspicuous constellations may be soon recognised.

The stars are believed to be so many suns, shining by their own light, and being each perhaps the centre of a system of planets, the abodes of sentient and intelligent existence. Their immense distance reduces them all equally to mere points of light; in the most powerful telescopes they shew no *disk*, and differ from one another, not in *magnitude*, properly speaking, but in brilliancy. Notwithstanding this seeming inaccessibility to observation, the spectroscope makes known to us with almost certainty not a few facts regarding their physical constitution. They have white hot cloudy photospheres like the sun, and contain pretty much the same substances; thus Sirius has been ascertained to contain sodium, magnesium, iron, and hydrogen.

For a long time the distances of the fixed stars were believed to be immeasurable. More refined modes of observation have recently detected the parallax of several stars, and determined positively how far off they are. To state these distances in miles conveys no idea. It is better to take some large unit, such as the distance light travels in a second, which is 186,000 miles; we can then give the distance of a star in the time its light takes to reach us. The sun's distance is sometimes taken as a standard. The nearest distance yet measured is that of a fine double star in the southern hemisphere (α Centauri), calculated at 224,000 distances of the sun, which it takes light three and a half years to traverse. 'From the measurements already made, we may say that, on the average, light requires fifteen and a half years to reach us from a star of the first magnitude, twenty-eight years from a star of the second, forty-three years from a star of the third, and so on, until, for stars of the twelfth magnitude, the time required is 3500 years.'—*Lockyer's Astronomy.*

Variable Stars.—Some stars undergo periodical increase and diminution of lustre, and are known as *variable* stars. There are several instances also on record of stars which have come into sight for a time, and then gradually vanished, to which the name of *temporary* or *new* stars has been given; the latter phenomenon, however, is no doubt only an extreme case of the former, the period being long, and the diminution of lustre excessive. The star Omicron, in Cetus, is a remarkable instance of a variable star. It goes through a series of variations in a period of about 330 days.

The analogy of our sun is thought to afford an explanation of this phenomenon. The sun is clearly a variable star, his light and heat varying with the increase and diminution of the spots on his surface, which follow, as we have seen, a period of ten years. The observations of Balfour Stewart and others go far to prove that the frequency of sun-spots is regulated by the position of the nearer planets. Mr Stewart holds that 'the approach of a planet to the sun is favourable to

increased brightness, and especially in that portion of the sun which is next the planet.' We have only, then, to suppose that a variable star has a very large planet revolving round it at a short distance; this will cause the part next the planet to be brighter than the rest; and thus the star will vary with a period equal to that of the planet.

Double and Multiple Stars.—Another variety in the nature of these luminaries is their being in some instances not *single* stars, as they appear to the naked eye, but a group of two or more, evidently, from their motions, forming one system. The star Castor, one of the Twins, is found, when much magnified, to consist of two stars, of between the third and fourth magnitude, within five seconds of each other. Upwards of 6000 such groups have been observed. It is generally observed that they move round each other within a certain time, and in elliptical orbits; the revolution of Castor, for instance, is supposed to be accomplished in 252 years.

Proper Motion of Stars.—When we speak of the stars being *fixed*, it is only as compared with the planets. There is no such thing as absolute fixity in the universe. Besides the revolutions of the double stars, a great many stars have been observed to be slowly but constantly carried away from their places in the heavens. This *proper motion*, as it is called, has in one instance shifted the situation of a star in the heavens, in the course of fifty years, over $\frac{1}{17}$th of a degree. Founding upon these displacements of the stars, it has been concluded that our sun, accompanied by his attendant planets, is in motion towards a region of space in the direction of the constellation Hercules.

Milky-way.—The stars are very unequally scattered over the sky. We may always observe a whitish band arching the heavens, called the *Milky-way*, which appears to the eye, and still more to the telescope, as a dense mass of starry dust. From this appearance it is inferred that the stars forming our firmament do not extend indefinitely into space, but are limited in all directions, the mass having a definite shape. Herschel conceived the stratum to be thin in proportion to the length and breadth, and that looking through the mass of stars forming the depth in these directions, gives the appearance of the Milky-way. As the Milky-way divides into two branches, there must be a bifurcation of the stratum. Our place in the system is conceived to be not in the centre, but nearer to one end and to one surface.

Remote Star-systems, Nebulæ.—From the grand idea of the solar system, we thus rise to the vastly grander idea of a *stellar* system, composed of countless myriads of solar systems, many of them, perhaps, surpassing our own in magnitude, and held together by the universal bond of gravitation. But this star-system, which we may call our own universe, inconceivably vast as it is, is but an item of the heavenly inventory. Far beyond its bounds, the modern telescope has descried similar systems in great numbers, each hanging in some tolerably defined shape in the depths of space.

A few of these remote systems are visible to the naked eye, as faint luminous spots in the heavens; but by means of powerful telescopes, thousands of them have been observed and catalogued. They are generally spoken of collectively as *nebulæ*, from their cloud-like appearance. Many of them are resolvable into individual stars, even with a moderate telescope, but others were found to resist even the powerful telescope of Sir William Herschel; and he accordingly made a distinction between clusters of stars, or resolvable nebulæ, and nebulæ properly so called, which presented no appearance of stars. These last were conceived to be elementary sidereal matter in a diffused and gaseous form—matter in the course of being condensed to stars and systems. But when the still more powerful telescope of Lord Rosse shewed that several so-called nebulæ, hitherto irresolvable, were really groups of stars, the nebular theory was thought to be overturned; for although many still resisted resolution, this was attributed to extreme distance, and the want of sufficient telescopic power. That wonderful instrument, the spectroscope, however, has recently reinstated the nebular theory, by shewing that among these appearances there are real nebulæ, devoid of solid or liquid matter, and consisting of masses of glowing gas—apparently nitrogen and hydrogen.

Nebulæ and Clusters.

These nebulous-looking objects, whether star-clusters or true nebulæ, present the most remarkable and sometimes startling shapes, of which a few specimens are represented in the figure. It is believed that Lord Rosse's telescope has brought within our ken objects whose light must take sixty thousand years to reach us!

GEOLOGY.

NATURE OF THE SUBJECT.

WE have most of us stood at the base of a great cliff, and looked upwards with awe at the rocks exposed on its weathered front. Such a sight might suggest many strange and interesting inquiries. How did these rocks come to be where they are? Of what are they composed? When were they formed? Whence the material for the vast thickness of rock that composes the crust of the earth? Whence have come the varied substances that form our limestones, coals, and sandstones? Whence also the strange shells, plants, and animals that a closer examination of their structure reveals? Are these the remains of bygone living organisms, or are they only marks in the rocks themselves? If they were once living creatures, what were their structure and habits? Such questions suggest themselves to every thinking person, and such questions Geology undertakes to answer.

Geology, from the Greek *gē*, the earth, and *logos*, a description, is, according to its name, a description of the earth. It examines the various rocks that compose its crust, and seeks to explain their appearance, form, structure, relative position, formation, age, and distribution throughout the globe. It also inquires minutely into their contents, animal, vegetable, and physical; the causes of their imprisonment in their stony tombs; and the structure and habits of the creatures there found. It pictures forth the physical history of the globe during the successive epochs through which it has passed, with their varied scenery and inhabitants, the formation of its many strata, and the structure and progress of the organic forms that successively waved in its atmosphere, moved over its surface, or swam in its seas. In short, it is the province of geology to describe the whole natural history of the globe during the various ages of the long past; and it includes the ancient zoology, botany, mineralogy, and geography of the earth, whose present conditions are the result of the numberless changes through which it has passed in these geological eras. The past it seeks to interpret solely by the present, assured that the laws of nature are invariable and universal, and that causes operating now produced like effects in the primeval earth.

ROCKS, THEIR KINDS, STRUCTURE, AND DISPOSITION.

In order to speak with precision in our study of this subject, it is necessary to have a distinct idea of what a rock is in geology, and to understand certain things regarding the kinds, structure, and arrangement of rocks.

What a Rock is in Geology.—In geology, the word rock has a wider meaning than it has in common language, where it means a mass of stone of considerable size. In this science, the word rock is used to designate *any of the materials that compose the crust of the earth*, of whatever size and softness they may be. Geologists reckon sandstone, marble, quartz, granite, and limestone to be *rocks*, as others do; but they also speak of coal, gravel, chalk, sand, salt, peat, and like soft and broken substances, as *rocks* or rock-formations.

Kinds of Rocks.—Rocks have different names, according to their appearance and structure. Every one knows what *sand* is, and that it varies greatly in fineness. The most of the sand we see is composed of small particles of rock ground to powder, but it often consists, as we shall afterwards learn, of numberless very minute shells. *Sandstone* is the usual rock of which houses are built, and which, in thin layers, is used for pavement. This rock is more common than any other, and has many varieties, and is, of course, so called because it is composed of particles of *sand* that have been made to cohere. When the particles of the sandstone are somewhat larger and sharper, the rock is called *grit*, from the particles having been *grated* down or broken: the rock of which millstones are formed is called millstone-grit, and its value depends on the hardness and sharpness of the grains of which it is composed. When the particles are larger still, and form small stones that do not cohere, the rock is called *gravel;* and when yet larger and more rounded, *shingle*, examples of both of which occur on the sea-beach. A mass of broken angular stones thrown up in a heap, as by a river after a flood, is called *rubble.* A stone when small is called a *pebble;* when large, a *block;* and when rounded and worn, a *boulder*, because it is *ball*-shaped. The fine sediment at the bottoms of rivers, lakes, and pools is composed of ground mineral, animal, and vegetable matter. When this is tough and plastic, it is called *clay*, because it *cleaves* or sticks; and the whole accumulation of mud, clay, and sand at the bottom of any water, is called *silt.*

The remains of vegetable matter found in various parts of the country, and used as fuel, are known as *peat;* and *coal* is nothing but such vegetable matter changed by heat, and hardened into rock by pressure. *Limestone* is the name given to the hard rock which, after being burned in a kiln, forms *lime.* When the limestone is hard and crystalline, it forms *marble*, which is of different colours, from deep black to pure white, and often beautifully variegated. *Chalk* is a variety of limestone, and obtains its name from this fact; the word chalk being another form of the Latin *calx*, lime.

Common *slate*, used for writing on and for roofing, is composed of thin layers of hard rock, of which some of our highest mountains are formed. The name *shale* is applied to a kind of rock which *shells* off or splits into very thin layers, and which may be seen in great heaps near coal-pits. Thin layers of sandstone used for pavement are called *flags.* The white pebbles so common on the sea-beach, and so easily broken, are made of *quartz*, and rock formed of it is called *quartz-rock.* Some varieties of quartz, called *rock-crystals*, are very beautiful and valuable, and are reckoned precious stones, such as agate, amethyst, and topaz. *Flint*

has much the same composition as quartz, and is very plentiful in chalk. The granular rock brought from Aberdeen and elsewhere, so beautiful when polished, is called *granite*, from its being composed of *grains* of other rocks. It has two chief varieties, the gray and the red, according to the prevailing mineral in its composition. It is composed of quartz, mica, and felspar. It composes the mass of some of the chief mountain ranges, and forms part of some of the grandest scenes in nature. It is in general of igneous origin, but is certainly not always such; its origin is the subject at present of much controversy. The particles that glitter like silver in the granite are pieces of *mica*,[1] which is so named because it *shines*. A mineral very like mica in appearance, but different in composition, is called *talc*, from its feeling somewhat greasy or *tallowy* when touched.

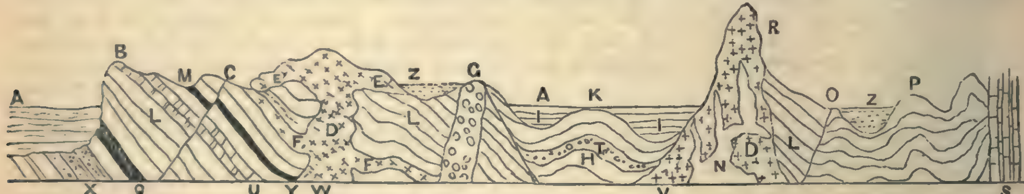
The molten matter that *flows* from volcanoes is called *lava*;[2] *pumice-stone*[3] is the *cinder* of such discharges; while the *ashes* that are thrown into the air are called *scoriæ*. In geologic times also there existed volcanoes from which lava issued; the rock this lava formed is called *trap*,[4] from lying in *stair*-like masses, as it flowed from the mountain; and one kind, *whinstone*, which is much used for roads. A common variety is known as *greenstone*, from its colour, of which Salisbury Crags, near Edinburgh, are composed. Another variety is called *basalt*, and is generally found in columns standing close together, which often form wonderful natural scenes, such as Fingal's Cave and the Giants' Causeway. Another variety is *porphyry*,[5] so called from its frequent *purple* colour, and is easily distinguished by its granular appearance. A kind of light porous rock, formed of cohering volcanic ashes, is known as *trap-tuff*, or *tufa*, a word that comes from Italy, the seat of so much volcanic action.

STRUCTURE OF ROCKS.—On examining the rocks forming the crust of the earth, we find that they may be divided into two great classes—the *stratified*, or those deposited in strata or layers; and the *unstratified*, or those not so formed. Sandstone and slate are stratified rocks; granite and trap are unstratified.

1. *Stratified Rocks*.—Any thin deposit of rock is called a *layer*, from its having been *laid down* under water; a *band*, from its being like a thin band; a *bed* or a *stratum*, when of greater thickness, from Latin *sterno*, to spread; and a *seam*, when of a peculiar character as compared with the rocks near it, as a seam of coal. *Stratum*, with the plural *strata*, is the general term for any layer of rock, and hence all rocks in layers are said to be *stratified*. Rocks that split up into very thin layers, a great number being included in the thickness of an inch, are said to be *laminated*, and the thin layers are called *laminæ*; these are formed by deposition. Slate-rocks have a remarkable tendency to split or *cleave* in one direction, which is called their *cleavage*. This in general does not coincide with the lamination, and may be at any angle. It is by the cleavage that the slates of commerce are separated. Some attribute this phenomenon to pressure, others to heat. Gneiss and other rocks have a tendency to split or *foliate*[1] into thin layers of different mineralogical character, as quartz, mica, and such like. This is called their *foliation*, and must be distinguished from their stratification and also from cleavage, which exists in rock of one mineral composition. Granite and other rocks are often split into large masses, more or less cubical, along certain lines at equal or varying distances. These lines of separation are called *joints*. They occur much in igneous rocks, as in basalt. These words should be carefully distinguished: thus shales are laminated; schists, foliated; igneous rocks, jointed; slates, subject to cleavage. When a rock is composed of rounded pebbles or boulders imbedded in other matter, it is called a *conglomerate*, and sometimes, from its appearance, *pudding-stone* or *plum-pudding stone*.

2. *Unstratified Rocks*. — Unstratified rocks assume various forms, according as they have been shot up amongst the stratified rocks; for, as we shall afterwards see, they have been erupted from volcanoes. Very often, like most volcanic substances, they are *porous* or *cellular*, like pumice-stone; frequently they form gigantic columns, when they are said to be *columnar*, like basalt; and often they are found in large *globular* or *spherical* masses, like bombs or cannon-balls.

DISPOSITION OF ROCKS.—1. *Stratified Rocks*. —When rocks lie parallel to the horizon, they are termed *flat* or *horizontal*, as A, in the following section; when at an angle to it, they are said to



Section of the Different Kinds of Strata.

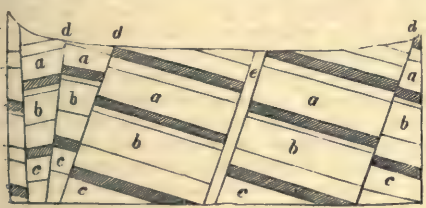
A, Horizontal and unconformable rocks.
B, Inclined strata.
C, A slip.
D, A disrupting mass.
E, Overlying trap.
F, Interstratified trap.
G, A dike.
H, Bent and rolling strata.
I, A basin or trough.
K, A ridge of rocks.
L, The dip of the rocks, 45°.
M, An outcrop.
N, Veins.
O, A fault.
P, Contorted or twisted strata.
Q, A seam.
R, Rocks tilted up.
S, Columnar basalt.
T, Conglomerate.
U, Limestones.
V, Granite, disrupting.
W, Trap.
X, Sandstones.
Y, Coal.
Z, Silt or gravel.

be *inclined* or *dipping*, as B; when one end has been thrown up by some other mass, they are said to be *tilted up*, as R; when so much inclined as to be straight up and down, they are said to be *perpendicular*, or *to stand on edge*. When inclined

[1] From Latin *mico*, to shine.
[2] From Latin *lavo*, to lave or flow.
[3] From Latin *pumex, -icis*, cinder.
[4] From Swedish *trappa*, a stair.
[5] From Greek *porphyra*, purple.

[1] From Latin *folium*, a leaf.

rocks come to the surface, they are said to *crop out*, and the exposed edge is therefore termed the *outcrop*, as M; the angle at which they are inclined is called the *dip* of the rocks, and is measured by the number of degrees from the horizontal in any direction, as 60° S.; and the line of the outcrop along the surface is termed the *strike* or *line of strike*, because it strikes or runs across the country. When the strata are not straight, they are said to be *bent* or *curved;* and when greatly bent, *twisted* or *contorted*, as P. When all the strata in a series lie at the same angle, they are called *conformable;* when at different angles, *unconformable*, as at A. Sometimes certain strata seem to have slipped down or to have moved up, so that rocks that should be opposite to one another are not so. The portion that has slipped is naturally termed a *slip*, as C; that which has been heaved up, an *upheaval* or *hitch:* where the strata at the slip lie at different angles, the slip is called a *fault*, as O. All such displacements of strata are known as *dislocations*, and they are much more frequent than the regular disposition of rocks on the surface of the earth. Below is a good example of such dislocations in coal strata, where they are abundant. The *slips* are marked *d;* a *dike*, of trap, *e;* *a*, *b*, *c*, shew the strata that have been torn up; the dark bars are coal seams. When strata are bent in wavelike undula-



Dislocations of Coal Strata.

tions, they are said to *roll*, as H; and the hollow or concave portions are termed *troughs* or *basins*, and the elevated portions *ridges*, as I and K.

2. *Unstratified Rocks.*—These rocks are thrown up amidst the stratified, and assume different positions according to the manner of their upheaval. Where they throw the strata into various angles, the rock upheaved is termed the *disrupting* mass, as V; at other times, they overlie the other rocks, and are then called *overlying*, as E; they are also interjected *between* the other *strata*, and are said to be *interstratified*, as F. Sometimes they intersect the other strata by masses like walls, which are called *dikes*, as G; and sometimes the disrupting mass breaks into branches, which are called *veins*, as N.

When a broad face of rock is exposed, and the different rocks shewn, as in a cliff on the seashore, a railway-cutting, or a quarry, such exhibitions of strata are called *sections;* and these may be delineated on paper. Sections of the underlying rocks may also be made, by examining the different rocks in a country, though no section be exposed in nature.

THE CONTENTS OF THE ROCKS.

The contents of the rocks receive the general name of *fossils*, from the Latin *fossus*, dug, because they require generally to be *dug* out of the earth. Fossils may be divided into two great classes, animals and plants.

Fossil Animals.—In the rocks we discover specimens of every class included in the animal kingdom. We find corals of all kinds, and of the most beautiful structure, some branched like some of the corals of the present seas, others standing in masses on the very spots where they lived and died, their remains giving beauty to our finest marbles. We see star-like creatures of all kinds, either spreading abroad their arms or curled up at rest, as they may be seen any day during the ebb of tide. Shells of every form, size, and colour meet us at every step, as distinct as we now find them on the shore; and some formations, of vast thickness and extent, are formed entirely of the habitations of these little creatures. We may also gather crustaceans, such as the crab and the lobster, the minutest parts of their structure being perfectly preserved. We discover fishes of every kind and size, sometimes entire, as they fell to the bottom at death, or crushed and broken in the convulsions to which the rocks have been subjected. We can gather the hard scales, that defended them like armour; can form collections of their teeth, their fins, their jaws, and their eggs; and can construct them again as they swam about in the ancient seas. Insects, too, we can gather of every kind, and can see them as they flew about in the old forests, and got entangled in the resin of the great old trees. Birds, too, are found, though not so plentifully as other creatures, as, from their manner of life, they were not so easily carried down by rivers, and deposited in the mud at their mouths. We find reptiles of immense size, crocodiles, and lizards, and flying dragons, with their terrible teeth, sweeping tails, and adamantine hides. We come upon beasts of every size, from little creatures that burrow in the ground, to gigantic deer, elephants, rhinoceroses, and mammoths; and may enter the very dens in which lived beasts of prey, and to which they bore their captured victims.

These creatures differ more or less from those that now inhabit the globe, but they are members of the same classes; and catalogues of them have been formed as of those of the present day. A visit to a museum in which fossils are exhibited astonishes every one with the multitude, variety, and beauty of those fossil creatures, and especially with the wonderful preservation of organisms the most delicate and frail.

Fossil Plants.—But the vegetable kingdom is as fully represented in the rocks as the animal. We find trees of the most varied kinds, with their roots, stems, branches, leaves, flowers, and fruit. We can look with wonder on the exquisite carving on the stems of mighty trunks, hundreds of feet in height, that once formed forests as dense and impenetrable as those of the Amazon. But more, we can behold the trees standing on the very places in which they grew and waved their great branches, and can trace their roots as they penetrate the soil beneath. We can also gather plants of all kinds—reeds, mosses, rushes, sea-weeds, and beautiful ferns—preserved entire, and spread out on the rock as delicate and perfect as in the finest herbarium. These fossil plants have, like the fossil animals, been examined and classified by botanists, and we possess elaborate volumes on the botany of the remote ages when these plants

grew, similar to those on the existing flora of our globe.

Traces of Natural Operations.—But the rocks bear traces of more than all this. On them, we can see the very dints of the rain-drops of these bygone ages, and can calculate the direction and force of the showers that impressed them. We can walk over the rippled sands of the old seas, just as we can do over those we played on in childhood. We can also look on the footprints of primeval birds, as they stalked in the mud of their lake or river homes; or gaze with astonishment on the great footprints, as large as a man's hand, of the huge reptiles that waddled among the reeds by the great old rivers. We can look into the craters of extinct volcanoes, can follow the flow of the destructive lava, and can gather the ashes that once illuminated the darkened heavens. We can trace the sources of ancient rivers, and dig in the mud brought down from their mountain sources; can draw maps of the continents and seas as they existed thousands of ages past; can tell where great ocean-currents flowed, bearing huge icebergs, that grated the sea-bottom, and left their indelible traces on the granite and trap of our present hills; and can shew where mighty glaciers once existed in valleys now famed for their beauty, where the genial sun sheds its warmest rays. In short, every element in nature, whether of air, river, or ocean, has left its deepest traces on the solid crust of our globe.

AGENCIES IN THE FORMATION OF ROCKS.

Any explanation of the manner in which rocks have been formed must account for *all* the phenomena, equally of composition, structure, arrangement, and contents. We must, for instance, explain how some rocks are stratified, and others not; how some are horizontal, and others inclined; and how plants and animals have come to be imbedded in them so far below the surface. Are there, therefore, any agencies engaged in the formation of rocks *at the present time* that produce effects the same in kind with these older masses? If we find that such exist, we shall have a key by which to interpret the rock-formations of the past. Let us consider, therefore, the Rock-forming Agents.

Volcanic Agents.—The most obvious rock-formers at present in action are volcanoes. From circular openings, called *craters*[1] from their *cup-like* shape, at the summits of these mountains, there issue forth at certain times great streams of molten lava, boiling water, red-hot fragments of rock, mingled with flames, and smoke, and steam, amidst confused and thundering sounds, and the general convulsion of the surrounding country. These lava-streams, increased by ashes and other substances, are often of great thickness, sufficient to bury cities; as Vesuvius once did Herculaneum and Pompeii, and Etna did Catania at its base, where the river of lava gradually rose round the walls, finally drowning the city in its burning flood, after it had flowed twenty-four miles! Successive accumulations of such outbursts deposit immense masses of rock, in the course of ages, round the centre of eruption; so great, indeed, that the larger portions of such mountains—and some of those in America are five miles in height—are formed of the successive accumulations of the crater itself. The molten lava assumes various appearances after it has lost its heat: under water, it remains hard and compact; in the open air, it becomes porous and cindery; and in certain cases, it assumes a columnar form. All around, lie light pumice-stone, slag-like masses, fine pulverised dust, and huge calcined blocks. Now, the Unstratified rocks resemble in every feature these volcanic discharges. We meet with the compact lava in our trap and greenstone; with the cinder, in the lighter porous rocks; with the ash, in our trap-tuffs; and with the columnar, in the basalt. In exposed sections, we see the very vent through which these masses burst and overflowed the strata above; and can trace the boundaries of the ancient molten streams in the cliffs and hills that everywhere vary the surface of the country. We can also see hardening and crystallising changes produced on the surrounding strata wherever the heat of the erupted matter penetrated. We have therefore found the explanation of one great class of the rock-formations, the Unstratified, in the volcanoes scattered over the globe, that are at this moment depositing masses similar in kind to those that issued from the bowels of the earth in bygone ages. These unstratified rocks, therefore, are termed *igneous*,[1] from being produced by *fire; volcanic*, from having issued from *volcanoes;* and *eruptive*, from being produced by *eruptions*.

Aqueous Agents.—Rivers, as they flow over their channels, gather accumulations of mud, sand, gravel, and animal and vegetable remains, according to the size of the stream and the character of the country through which they pass; and these they deposit at their mouths in seas or lakes. Sometimes the amount of débris thus deposited is so great as to form large tracts of land, as at the protruding mouths of the Ganges, Nile, or Mississippi. Even in historic times, the land thus gained is of great extent. For example, at the mouth of the Po, a minor stream, the town Adria, which gave its name to the Adriatic Gulf from its extensive commerce in Roman times, is now nine miles from the sea! The mass of matter held in solution or borne along by the running water, sinks to the bottom when it reaches the sea, in a certain order. First, the heavier masses are deposited, such as boulders and gravel; then, the sand; and last, the mud. Mingled with these are various animal and vegetable remains that have been washed into the stream. Thus, every river-mouth presents an ever-growing series of beds of varying thickness and material, superposed the one on the other, and enclosing various remains of animal and vegetable life. These deposits would, in the above order, be converted, by pressure, into conglomerate, sandstone, slate, shale, and coal. Thus, again, we have found a beautiful and perfect explanation of the Stratified rocks as they are presented everywhere, by which their composition, stratification, and contents are fully accounted for. Stratified rocks, therefore, obtain the various names of *sedimentary*, because formed of the *sediment* of rivers; and *aqueous*,[2] because deposited under *water*.

Organic Agents.—But animal and vegetable

[1] Greek *kratēr*, a cup.

[1] From Latin *ignis*, fire. [2] From Latin *aqua*, water.

life is also busy in the formation of rocks. Away in the warmer seas of the Pacific, lives the coral insect or zoophyte, the skeletons of which compose the remarkable coral reefs that form the chief part of the numerous isles that stud that greatest of seas. These reefs extend thousands of miles, in broad barriers, over which the wild waves dash, or in detached groups that gradually gather material round them, and form new islands. In the rocks, we also find the remains of like corals, standing where they grew, or drifted away, and appearing as extensive formations of limestone.

Again, the bottom of the sea is covered with accumulations of minute shell-fish, of great depth and extending over wide areas, as is proved every day by soundings with the lead. The old rocks also exhibit strata identical in composition with these microscopic shells; some limestones and chalks, for example, being composed of millions to the square inch of perfect bivalve shells. Again, the sea-bottom contains beds of shell-fish, of different kinds, and of great extent and thickness. If these were to die, and be subjected to sufficient pressure, they would form a rock, exactly like the shell limestones so common in our rock-formations, and so valuable in agriculture and building.

Then we possess the remains of ancient forests in our great mosses; and luxuriant growths of swampy plants and impenetrable jungles in the mud islands of the deltas of our great rivers in the tropics. These, submerged and acted on by heat and pressure for ages, would become coal, similar to what we daily use for fuel. Thus, organic life of all kinds is everywhere busy in forming rock-masses, similar in character and appearance to those presented to our investigation in limestone, chalk, and coal.

AGENCIES IN THE ALTERATION OF ROCKS.

DISTURBING AGENTS.—Stratified rocks in their natural state would be more or less horizontal and continuous. How, then, are we to account for the tiltings, upheavals, faults, and various dislocations so prevalent among the strata? Igneous forces furnish the solution. The whole globe is subject to convulsive movements produced by internal forces, which are seen in earthquakes, and by which the ground is torn into fissures, and the solid crust made to move in mighty undulations, that destroy and swallow great cities. Extensive tracts are also sometimes suddenly raised or depressed. Sometimes, too, great yawning craters open where previously volcanic movement was unknown, and continue for a time in active eruption. In these upheavals and subsidences, sudden or gradual, of extensive tracts, we see the causes at work of the dislocations of the rocks of former times, and of the elevations and depressions that occurred throughout the geologic eras.

Again, we know that in order to the deposition of strata of any thickness, the sea-bottom must have gradually subsided: does any such gradual subsidence take place at the present time? It is ascertained, from extended observations, that on the northern shores of the Baltic, for instance, there has been a gradual rise at the rate of 4 feet in a century; and, in South America, a rise of 85 feet during the human period, at Valparaiso, of 19 feet in 220 years; while over all the world, and even round our own coasts, ancient sea-beaches may be seen at various elevations, marking former sea-levels. On the other hand, the south coast of Sweden, the coast of Greenland over 600 miles, and parts of South America for the last 300 years, have been slowly sinking; nor are the British shores free from such oscillations.

Thus, again, we see that existing causes perfectly explain the *gradual* subsidences and upheavals necessary to the formation of the rocks and to their subsequent elevation into dry land.

DISINTEGRATING AGENTS.—Every stratified rock in the immense thickness of the crust of the globe has been formed of the débris of pre-existing formations, that have been ground down and held in suspension till deposited in the layers afterwards hardened into rock. Whence, then, this immense accumulation of matter, and what the disintegrating agents?

1. *Atmospheric Agency.*—The atmosphere, by its chemical action, and by the combined effects of alternate heat and cold, wetness and dryness, is continually crumbling down all exposed surfaces, forming new soil, and thus increasing the earthy covering of the globe. The wind, also, has an incredible power of drifting and heaping up sand-hills along the shore—as in the county of Elgin, where an ancient barony has been entirely reduced to a desert through this means—and of raising the waves of the sea, and wearing the rocks through the mighty force of its swooping billows. Frost, too, is one of the quietest but most powerful disintegrating agents; for when water has percolated a mass of rock, the act of freezing exerts a great expansive force, which cracks the rock. But frost can work on a grander scale, for to its agency is due the existence of avalanches, glaciers, and icebergs; which, whether sweeping with overwhelming convulsion, or crawling down the mountain side, or floating and grating on the ocean floor, continually and with terrible effect, wear down or dash to pieces every rock that obstructs their irresistible course.

2. *Aqueous Agency.*—The most extensive aqueous agent is rain, which wears, softens, percolates, and gradually wastes away the rocks on which it falls. Rain-water also gathers under the ground in large cavities, where springs are formed, which dissolve the interior rocks, and, bursting out, deposit their solutions of lime, iron, sulphur, soda, flint, and bitumen. One of the most powerful degrading agents is, of course, the sea, which, as it beats on its rocky shores, wears, rolls, and grinds to powdery sand the flintiest rocks, and presents, as monuments of its mighty power of waste, those lofty cliffs that guard its shores. But more powerful, but less obvious agents of destruction than the sea, are seen in the many streams that everywhere traverse the land on their way to this boundless reservoir. The power of rivers in excavating and wearing away the surface of the globe, is much greater than at first thought might be supposed. Most river-valleys, however deep, have been mainly worn down by river-action, extending over immense periods of time. When we contemplate the mighty valleys, inclosed by towering peaks capped with eternal snows, that lie hid amidst the mountain solitudes of the Alps, the Andes, or the Himalaya, we may well be astonished at such a statement. But that these huge excavations have been mainly produced by the combined action of air, frost, rain, and river, has

been demonstrated beyond a doubt by a vast accumulation of facts and reasonings on phenomena in all parts of the globe. Hence, valleys thus excavated are termed *valleys of erosion*,[1] from being ground out by the powerful action of these mighty agents. This being proved to be the case even during the human period, we have little difficulty in accounting for the great denudation everywhere seen, and for the immense accumulations of sedimentary matter that forms so much of the solid crust of our globe.

TRANSPORTING AGENTS.—We have also to account for the deposition of strata in one part of the country, the materials for which have been obtained at great distances; and for the transport of immense boulders hundreds of miles from their original seats, as exhibited in all parts of the globe.

1. *Aqueous Agency.*—The most obvious agents of transport are rivers, that bear down from every part of their courses the débris deposited at their mouths. Their power of carrying masses of the heaviest materials is immense, as may be seen after a flood in the smallest streams in our neighbourhood. Waves have also a wonderful power in removing and carrying to a distance the blocks on which they daily dash. But the currents that flow through the ocean, which are but mighty ocean rivers, have the greatest power in this respect. By their means, materials of all kinds, organic and inorganic, are conveyed to incredible distances. The Gulf Stream, for instance, conveys substances from the South African coasts to those of Norway and the far north.

2. *Ice Agency.*—But the transporting influence of these currents in bearing rock-masses is greatest when icebergs are carried on their surface. These huge frost-mountains have imbedded in their mass huge blocks, which are gradually dropped over wide areas as the ice slowly melts away. The size and number of some of these transported rocks are often almost incredible. Every country exhibits such travelled rocks, which are called *erratic*[2] *boulders;* and our own little island presents no mean examples of such ice-borne masses.

But ice also acts as a transporter in the form of glaciers—those great ice-rivers that fill the upland valleys of the Alps, Himalaya, and other mountain systems. In front of every glacier, along its sides, and on its surface, are great collections of rocky fragments of every size, borne down by the ice-stream, and left as evidences of its existence when the glacier has melted away. Such collections of rocks are called *moraines*,[3] from their *mural* or wall-like aspect as seen running across a valley. The distance to which such blocks are borne is astonishing, and depends on the size of the glacier. Evidences of extinct glaciers are seen in most countries, and we may trace their remains in our own island, where now not a particle of glacier ice can exist.

3. *Igneous Agency.*—It is evident that volcanoes have a great power in throwing out masses of different materials to great distances, and of carrying many substances on their mighty lava-streams; and evidences of their power in this respect in geologic times are everywhere apparent. Sometimes the fine ashes that issue from the crater are borne by the wind to great distances, often fifty or a hundred miles, where they are deposited as a layer of finest dust; and this may account for the existence of trap-tuffs in places where no volcanic eruption seems to have taken place.

TRANSFORMING AGENTS.—Rocks have also undergone great changes in structure, character, and hardness from the state in which they were originally deposited. Thus limestone has become marble; sandstone, quartzite; coal, anthracite. Such change is known as *metamorphism*,[1] and the rocks so changed are called *metamorphic*. The chief agencies producing such remarkable transformations are these:

1. *Pressure.*—The effect of pressure is at once apparent when we reflect that by it chiefly the loose materials of rocks have been made to combine and form solid strata—as sandstone from sand, coal from vegetable remains. But pressure exercises a much greater influence than would at first sight appear. For example, the melting-point of substances is greatly affected by pressure, some substances melting with much less heat under pressure than without it, others requiring more. The metamorphosing power of heat is greatly affected by pressure. Thus chalk, by heat, becomes lime in the open air; but under pressure fuses and becomes marble. Pressure is one cause, and may be the chief cause of cleavage in slates: this is one theory, known as the mechanical; the other being that of heat, and known as the crystalline.

2. *Chemical Action.*—This is one of the most secret, but one of the most general, transforming agencies, and its influence can only be indicated here. By it, substances are held in solution, or precipitated; new substances are formed; rocks become entirely changed through the chemical affinities between their contents, or by being permeated by streams and waters bearing other soluble substances; the different materials in rocks become aggregated, and form layers or masses: in short, it manifests itself by countless secret and potent effects.

3. *Heat.*—The greatest metamorphic agency is heat, whether general or local. By it rocks are wholly or partially fused, and undergo rearrangement of their component crystals, and thus become changed in form and structure; or they are subjected to partial change of all degrees of intensity. The influence of heat is always seen more or less near igneous rocks, and the eye can follow the change from the natural rock, and note the gradual increase of metamorphism as it approaches the igneous seat. By heat the most varied transformations have been effected. Thus limestone and chalk have been changed into marble, schists into jasper and granite, sandstone into quartzite and hornstone, shales into flint and jasper, clay into Lydian stone, &c. But whole systems of rock have also been affected by heat, which are known as the metamorphic or crystalline systems. The chief metamorphic rocks are gneiss, quartzite, mica-schist, with hornblende and chlorite schists, clay-slate, and metamorphic limestone. These were originally sedimentary rock, with fossils; but the metamorphism has more or less obliterated the lines of deposit, and more or less destroyed

[1] From Latin *e*, out, away, and *rodo, rosum*, to gnaw.
[2] From Latin *erro*, to wander.
[3] From Latin *murus*, a wall.

[1] From Greek *meta*, change, and *morphē*, form.

their organisms. Hence they are characterised by great absence of fossils.

Gneiss,[1] so named from its thin layers, is a hard crystalline rock, in extremely thin bands, often twisted in a remarkable manner, and consists mainly of the same materials as granite. Quartzite is a metamorphosed sandstone, and is so called from its quartzy appearance, arising from the fusion of the sandstone. It must, however, be distinguished from quartz itself. The schists are named from their chief ingredients. Clay-slate is that most useful rock which, when split up into thin layers, forms the familiar blue slates of our roofs, and the slate and slate-pencil of our schools. These rocks are often grouped together in nature, as in the Highlands of Scotland, where they form the mass of the mountains, and enter into the grand and beautiful scenery of that picturesque region. They occur most extensively in the older formations, as the Laurentian, Cambrian, Silurian; but it must be carefully noted that metamorphic rocks are found throughout all the geologic systems up to the Recent. For example, Carrara marble, which was long thought to be primary, is metamorphic oolitic limestone; and, in the Alps, tertiary strata have been so changed as to be with difficulty distinguished from the oldest rocks.

It thus appears that the agencies now at work on our own globe are adequately sufficient to account for all the phenomena of the forming, disturbing, disintegrating, elevating, depressing, transporting, and transforming of the rock-masses that form the crust of the earth. Such being abundantly proved, and the laws of nature being uniform and unchangeable, we are not only warranted, but compelled, to infer that the same influences were at work in these bygone ages, and were the joint causes of the formation of our rock-systems as they are now presented to our eyes and subjected to our investigation.

ROCKS AS RELATED TO TIME.

The Length of Geological Periods, or Geological Time.—In studying geology, it is necessary to have an accurate notion regarding the nature of the periods spoken of. It is to be carefully noted that, in geology, time cannot be measured by years. When we examine any stratum of rock, with all its enclosed organisms, it is natural to inquire how long this mass of rock took to be deposited. We can judge of this only in the following way. From observation of river-action as at present exhibited, we see with what extreme slowness rock-masses are worn down into sand; how a thousand years make an almost imperceptible change on a boulder, and even on the gravel by the shore. Yet we know that the sandstone before us, often hundreds of feet in thickness, is composed of grains of rock ground down by water-action, transported by rivers to the sea-bottom, and deposited there till other strata were heaped upon it; and that in after-ages the grains united, and were hardened by pressure into the rock we see. What incalculable ages, therefore, must this sandstone bed have taken to be thus formed! The more we think of these slow-working causes, the more are we astonished at the enormous periods of time that must have elapsed before the formation of even the thinnest layer of rock. Geological periods, therefore, are quite indefinite in the matter of *years*. This inability to assert a definite number of years in regard to any formation, is no defect in the science, for the knowledge of this would add nothing to the conception we already have of the immense periods presented to our contemplation by geology.

[1] From Anglo-Saxon *gnidan*, to rub.

The Relative Ages of Rocks.—When we speak of the different ages of rocks, we can do so only by comparison with others. Our ideas on this point are merely relative. We can assert that one layer must have been formed before another; or that, after its formation, and before the deposition of a certain other rock, a rise or fall in the strata took place; or that, at a certain point in the series, a volcanic eruption threw up a mass of igneous rock; and make like statements based on comparison of the rocks with one another. Our conceptions, therefore, regarding the connection in age between the various rock-formations are merely relative, one rock being proved to have been formed before, or after, or during the formation of another.

The Order of the Rock-formations.—By long-continued and widely extended observations in various parts of the globe, based on numberless data of composition, structure, inclination, and fossil contents, geologists have been able to form a definite list of the various rock-formations from the earliest to the most recent, arranged in the order of time. They have divided the whole of the rocks composing the crust of the earth into sections called 'systems,' and have subdivided these again into 'groups,' in a certain well-defined order. So that when a rock is presented to their observation in any part of the globe, they can state, with more or less certainty, the system to which it belongs, and the period in the past history of the earth at which it was deposited. Regarding these rock-systems, one point is to be very strictly noted. Suppose that we represent the various rock-systems by the letters of the alphabet—the earliest by A, the second by B, and so onwards to the last and most recent, represented by Z. Now, the various rock-systems always stand in this relative historic order; so that the formation indicated by M comes after L, and before N, and cannot occur in any other relation to these two systems, wherever they may be found. At the same time, certain formations, one or more, may be wanting in some parts of the world, not having been deposited there; so that one or more systems may not be represented in these districts. Thus, L and M may be absent. What two systems will then be found together? Certainly and unvaryingly, K and N. But here the historic order is not violated, as it would be if N preceded K. The various rock-systems are, therefore, always presented in an unvarying succession in the order of their formation; although, in different parts of the globe, certain strata, and even whole systems, may not be found.

CLASSIFICATION OF THE ROCKS—THE ROCK-SYSTEMS.

We now proceed to describe, in the order of their formation, the different kinds of rocks that compose the crust of the earth, and their fossil

contents. As already said, geologists have divided all the rocks into different classes, according to their relative position and the fossils they contain. The whole of the stratified rocks are divided into eleven great systems, and each of these into separate groups, to which names have been given, more or less descriptive of the strata to which they are applied. The systems have been named chiefly from localities in which they are largely or typically developed, as the Laurentian; in some cases from important rocks they contain, as the Carboniferous; in others from their position or order, as the Recent. They are given tabularly below, with the reasons for the names, and their chief rocks, to give a definite idea and to assist the memory. This list should be carefully studied and comprehended before going farther. These systems are also grouped into three great Periods, and into two great Cycles, according to the character and advance of the organic life they contain.

ROCK-SYSTEMS.

Systems.	Reason of Name.	Characteristic Rocks.	Periods.	Great Cycles.
I. LAURENTIAN.	From the *St Lawrence* in North America.	Eozöon limestone and gneiss.	PALÆOZOIC[1] or Ancient Life Period.	PALÆOZOIC or Great Ancient Life Cycle.
II. CAMBRIAN.	From *Cambria* or North Wales.	Sandstone flags with fossils.		
III. SILURIAN.	From *Siluria* or South Wales.	Slates.		
IV. DEVONIAN and OLD RED SANDSTONE.	From *Devon* and its *red sandstone*.	Old red sandstone.		
V. CARBONIFEROUS.	From its *coal* strata.	Coal and iron.		
VI. PERMIAN.	From *Perm* in Russia.	New red sandstone.		
VII. TRIASSIC.	From consisting of *three* groups.	Magnesian limestone, rock-salt.	MESOZOIC[2] or Middle Life Period.	NEOZOIC[4] or Great New Life Cycle.
VIII. OOLITIC or JURASSIC.	From its *egg-grained* rocks, and from *Mount Jura*.	Egg-grained rocks.		
IX. CRETACEOUS or CHALK.	From its *chalk* rocks.	Chalk and greensand.		
X. TERTIARY.	From being the *third* of the old geologic systems.	Clay and marl.	CAINOZOIC[3] or Recent Life Period.	
XI. QUATERNARY or RECENT.	From being the old *fourth* system, and from being *recent*.	Peat and gravel.		

These systems we shall describe in order, beginning with the earliest, down to the most recent, giving the appearance and composition of the rocks, the uses to which they are applied, and the fossils they contain. We shall also endeavour to realise the state of the earth at each successive epoch, the scenery then exhibited, and the plants and animals that then enlivened the landscape. Below the Laurentian, another system is sometimes given as existing, called the Metamorphic or Primary or Non-fossiliferous. It seems necessary to abandon this system. As shewn (p. 22), metamorphic rocks occur in all systems. The assertion of the absence of fossils is premature, and has always proved so in regard to other rocks, and is unscientific. The term primary is objectionable on like grounds. All existing rocks, as far as yet known, seem to be comprehended under the eleven systems given above, which we now proceed to describe.

I.—LAURENTIAN SYSTEM.

Description.—Immediately above the Non-fossiliferous Metamorphic rocks lie the lowest of those that contain fossils. These have received the name of the *Laurentian System*, from their great development on the shores of the St Lawrence, in Canada. It was only quite lately, in the year 1863, that these rocks were grouped into a distinct system, from the discovery in them of certain fossil remains in Canada, having previously been reckoned metamorphic. The Laurentian System consists of certain schists, quartzose rocks, and limestones, all very highly crystallised—shewing good examples of metamorphic rocks. They form two groups, upper and lower. They contain no sandstones or shales, that occur so frequently in higher formations, such of these as once existed having been changed by heat. The limestones are very highly crystallised and metamorphosed, and of great thickness. The rocks, however, are all truly sedimentary, deposited under water, and have received their present aspect mainly through the agency of heat. They are found in Canada, Ireland, Norway, and Sweden, and, perhaps, in the north-west of Scotland.

Organic Remains.—The discovery of the fossil remains that caused these rocks to be formed into a separate system, was made in Canada, and excited interest amongst geologists, because belonging to a period when organic existence was thought impossible. The organism discovered received the name of the Canadian Eozöon[1] or

[1] From Greek *palaios*, ancient, and *zōon*, an animal.
[2] From Greek *mesos*, middle, and *zōon*, an animal.
[3] From Greek *cainos*, recent, and *zōon*, an animal.
[4] From Greek *neos*, new, and *zōon*, an animal.

[1] From Greek *ēōs*, dawn, and *zōon*, an animal.

Dawn-animalcule, and consists of minute tubes or cells that are visible only under the microscope. Some still deny that this structure is organic, and regard it as merely a mineral appearance; but these are few. The general opinion now is, that here we have the earliest life-remains yet discovered on our globe; and this is all the more certain, that worm tracks and burrows were found in 1866 in the same formation. The discovery of these evidences of organic life, so long sought in vain, shews that more minute search may result in other remarkable discoveries, and that in all likelihood the name of Eozöon will be found to be premature.

II.—CAMBRIAN SYSTEM.

Description.—Immediately above the Laurentian, lies a series of slates, schists, and crystalline limestones, called the Cambrian System. It is so named from being first most fully described as it is found in North Wales, which in Roman times was called *Cambria*. The rocks in this series are less changed than the Laurentian, and therefore the remains in them are more numerous and better preserved. They are of great thickness, and are found in Wales, Cumberland, Ireland, North America, and elsewhere. They are divided into two groups, upper and lower. Along with the older rocks beneath them, they everywhere form mighty, rugged, peaked mountains, like those of Wales; and their worn, rugged aspect is due to their being so long subjected to wasting influences from their great antiquity. All these earlier rock-formations, from the Laurentian to the Silurian, are exceedingly rich in mineral wealth, most of the precious metals being obtained from them. Shooting through their hard crystalline masses, we find veins of iron, copper, silver, and gold; and, from the presence of these metals, bare mountain tracts have teeming populations, where even the sheep with difficulty finds its scanty food.

Organic Remains.—The fossil remains are all of the very lowest kinds of life. Sea-weeds and shells of different kinds have been discovered, and some crustacea—especially one that occurs abundantly in the next formation, called the trilobite. The tracks and burrows of worms, formed in the sand of the ancient seas, may also be seen perforating these hard masses.

Scenery of Period.—During the Cambrian age, quiet seas heaved their waters as now, tenanted with shells and crab-like creatures, while waves rolled on the sandy shores, over which worms crawled, and into which they burrowed; facts interesting as shewing that creatures had then the same kinds of habits as now, and that what we can see any day along our own shores, sends us back to the distant ages when the world was young.

III.—SILURIAN SYSTEM.

Description.—The Silurian System contains rocks less changed by heat than those below, and exhibiting more abundant life. In many of those already mentioned, the metamorphism has been so great as to render it difficult to say with certainty how the rocks were originally formed, but henceforth all hesitation vanishes. They form two groups, Upper and Lower Silurian. They contain slaty sandstone, finely laminated, and often exhibiting ripple-marks; conglomerates chiefly of rounded pebbles, clays, and limestones, with corals and other fossil remains, all of great thickness. The system has received the name of Silurian from being very fully developed in a part of South Wales anciently called *Siluria*.[1] From these rocks are obtained roofing-slates, freestone for building, flagstones for paving and other purposes, limestones from which lime is got by burning, and valuable ores of lead, copper, silver, mercury, and gold.

Organic Remains.—Parts of the stems and leaves of water-plants and club-mosses, and a few sea-weeds, are found, but all scarce and much broken. No land *animals* have yet been obtained, and though it would be rash to say that they do not exist, much seems to render this very probable. But marine fossils are numerous and well marked, some of them being very beautiful. We find corals of different kinds, named according to their appearance, such as the sun, star, cup, pipe, chain, spider, and honeycomb corals. One of the commonest forms in the Silurian rocks is a very beautiful curved creature like the plume of a goose-quill, called the *Graptolite*,[2] from looking like a *pen* on the *rock;* some single, others double, some straight, others beautifully spiral. Another very abundant form is the Encrinite, a coral creature more numerous in the Carboniferous System. We find also star-fishes, one beautiful and 'almost as uncompressed as if just washed up on the sea-beach,'[3] and numerous fine shells with single and double valves, some, like the periwinkle and cockle, being abundant. But the creature that swarmed most in the ancient Silurian seas was the *Trilobite*,[4] so called from its body consisting of *three lobes* or divisions, above which was set its head with large

Coral (*Astrea*). Trilobite (*Asaphus de Buchii*).
Silurian Fossils.

double eyes, still to be found entire. It had various forms, and seems to have been very active, and was of all sizes, from mere specks to fine specimens ten or twelve feet long. Creatures like the scorpion, with toothed toes, are also obtained, and, in the upper beds, fishes interesting as the most ancient fossil-fish.

Scenery of Period.—Of the dry land, we know little or nothing, except that it did exist, and nourished certain aquatic plants and club-mosses, whose remains were floated down into the great seas. But we can see mighty oceans, in which corals flourished, and encrinites waved their lily stems. Shells were abundant, and numerous creatures gambolled in the bright sun. These seas were fringed by sandy shores, on which worms

1 Inhabited by the ancient tribe of the *Silures*.
2 From Greek *graphō*, I write, and *lithos*, a stone.
3 The *Valæaster asperinus*. See Lyell's *Student's Elements*, p. 456.
4 From Greek *treis*, three, and *lobos*, a lobe.

crawled and left their tracks; gravelly beaches, that have become conglomerates; and great beds of shells, that have given origin to thick limestones. Life gradually assumes more activity, and living forms become more numerous and elevated in the scale of existence, as we ascend in the system towards the active period that follows.

IV.—DEVONIAN AND OLD RED SANDSTONE SYSTEM.

Description.—This system of rocks has been rendered famous through the writings of several geologists, especially the celebrated Hugh Miller, and is one that in itself possesses the very greatest interest. In early geology, the Coal-measures were considered very important; and as both below and above them a great thickness of red sandstone is found, the rocks above were named the *New Red Sandstone;* while those below, being of course older, were called the *Old Red Sandstone*, or, shortly, the *Old Red.* This system consists of two types, the Fresh-water or Old Red, and the Marine or Devonian, so called from being extensively developed in Devonshire. These two types may not be of the same age, or if so, were deposited under different conditions. The Old Red is largely developed in the centre and north of Scotland, especially in Forfarshire and Caithness, where it is extensively quarried, and in parts all over the world. The name 'Old Red' indicates that the chief rock is a red sandstone, which is used very extensively for building. This also occurs in fine flags used for pavement, generally of a gray colour, yielding the famous Arbroath and Caithness pavements. The remarkable rock called Conglomerate or 'Plum-pudding Stone,' which looks as if it consisted of a consolidated sea-beach, is also extensively found at the base of the system. Like strata abroad coincide more with the Marine or Devonian than with the Old Red. They are found in many parts of the world, and extensively with fine fossils in Russia and North America. Both types are divided into three groups—Lower, Middle, and Upper.

Organic Remains.—There are fewer plant than animal remains found in this system. We find sea-weeds of different kinds, marsh-plants like our bulrushes, sedges and horse-tails, tree-ferns and reeds, &c. Late discoveries have greatly increased the number of plants, so long thought to be so meagre, to above 200, rendering this system almost half as rich as the Coal-measures in this respect. Animal remains are numerous, varied, and beautiful. There are many species of corals and shells. The tracks of certain creatures, and deep burrows, sometimes eighteen inches deep and one and a half across, made by large burrowing worms, are frequently found. Many crustaceans are obtained, one of which is a huge kind of crab, sometimes six feet long, with terrible-looking toothed claws, called the *Pterygotus*[1] or ear-wing. Reptiles are also found, two very large lizards being most frequent.

But by far the most numerous specimens of ancient life are gigantic fishes. These creatures are all covered with hard bony scales, burnished with enamel, with fierce teeth, and great fins armed with long sharp spines, with which they defended themselves or attacked their enemies.

Cephalaspis,[2] or Shield-head.

Coccosteus,[3] or Berry-bone.

Pterichthys,[4] or Winged-fish.

Old Red Sandstone Fishes.

These fishes have received different names, according to peculiarities in their structure or appearance, and have been brilliantly described by Hugh Miller, who, when cutting the Old Red Sandstone as a mason, had his attention first drawn to geology by the brilliancy of their scaly armour.

Scenery of Period.—The wide oceans in which the thin fine-grained flags were deposited must have been smooth and tranquil. Round the coral islands that rose in its gleaming waters coursed huge fierce fishes. The sandy shores became the coarser sandstone. Within tide-mark, numerous great crabs lived, and caught their prey in their toothed claws; shrimp-like creatures danced over the sands, and in them worms burrowed; the waves ebbed and flowed, leaving their ripple-marks on the rocks we now see; gravel beaches fringed the shore, where the surges rounded the pebbles and rolled the stones, helping to create our

[1] From Greek *pteron*, a wing, and *ous*, *otos*, the ear.
[2] From Greek *cephalē*, the head, and *aspis*, a shield.
[3] From Greek *coccos*, a berry, and *osteon*, a bone.
[4] From Greek *pteron*, a wing, and *ichthys*, a fish.

conglomerates; rain-showers fell, and left their impressions on the sandy bays pelted with their drops; forests of sea-weed waved in the green waters and on the rocky reaches; and shells adorned the rocks. Into the seas flowed great rivers, whose banks were fringed with reeds and flags; ferns waved on the hill-side, tree-ferns reared aloft their feathery plumes, and broad-leaved plants clothed the surface of the landscape; while large reptiles roamed through the forests, or crushed the reeds by the river-sides.

V.—CARBONIFEROUS SYSTEM.

Description.—Above the Devonian rocks lies a series of strata perhaps more generally known than any other, as they afford us what is so necessary to our comfort, the remarkable combustible stone called coal. They receive the name *Carboniferous*[1] from the fact that they contain *coal*, although they furnish many other important products. These rocks are found in most regions of the globe; but in none are they more fully developed, compared with the size of the country, than in the British Isles. They consist of sandstones, limestones, shales, clays, ironstone, and coal. The sandstone is of various qualities and colours, some of it very valuable and durable; the beautiful stone of which the New Town of Edinburgh is built is from this system. The limestones are largely developed, and are of the greatest service for building and agriculture. The shales have of late become very valuable, as from them are distilled oils and other substances, including the celebrated paraffine oil and candles. The ironstone is of the very greatest value, and contributes very largely to England's wealth.

It must not be thought that coal is found only in the Carboniferous rocks. Coal, being chiefly compressed vegetable matter, may be found in any rock-system in which plants are preserved. It is accordingly found in other systems, and often in great abundance. For example, the coal-fields of Virginia, some thirty or forty feet thick, belong to the Oolitic; and coal of various kinds can be obtained, more or less, from most systems.

The same is true of other products, such as limestone, sandstone, and iron, which last, though found in greatest abundance in this system, yet occurs in many others from the earliest.

The Coal-strata are divided into three great groups—the Upper and Lower Measures, and a thick deposit of limestone, which separates them, known as the Mountain or Carboniferous Limestone. The Upper Coal-measures are also called the True Coal-measures, as they contain the greatest amount of workable coal; the Lower Coal-measures consist chiefly of sandstones and shales. The Mountain Limestone is so called because where it is most largely developed, as in Yorkshire, it rises into hills with great limestone cliffs.

The industrial products of this system are numerous and important. We find coal of all kinds for household purposes and gas; iron, sandstone, limestone, and fireclay. From the shales are obtained alum and the remarkable paraffine oil. So abundant in America and elsewhere is this ancient oil, that when the earth is bored, a flood of it issues forth yielding thousands of gallons daily.

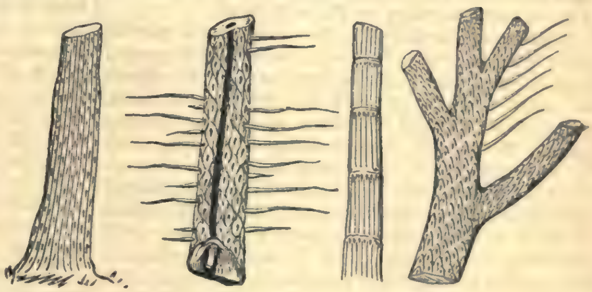
Organic Remains.—The organic remains found in this system are very abundant and remarkable. Plants are numerous, varied, and beautiful. Ferns are found with the most perfect fronds, as distinctly traced upon the rock as a modern dried fern on the pages of a book. We find also large and beautiful club-mosses exquisitely exhibited. But the most luxuriant and beautiful of all are the great pine-like araucarias, the fruit[1] of which

1 2 3 4

Carboniferous Plants.

1, Branch of *Asterophyllites foliosus*, a kind of reed; 2, 3, 4, Ferns.

may, in some places, be gathered by the bushel; the tree-ferns, and tall reeds that grew in boundless swamps and jungles along the banks of the rivers, that swept in mighty volume to the carboniferous seas. We see the *lepidodendron*[2] or scale-tree, with its pine-like leaves, beautiful scaly bark, and great cones,[3] from which the seed of the ancient pine may be gathered in hundreds to this very day; the *sigillaria*[4] or seal-tree, with its seal-stamped trunk and great pitted and branched root, called *stigmaria*,[5] long thought to be a tree of a different species; the *calamite*[6] or



1 2 3 4

Carboniferous Trees.

1. Sigillaria; 2. Stigmaria, root of Sigillaria, with rootlets attached, and pith; 3. Calamite; 4. Lepidodendron.

[1] From Latin *carbo*, coal, and *fero*, to bear.

[1] Called *Trigonocarpum*, from Greek *treis*, three, *gonē*, a corner, and *carpos*, fruit.
[2] From Greek *lepis*, *-idos*, a scale, and *dendron*, a tree.
[3] Called *lepidostrobi*, from Greek *lepis*, *-idos*, a scale, and *strobilos*, a fir-cone.
[4] From Latin *sigilla*, a seal.
[5] From Latin *stigma*, a mark.
[6] From Latin *calamus*, a reed.

reed, rising high into the air, like the bamboo, with its joints and leafy branchlets; and many more equally beautiful and well preserved.

The animal remains found are numerous and strange. Corals are abundant and beautiful. But no sea-creature was more common than the *encrinite*,[1] which rose on its long jointed lily-like stalk, and head with its hundred fingers, that moved on all sides to secure its prey, like the anemone of our own seas. The remains of encrinites are in some places so abundant as to form thick beds of limestone, called Encrinital Limestone; and when these, hard as marble, are polished, they present a most beautiful surface, through which is seen the exquisite carving of the encrinite stars. The little joints of the stems are often found detached, with a hole through the centre; these are known as Fairy Beads and as St Cuthbert's Beads; and when strung together, were used as a rosary, and no more beautiful ornament was ever hung round the neck of a saint. We also find star-fishes and sea-urchins; and the spines of the latter may be seen running through the limestone like threads of burnished silver. The shells are very numerous and varied; univalves and bivalves of both sea and land being everywhere found, and some of these can hardly be distinguished from shells gathered on our own shores, so perfect are they in form, colour, and structure. They may be detached from the rock, and collections made of them as easily as of modern shells. We find also crustaceans of different kinds; and the last trilobites are found in the Coal-measures. Fishes are numerous and formidable, but less so than in the Old Red Period. Reptiles in both salt and fresh water have also left their remains, and their footprints may be seen on certain sandstones, as distinct as if made but yesterday on the soft mud.

Scenery of Period.—In this remarkable period there stretched wide shallow seas, in which sported huge sharks, and whose waters washed the shores of many islands, guarded by great coral reefs, where the beautiful encrinite spread its waving arms. By the shores lived numerous shells, often in immense beds, that now form the mussel-band of the miner; and into these seas flowed Amazonian rivers, bearing into the deep the spoils of their wooded and reedy shores. By their wide estuaries and along their banks lay extensive impassable swamps and jungles, in which gigantic reeds, calamites, and tree-ferns flourished in tropical luxuriance. Amidst these lurked fierce crocodiles and mighty lizards, which have left their footprints on the yielding mud. The whole surface of the land was covered with tall pines and tree-ferns; the seal-palm, the scale-tree, and star-leaf shot into the air in impenetrable thickets, shaking their numerous cones in the breeze, while the hum of insects sounded through their still recesses. In the distance might be seen towering snow-peaks, and here and there the smoke of the volcano, the existence of which was felt in the numerous earthquakes that shook the ground.

VI.—PERMIAN SYSTEM.

Description.—Immediately above the Carboniferous strata, we find certain strata that used to be called, as already explained, the *New Red Sandstone*, in contrast with the rocks below them, called the Old Red Sandstone. This New Red Sandstone series has been of late more thoroughly examined, and found to consist of two distinct portions, whose remains are so different that the series has been formed into two distinct systems, known as *Permian* and *Triassic*. The name Permian has been given to the system we now describe, from being developed very extensively in Perm, a province in the north-east of Russia. These rocks are found in many parts of the world, and largely in Scotland, England, Germany, and Russia. They consist of red and whitish sandstones, shales, and limestones, containing much magnesia. The rocks are remarkably variegated in colour, so much so as to be called the Variegated System; while the limestone receives the distinctive name of the Magnesian Limestone. As the old name suggests, the sandstone is of a reddish hue, and the two chief rocks, therefore, are the Red Sandstone and the Magnesian Limestone. The sandstones are used for building, as are also the limestones, which have been employed in the construction of the Houses of Parliament. Copper is also extensively obtained from one of its shales in Germany, and also lead and zinc, but not very abundantly.

Organic Remains.—The plants resemble greatly those of the Coal-measures. We find sea-weed, fine-leaved ferns, tall calamites and reeds, great pines with cones, tree-ferns, and palms like the modern fan-palm. The animal remains are not nearly so numerous as in the coal rocks. There are sponges, corals, sea-urchins, and beautiful shells. We also find fishes like those of the Coal-measures; and the Permian is remarkable as the system where the ancient form of tail, in which the spine of the fish was continued into the upper lobe of the tail, becomes almost extinct, seldom to appear again. The reptiles of this system are numerous and perfectly developed, some of them being of gigantic form. Their footprints, in particular, are remarkably abundant and large, and from these alone, the whole animal has been constructed by learned men, the truth of their drawings being proved by subsequent discovery of the entire creature. Even pouched animals, like the kangaroo, are found in the American Permian, thus shewing a gradual but slow approach to modern life forms.

Scenery of Period.—The Carboniferous Period was remarkable for the great activity of volcanic agents, but this period seems to have been comparatively tranquil in this respect. The rivers carried in their waters much iron, as they did in the Old Red Period; the seas appear to have been shallow, bearing in solution magnesia and salt, while animal and vegetable life seems scarce, as compared with other epochs. From the existence of a rough conglomerate in the west of England, it has been argued that the greater part of the period was one of glacial action, with icebergs bearing blocks and rounded débris; and if this was the case, we have a conclusive explanation of the scarcity of life during this period.

VII.—TRIASSIC SYSTEM.

Description.—The upper part of the old system, known as the New Red Sandstone, has received

[1] From Greek *krinon*, a lily.

the name *Triassic*, which means *triple*, from being found in Germany in three distinct groups, of which the first and third alone exist in Britain.

The system contains sandstones of different colours, shales, and conglomerates; but the distinguishing product is rock-salt. This occurs in beds of from seventy to one hundred feet thick in Cheshire, whence we obtain salt for daily consumption. Salt-springs also abound in salt districts, being formed by the issuing of water through the salt rocks below. The Triassic rocks are found in patches in the British Isles, but extensively on the continent of Europe and in America.

Organic Remains.—The organic remains are very scanty, especially when compared with the exuberance of life in eras before and after. Plants are rare both in number and species. We find horse-tails, calamites, and ferns. The gigantic trees of the Coal-measures no longer exist, and we have instead short palm-like trees, like the modern cycas. The vegetation is mostly of a tropical kind.

Animals are far from abundant, but are more numerous than the plants. We have no corals, and few encrinites, and bone-plated fishes are rare. There are a few shells, some crustaceans, and several great shark-like fishes. Reptiles, however, are numerous, and of gigantic size. One brute in particular, called the *Labyrinthodon*,[1] from the *labyrinth*-like structure of a section of its *teeth*, is an uncouth, frog-like creature, with great staring eyes, and immense toothed jaws. The most abundant remains in the Triassic are the great footprints of large lizards. These are found in Scotland, but are so numerous in America, that above one hundred species of creatures have been distinguished, as indicated by these footprints. Huge birds, too, were numerous, and have also left their marks upon the rocks. These rocks

Labyrinthodon.

furnish the earliest evidences of warm-blooded mammals.

Scenery.—The scenery of the old Triassic age seems to have been peculiar, and we can form but a dim notion regarding it. We can easily see that the seas were shallow, with bordering lagoons, in which the salt waters were evaporated in the strong sun-rays, and left the salt-beds that are now of such service to us. By the muddy rivers lived great crocodiles, that lurked amid the reeds and pines, and fed on shell-fish and crustaceans, and left their footprints on the yielding mud; while on the dry plains above, grew plants adapted for an arid soil and tropical climate.

[1] From Greek *labyrinthos*, a labyrinth, and *odous*, *odontos*, a tooth.

VIII.—OOLITIC OR JURASSIC SYSTEM.

Description.—We have now arrived at a remarkable epoch, whose remains, abundant and wonderful, have been more fully investigated and described by celebrated men than perhaps any other. The forms of life, habits, and scenery are more like those of our own times, and can therefore be restored with the greater certainty.

The term *Oolitic* is applied to a series of rocks

Oolitic Plants:

1, Palm; 2, Tree-fern; 3, Cycas; 4, Pandanus; 5, Zamia.

which in England form three distinct groups—the Lias, Oolite Proper, and Wealden.

The Lias is the oldest, and receives its name, a corruption of *liers* or *layers*, from the thin variegated beds of which the rocks are composed, and which present a remarkable ribbon-like appearance not easily forgotten. The Oolite[1] is above the Lias, and is so called from the rock being greatly composed of small round grains like the eggs of the cod, so that it signifies the *egg-rock*. It is also called *roe-stone* and *pea-stone*, according to the size of the particles. These strange granules consist almost entirely of lime or grains of sand coated with lime. The Wealden is the highest rock in the series, and receives its name from being developed largely in the *Weald* in Kent and Sussex. The name *Oolitic* has been applied to the whole system, because the egg-structure is common to all the rocks in the series; the term *Jurassic*, from its being largely found in Mount Jura, is also given to it.

The Oolitic system consists of a series of sandstones, limestones (sometimes so hard as to be used as marble), shales, and clays, while ironstone bands, coal, lignite, and jet are abundant. The sandstones are useful as building-stone, the celebrated Bath and Portland stones, so much used in London and the south of England, being varieties. The limestones are burned for agricultural purposes; the clays are extensively developed, and receive different names in different parts, and yield alum, sulphur, and fuller's-earth. Ironstone is abundant and good, and furnishes a great part of the iron of Yorkshire, being eleven feet thick. The coal is workable and abundant, which disproves the notion, too prevalent, that coal can be obtained only from the Coal-measures.

[1] From Greek *ôon*, an egg, and *lithos*, a stone.

Lignite is a less hard variety of coal; and the jet, which is only a crystallised coal, yields the beautiful jet of Whitby, so much used for ornaments.

Organic Remains.—The remains of plants and animals are so abundant, that their enumeration and description would fill volumes, and we can merely roughly indicate some of their wonderful forms.

Vegetable life was abundant, requiring a warm climate like that of Australia. We find seaweeds, beautiful tree-ferns, lily-like leaves, palms like the pandanus, and pines like the araucaria and yew. The clays that occur were the very soil on which those ancient forests grew, and in some of them, known as 'dirt-beds,' the roots are seen in natural position, with part of the trunk broken over, while the tree itself lies close by, as if cut down by the woodman but yesterday.

The animal remains are abundant and remarkable. We find sponges, exquisite star-corals, beautiful encrinites, sea-urchins, worms, and lobsters. The shells are very beautiful and varied, the most remarkable being the ammonite, of which there are one hundred and thirty species, and the nautilus. Gigantic cuttle-fish floated and spread their black ink through the oolitic seas. Fishes were numerous and large; huge plated sharks devoured their prey, their very names telling terrible things, such as 'strong-tooth,'[1] 'star-spine,'[2] and 'great-jaw.'[3] Tortoises also floated on the summer seas.

Ammonite.

But the most striking remains are those of reptiles, so numerous, strange, and uncouth, that the Oolite has been designated the 'Age of Reptiles.' We find enormous skeletons, some of them thirty feet long, of large lizards and crocodiles, as of the Ichthyosaurus[4] or Fish-lizard, all being more or less strange and terrible.

In these rocks, too, a most interesting discovery has lately been made, that of the earliest feathered creature—a real bird—in which the bones, claws, and full-spread plumage are finely seen. The remains of warm-blooded animals have also been found, especially of a kind of pouched creature like the kangaroo.

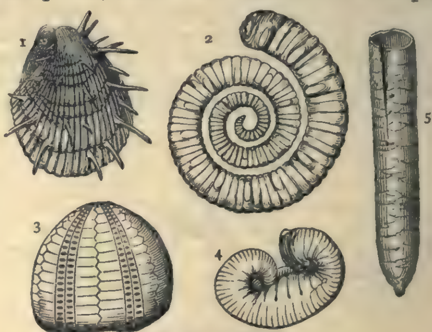
Scenery.—The scenery and animals of the Oolitic Period resemble, to a remarkable extent, those of Australia, both in vegetable and animal remains. The land and water went through many changes during this long period. In the Lias times, the seas were deep and tranquil; under the Oolite, exposed coral beaches were dashed by great breakers, that have left their work in broken shells and marls; while the Wealden seems to have been the carried deposits laid down in the estuary of a mighty river, that rolled into the sea in what is now the south of England; and the present icy lands of the arctic regions were covered with the vegetation of a warm climate, which now appears as Oolitic coal strata.

[1] *Pycnodus*, from Greek *pycnos*, strong, and *odous*, a tooth.
[2] *Asteracanthus*, from Greek *aster*, a star, and *acanthos*, a spine.
[3] *Eugnathus*, from Greek *eu*, well, and *gnathos*, a jaw or thorn.
[4] From Greek *ichthys*, a fish, and *sauros*, a lizard.

IX.—CHALK OR CRETACEOUS SYSTEM.

Immediately above the Oolite lies a system in which the chief rock is the well-known substance chalk, and which has hence received the name of the *Chalk*, or, what is the same thing, *Cretaceous*[1] System. In this system, other rocks also occur—namely, chalk-marl or blue clay, known by the local name of *Gault* or *Golt;* thick beds of green-coloured sand, called *Greensand;* and, imbedded in the chalk, nodules of flint, which, when less pure, is called *Chert;*[2] and coal, in Vancouver's Island. The chalk is used for many purposes: when it is burned, it forms a useful lime; when hard enough, is used for building-stone; and when crystallised, forms a fine white marble. The flints are an important ingredient in china, porcelain, and glass, and from the sands we obtain fuller's-earth. The whole system has been generally divided into two groups, the upper being called the Chalk, and the lower the Greensand.

Organic Remains.—The plant-remains are rare and imperfect, and seem to have been all drifted. Leaves of different kinds, palms, fruits, cones, and bits of pines have been discovered. Animal remains, however, are very numerous, and most beautifully preserved. We find sponges, corals, sea-urchins complete in form and structure, beautiful star-fish, numerous crustaceans, and varieties of the lobster tribe. The shells are plentiful, and exquisitely beautiful in form and even in colouring, and are the finest fossil preservations found in any system. They include splendid ammonites and nautiluses, and hundreds of other species, whose mere names would fill pages.



Chalk Fossils.

1, Plagiostoma spinosum; 2, Hamites intermedius; 3, Galerites albogalerus; 4, Scaphites striatus; 5, Belemnites mucronatus.

Fishes are not numerous, but are well preserved, and, as in other systems, are named from peculiarities in form or structure, such as the 'twisted-tooth,'[3] the 'wrinkle-tooth,'[4] 'thick-tooth,'[5] and such like. Reptiles are also found similar to those in the Wealden. Bones of birds have been discovered, as also bones of what seems to be a species of monkey.

Scenery.—The Chalk series appears to be

[1] From Latin *creta*, chalk.
[2] Irish *ceirthe*, stone; Welsh *cellt*, flint.
[3] *Gyrodus*, from Greek *gyros*, a twist, and *odous*, a tooth.
[4] *Ptychodus*, from Greek *ptychos*, a wrinkle, and *odous*, a tooth.
[5] *Pycnodus*, from Greek *pycnos*, thick, and *odous*, a tooth.

wholly a marine deposit. The land we know little or nothing of; sufficient, however, to shew that it was clothed with vegetable life, as in other periods, but little to picture its appearance. Over it, huge Wealden reptiles sought their prey, birds flew, and great apes swung from tree to tree. But the ocean swarmed with varied life, mild sea-breezes blew, and smiling sunbeams sparkled upon its waters; for the climate was warm, as shewn by the corals, reptiles, and monkeys. In the tepid waters lived numberless fishes and shells, and on their surface the nautilus spread its coloured sail.

The origin of chalk is a problem not yet satisfactorily settled, but the generally received opinion is, that the shores were fringed by coral reefs, which the dashing waves gradually wore down into fine powder, as they still do in tropical seas; while millions of shell-fish teemed in its waters, and left their white shells as an impalpable sand, that, under the microscope, shews the tiny houses of the old inhabitants as perfect as on the day they died. Flint seems mostly to consist of concretions round sponges, corals, and other substances. It may be found at any epoch, and occurs in many other formations besides the Chalk, though there in greatest abundance.

X.—TERTIARY SYSTEM.

We have now arrived at a new epoch in the history of the rocks, known as the Epoch of Recent Life. Henceforward, the plants and animals bear not only a close resemblance to those now existing, but a great proportion of them are identical. We discover real exogenous trees, the same corals, crustaceans, and shells, equal-lobed fishes, birds, and mammals of existing families—and all these not only more numerous than hitherto, but also more perfectly preserved. The name given to this system is a relic of the names used in early geology, when all rocks were divided into Primary, Secondary, and Tertiary. In the Tertiary System, two great periods are easily distinguishable: 1. The *Warm Period;* 2. The *Cold Period.*

1. THE WARM TERTIARY PERIOD.—This system exhibits clays, sands loose or hard, gypsum or plaster of Paris, and marls. The only true rock is limestone, made up of innumerable little shells, so numerous, that the rock is named, from its *coin*-like shells, nummulitic,[1] and is extensively found throughout the world. The limestone is burned for various purposes; the clays are extensively used; the harder sands are employed for building; and amber is also found. The strata occur exclusively in patches known as *basins*, the London and Paris basins being the most important.

Fossil Remains.—The remains are both numerous and important. Of plants there are few marine specimens, as these seem to have been too tender to be preserved. We find, however, mosses, palms, ferns, leaves, fruits, seeds of different kinds, and whole pods of pea-plants. We have real exogenous timber, with specimens of palm, cypress, and fir.

The animals resemble or are identical with existing species, and the Tertiary System has been divided into periods according to the percentage of life-remains. We have corals, star-fish of the same species as those existing, and the shells are very beautiful, finely preserved, and scarcely distinguishable from those to be gathered on our present shores.

Among the fishes, we find various species of the shark, ray, sturgeon, sword-fish; and of fresh-water kinds, the perch and the carp. Among the reptiles there are the crocodile and alligator, and the turtle. Birds are numerous, one specimen found in the Paris basin being gigantic. Mammals are found of every existing order, amongst others, the whale, elk, stag, antelope, camel, llama, tapir, hog, rhinoceros, hippopotamus, beaver, hare, squirrel, monkey, elephant, horse, tiger, and hundreds of others. So numerous are these remains in some parts, that one rock in Norfolk is known as the *Mammaliferous Crag.* But the most remarkable of the ancient animals are the huge monsters whose skeletons, carefully reconstructed, may be seen in the British Museum, some of them above 10 feet high, and 20 feet long. The most wonderful is the mammoth, with two great tusks like an elephant. Others are the *dinotherium*[1] or 'fierce beast,' the *megatherium*[2] or 'great beast,' and the *mastodon.*[3] In different parts of the world, including many places in England, remarkable caves are found filled with bones of various animals in clay or sands, known as 'bone-caves.' These caves have some of them been the dens of savage tigers and other brutes, the bones of their prey being still found; some have formed the abodes of different creatures at different times who have lived and died there; while others have had their contents washed into them by floods.

Scenery.—During this period shallow seas rolled under a genial sun, in which low islands rose crowned with palms, while the savage shark and sword-fish swam in the surrounding waters. The elephant ranged through the tall groves on shore; the hippopotamus wallowed in the fresh-water lakes; the rhinoceros crashed through rank jungles; the mastodon, mammoth, and tapir trod in forests of palm; and the wild ox and buffalo roamed over wide grassy prairies.

2. THE COLD TERTIARY PERIOD.—Immediately above the strata just described, with these strange organisms that speak of a warm climate, are found remarkable accumulations of sand, often found pure in hillocks; gravel, and clay interspersed with rounded worn boulders, known under the general title of the 'Boulder-clay,' some of the boulders being of enormous size. From various phenomena, it has been proved that the climate became arctic in character, and our country and others were enveloped from shore to shore in a vast ice-sheet, like the Greenland of to-day. From the ends of this huge ice mantle, immense masses broke off and floated away as icebergs. By and by, however, the climate became milder, and Britain looked like Norway and Iceland, with glaciers on the higher grounds, reaching here and there to the sea. Gradually the great ice-fields melted away under the rays of the genial sun, and our country looked like the present Switzerland, till at length the last glacier disappeared from the highest hills. The effects of all the wear and movement of these

1 From Latin *nummus*, a coin, and Greek *lithos*, stone.

1 From Greek *deinos*, terrible, and *thērion*, beast.
2 From Greek *megas*, great, and *thērion*, beast.
3 From Greek *mastos*, a nipple, and *odous*, *odontos*, a tooth, from nipple-like projections on its grinders.

ice-masses, whether grinding down the land or grating on the floor of the ocean, or dashing against opposing islands, are seen in the thick clay and sand deposits everywhere around us, inclosing worn stones and gravel; the scratched and rounded rock-surfaces, often bright and smooth as polished marble; the 'erratic boulders,' perched on our hill-tops and plains; and the general wavy outline of all higher ground throughout our land. This glaciation has been ascertained to extend over the whole of Northern Europe and America, and round the shores of the Antarctic Ocean.

XI.—QUATERNARY OR RECENT PERIOD.

We have now reached the last of the great geological epochs, during which sea and land, plants and animals, were much the same as they are now. This last system has been variously named the *Post-tertiary*, *Quaternary*,[1] or *Recent*.

The whole system may be divided into two chief periods:

1. *The Prehistoric*, or that before history was written.

2. *The Historic*, or that since history was written.

During the whole epoch, there is little or no solid rock, the whole deposits consisting of clay, sand, gravel, mud, peat, and the like.

Of *prehistoric* deposits, we find such remains as these: plants of all kinds, all common shells and corals, and common animals, with a few now extinct, such as the long-fronted ox, the gigantic Irish deer—a creature ten feet high to the top of its horns—the elephant, rhinoceros, hyena, bear, and mammoth, besides human remains in the shape of bones, canoes, ashes, dwellings, and weapons.

In *historical* times, we find similar remains, but the deposits are comparatively small, and the plant and animal remains are almost solely those now existing in each country. Men have left traces of themselves in buildings, coins, implements, weapons, and works of art. While peat-bogs have been formed, forests have been submerged or cut down, and considerable changes in sea-level have taken place.

Since the Glacial Period, in the Tertiary, a series of changes has been going on without intermission, accomplished by various causes and in various ways. The land has changed its level several times both by elevation and depression, the sea thus alternately encroaching on and retiring from the land. Whole countries have been gained from the ocean, such as the Fens in England and the greater part of Holland. Old beaches may be distinctly traced, with their cliffs, shores, and shells far above sea-level. Whole forests have been submerged, whose old trunks and fruits are thrown up by every storm. Huge accumulations of sand, blown or washed, have been found along its shores. Rivers have been depositing new matter under the ocean at their mouths, increasing the land by the formation of deltas, sometimes hundreds of miles in extent, laying down fine carse-land along their banks, that now forms the richest soil of the farmer, and leaving terraces far above their present level, to mark their former beds. Many lakes have been formed, others have been gradually silting up from the earthy matter brought down by rivers, while some have become dry, their beds being now waving with corn. Animals have been busy forming new islands and continents, as in the Pacific, where the coral insect leaves its skeleton to form the nucleus of future islands. Igneous agencies have been and are as active as in the olden times in changing the land and throwing out vast deposits of lava and ashes.

Man.—It is an interesting question how far back man extends into these geologic eras, and this important inquiry has of late years received great attention. Striking results have also been arrived at. It seems to be indisputably proved that man existed as far back as the great Glacial Period, at the close of the Tertiary epoch, and that he was contemporary with the hairy rhinoceros, mammoth, woolly elephants, and other gigantic creatures now long extinct, which he no doubt hunted, as he now does the fox and the deer; at which period Britain was united to France, where now the sea flows in the Strait of Dover. But this inquiry is yet in its infancy, and it would, therefore, be unwise to make positive statements where our data are insufficient. Enough has, however, been discovered to shew that in our own quiet land men lived for many ages with strange denizens, and under conditions very different from the present.

[1] From Latin *quaternus*, fourth, as coming after the Tertiary.

Rocking Stone, Fall river.

METEOROLOGY.

METEOROLOGY explains the laws which regulate weather, seasons, and climates. It involves particularly the consideration of the atmosphere—its pressure; its moisture; the alterations made upon it by heat and cold; and its electrical condition. It is by an accurate knowledge of these that we are enabled to understand the nature and causes of the incessant movements and changes going on in the air around us, and of the ever-varying appearances of the sky over our head; including the phenomena of winds and storms, of rain, dew, hail, snow, mists, and clouds, and their connections with one another, and with seasons and places.

THE ATMOSPHERE.

Its Composition—General Structure—Density—Pressure.

The atmosphere is a vast ocean of invisible gaseous matter, enveloping the terraqueous globe, and extending to a considerable height. Although it cannot be seen by the eye, it is yet felt to be an inert, material mass, which resists bodies in their motion through it, and when set in motion itself, possesses momentum or impetus, like a flying ball or a running stream. Another property of the atmosphere, which proves its genuine materiality, is its weight or pressure. It presses upon the earth, exactly as the sea does, under the influence of gravitation. At the sea-level, the average pressure is $14\frac{2}{3}$ pounds on every square inch; it is nearly the same as the pressure of a lake of water 33 feet deep, or a lake of mercury $2\frac{1}{2}$ feet deep. The construction of the barometer, or instrument for constantly measuring this weight, and shewing the degrees of its fluctuation from day to day, is explained under PNEUMATICS.

The fluid of which the atmosphere consists, is found to be not a single substance, but a mixture of several substances, totally distinct in their properties, and serving quite different offices in the economy of nature. The two chief ingredients—nitrogen and oxygen—which make up more than $\frac{99}{100}$ths of the whole mass, are as different in their character as water and alcohol. The proportions of these two are very nearly 77 of nitrogen to 23 of oxygen by weight. The nitrogen is therefore the principal element in point of quantity; but the oxygen performs the greatest variety of functions: it is the supporter of life, and the indispensable agent in combustion, in putrefaction, and in many other natural processes.

Deferring in the meantime the consideration of the other ingredients of the atmosphere, we have to study in the first place the mode of mixture of these two gases, and the general structure of the mass they compose. Although the mechanism and constitution of a gas are not apparent to our senses, yet we can infer with certainty that it is made up of atoms or molecules which keep one another at a distance by a repulsive force. From the fact that any gas can be compressed into a very small fraction of its ordinary bulk, we are sure that its particles are usually at a great distance from each other in comparison with their size. Now, suppose two flasks connected by a tube having a stop-cock, by which communication can be cut off, and suppose the one filled with nitrogen, and the other empty; on turning the stop-cock, part of the nitrogen will rush into the empty flask until it is equally spread over the whole space; for there is no stable balance of the repulsion if a particle is nearer its neighbour on one side than on the other. This uniform diffusion takes place almost instantaneously when the one flask is empty. But now, suppose both filled, the one with nitrogen, and the other with oxygen; when the communication is opened, each gas spreads itself uniformly through the whole space of both flasks, precisely as the nitrogen alone did, only in this case time is required. The gases mutually interpenetrate, and the molecules of the one retard the progress of those of the other, but do not otherwise affect the ultimate result. Each gas is independent, and distributes itself, and exerts its pressure precisely as if the other were not there. It is owing to this important principle that the proportion of oxygen to nitrogen is the same in all parts of the world and at all heights. The same law of uniform diffusion, and independence of the presence of other gases, holds with regard to the carbonic acid gas and the aqueous vapour existing in the atmosphere, although, in the case of aqueous vapour, its constant liability to condensation prevents its ever attaining to a state of actual uniformity.

Taking the entire mass of the atmosphere, considered as an ocean of gaseous or elastic fluid, its density must diminish as we ascend from the earth. The rate at which the density of the air diminishes upward, and the estimation of its entire height, are complicated by the decrease of temperature that is found to take place as we ascend (see page 41). It may be stated here, in a general way, that one-half of its material mass lies within three miles from the earth, and three-fourths of it within less than six miles. From the observation of luminous meteors, it is inferred that it is at least one hundred miles high, and that, in an extremely attenuated form, it may even reach two hundred miles.

MOVEMENTS OF THE ATMOSPHERE.

All the movements and changes to which the air is subject, originate, some way or other, in the unequal distribution of heat.

If two adjoining spots of ground are of unequal temperature, and communicate an unequal temperature to the columns of air lying upon them, the column which is most heated will be expanded, so as to overtop the other, and will also be made rarer or lighter. Two effects will arise from this: a lateral or horizontal movement of the air from the cold to the warm column will take place *below*, according to the general law of hydrostatics, that a heavy fluid buoys up a light one. But if we consider the condition of the two columns *above*, or at their upper ends, we will find that the

opposite effect must arise. Not only will the uppermost portion of the long column, which rises to a point where the short column has ended, and has therefore nothing but a vacuum to flow to, have a side-movement towards the other, but portions far beneath the top will have a pressure so much greater than the contiguous portions of the shorter column, that they too will flow out laterally, and determine a current tending to equalise the difference of heights and pressures.

When a difference of temperature exists between two spots that lie near one another, the effect of the aërial currents which take place between them is to equalise the temperature. Its lateral currents are the effect of unequal heating, and in some measure the remedy. These lateral currents are felt and recognised by us under the name of *winds*. If the differences of warmth that originate them were only limited and temporary, the carrying of heat to and fro would bring about an equality, and then the air would come to a perfect repose; but these differences of warmth are perpetually kept up; hence the lateral currents go on for ever without ceasing. The middle band of the earth, or the equatorial zone, is exposed to the burning radiance of a direct sun, while the two polar regions are so faintly heated, that snow never melts upon them; and this great standing inequality keeps up two grand sets of movements, which encompass the globe. The equatorial air, being warmer and lighter below than the air on each side, is buoyed up by the cold masses moving in upon it from north and south, and thus two great under-currents are maintained between the poles and the equator. The equatorial mass being expanded far upwards, overtops and overpresses the upper portions of the colder columns on each side, and therefore flows in upon them on both sides; thus causing two great upper-currents towards the poles, while the under-currents are moving from the poles. The inequality of the equatorial and polar regions in respect of heat is thus in some degree mitigated; but it is by far too great to be entirely done away.

We have supposed, for simplicity's sake, that the atmosphere is divided into an equatorial and two polar masses; but in reality there is a constant gradation from the equator to the polar regions, and the movements will take place between every two adjoining portions of atmosphere of which one is farther north or south than the other.

Although, as a general rule, the temperature of the earth decreases from the equator to the poles, this is not strictly or at all times true. Various causes occur to render a high latitude as warm as, or warmer than a lower, and in such a case a contradiction will arise to the general movement, which will have peculiar local consequences.

VAPOUR OF THE ATMOSPHERE.

Vaporisation—Dew—Mist—Clouds—Rain—Hail—Snow.

Next in quantity to nitrogen and oxygen, although very small compared with these, is the vapour of the atmosphere; that is to say, the gaseous water or steam that is constantly present in it. Although comparatively small in amount, this ingredient of the atmosphere is of immense importance in its effects. Unlike the other gases, it is easily reduced from the aërial to the liquid form, or to water as we usually find it; and it is constantly going through the processes of becoming liquid and descending to the earth, and again rising into the air in the gaseous or invisible form. The great agency connected with these transformations is heat. When water passes into steam, it takes in a large amount of heat, which is rendered insensible to the feeling or to the thermometer; and when steam or invisible vapour is condensed into water, all this heat is given out again (see NATURAL PHILOSOPHY).

It is essential to bear in mind that true gaseous water, steam, or elastic vapour of water, which all mean the same thing, is invisible, like the other portions of the atmosphere; and that the white cloud that appears at the chimneys of steam-boats and locomotives, and at the spout of a kettle, is not gas or elastic vapour, but vapour partially condensed, whose particles only require to be brought together to become drops of water. It is, in fact, water in the form of something like dust. Mist, fogs, and clouds are of the same character: they are not gaseous steam, but precipitated watery particles destitute both of mutual repulsion and of the latent heat of steam. When the atmosphere contains nothing but true steam, it is transparent and cloudless.

The formation of steam out of water is most conspicuous in the process of boiling, where the surface is kept in an intense bubbling state, each bubble containing a mass of steam, which forces its way up into the air. This boiling takes place at 212° of the thermometer, called for that reason *the boiling-point*. The steam thus formed has an elastic force equal to the pressure of the atmosphere, or a force of $14\frac{2}{3}$ pounds to the square inch. The reason for the *violent* escape of steam at 212° is, that it has attained a force equal to the weight of the atmosphere pressing on the water, and is therefore able to set aside this pressure, or make its way in spite of it. But even at temperatures below boiling, water passes into steam slowly and invisibly. It is well known that a wet surface soon becomes dry; in other words, that the water upon it disappears. Water, however, cannot be annihilated; in the drying process, the liquid water becomes gaseous invisible water or steam, and mixes with the other steam contained in the air.

The rapidity of the process of drying up, or of the passing of water into steam, depends, in the first place, on the temperature of the water. We have seen that it is abundant and violent at 212°; and it is less and less for every degree downwards. The elastic force of the steam produced also depends upon the temperature. The elastic force of steam at the boiling-point is equal to the pressure of the atmosphere; while the elastic force of steam produced silently at 80° is only $\frac{1}{30}$th of the elasticity of the atmosphere, or equal to one inch of the barometer.

Now, the entire quantity of steam that can rise is limited by the temperature in the same manner as the elasticity is limited. Water at 80° will give forth vapour, until as much has been produced in the atmosphere as would counterbalance one inch of mercury; evaporation then ceases, and the air is said to be *saturated* with steam. Whether the steam rise freely into the atmosphere, or rise into a vacuum, no more will be produced at 80° than this quantity. If the temperature were raised to

90°, there would be the means of supporting an additional quantity of steam, and evaporation would again go on, until as much were distributed through the air as of itself would counterbalance 1·36 inches of mercury, or about $\frac{1}{22}$d of the weight of the whole atmosphere. With every new addition of heat, new evaporation would go on, which would be of the silent kind up to 212°, when the full pressure of the atmosphere would be reached. But as the water on the earth's surface does not rise much above 80° even at the equator, and is far below this temperature in other regions, the whole weight of vapour in the air rarely amounts to one inch of mercury; so that, if the pressure due to nitrogen and oxygen by themselves were 29½ inches, the whole pressure, including the vapour, would be only about 30 inches, and at the utmost 30½ inches.

It has been stated, that at 80° vapour rises till as much exists in the air as weighs an inch of mercury; and that if the heat be increased, an additional quantity can be produced and supported. Let us now consider what must happen if the air were saturated with all that could be maintained at 80°, and if the temperature were then lowered, say to 60°. While at 80°, the vapour may amount to an inch; at 60°, it amounts only to ·52, or little more than half an inch. If, therefore, the full quantity which can subsist at the higher temperature has been produced, and if the temperature then descend to the lower point, there will be nearly half an inch too much for the reduced temperature, and this excess will be thrown out in the state of visible non-elastic vapour, or fall down as liquid drops. There will be either some kind of fog, cloud, or mist, or the aggregation of these into watery coherence.

Tables have been formed, the result of accurate experiment, shewing the elasticity of the vapour that can be maintained at each degree of Fahrenheit, from 0° to 90°, expressed in inches of barometric pressure.

If less steam is formed than could be supported at the temperature, there is said to be a certain amount of *dryness* or *thirstiness* in the air; meaning that there is room for further evaporation.

If the quantity of vapour in the air is less than what is supportable at the temperature for the time being, there is some lower temperature which this quantity would completely saturate. Such temperature is called the temperature of the *dew-point*. The dew-point is the lowest point to which the air can be cooled down without giving out visible moisture. If the air were saturated, the temperature and the dew-point would be the same; if the air is dry, or not saturated, the dew-point temperature is below the air temperature; and the difference between the dew-point and the temperature of the air is a measure of the dryness.

The number of degrees of Fahrenheit between the air temperature and the dew-point temperature is not, however, the exact estimate of the dryness, as will be seen from the following example. Suppose the temperature of the air 80°, and the dew-point 70°, then the amount of additional vapour that could be supported would be found thus:

Vapour sustainable at	80°,	1·001 inches.
" "	70°,	·727 inch.
Difference, . . .		·274, above 1-4th of inch.

Thus a difference of 10° of temperature makes a vacancy for a fourth of an inch of vapour. Take now a difference of 10° farther down in the scale. Suppose the air 40°, and the dew-point 30°:

Vapour sustainable at	40°,	·264 inch.
" "	30°,	·186 "
Difference, . . .		·078, about 1-12th of inch.

So that a difference of 10° between 70° and 80° makes a dryness or deficiency three times as great as a difference of 10° between 30° and 40°. Water would disappear three times as fast in the one case as in the other.

As the mercurial column expresses only the pressure of the sum-total of the atmosphere, some other means must be adopted for finding the amount of vapour by itself. Instruments used for this end are called *hygrometers;* from the Greek *hygros*, moist, and *metron*, a measure.

Apart from instruments, we judge of the dryness of the air, or of the additional amount of vapour which it could sustain, by the time required to dry wet bodies, such as the ground, or wet clothes hung in the air.

The chief instruments for determining with accuracy the dryness of the air, and the actual amount of aqueous vapour that it contains—technically its *hygrometric condition*—are Daniell's hygrometer, and the wet-and-dry-bulb thermometers.

The principle of Daniell's hygrometer is to cool the air down upon some surface till dew appear, and to mark the temperature when this happens. Thus, suppose a tumbler standing in the open air is cooled by pouring in cold water, or any other cold liquid, until the sides of the tumbler are covered with dew, the temperature of the glass at the moment that the dewing begins will be the temperature of the dew-point. In the actual instrument, the cooling is produced by the rapid evaporation of ether. But as the process of observation is rather delicate, and attended with trouble and expense, the wet-and-dry-bulb thermometers have come into more general use.

The determination of the dew-point by the wet-and-dry-bulb thermometers depends on the effect of evaporation in causing cold. When water passes into invisible vapour or steam, it absorbs from whatever substances it touches a large amount of heat, and the more intense the evaporation, the greater will the cooling be. In applying this principle to measure the humidity contained in the air, two thermometers are taken—one of the ordinary construction, which serves simply to give the temperature of the air; and the other having its bulb covered with a piece of rag, which is kept constantly wet by communicating with a cup of water by an absorbent wick. The water round the bulb will be constantly evaporating when there is any dryness in the air; and the greater the dryness, the more intense the evaporation, and consequently the greater the cooling of the bulb. Hence this moist-bulb thermometer will fall in proportion to the dryness of the air at the time. We have therefore only to compare the two thermometers—the one giving the air's temperature, and the other a reduced temperature depending on the rate of evaporation or the degree of thirstiness—in order to judge of the comparative quantity of moisture existing in the surrounding atmosphere. Tables

are used along with this hygrometer for calculating the dew-point temperature, which is ascertained, without calculation, by Daniell's instrument.*

The force of evaporation, or the quantity of water which is converted into invisible vapour in a given time, depends upon the dryness of the air, and upon its stillness or motion. The effect of a current of air is to carry off the vapour from the surface as it rises, and leave the space free for an additional supply. The more rapid the wind, the faster every wet surface dries up.

Clouds.—We must now consider more particularly the peculiar forms of visible vapour. Mist, fog, and cloud are names for nearly the same thing. When there is a general haze of precipitated vapour covering the whole sky, and coming down to the surface of the earth, it is termed a *fog*. When a white smoke is seen to rise from the courses of rivers and wet land, it is called a *mist;* but mist and fog are often indiscriminately applied to the same appearance —namely, to a vapoury haze lying upon the ground. *Clouds* are the masses of haze or fog which are seen floating in the higher regions, and which do not descend to the ground.

The steam of a kettle when it becomes visible, the white cloud of a steam-chimney, our breath in a moist or cold day, are all precipitated moisture or mist. Sometimes this mist is rapidly reabsorbed as it spreads out, shewing that there is a certain dryness or vacancy in the air sufficient to take it in among the invisible steam, when it is distributed over a somewhat larger surface.

If the air is exposed to a cooling, so as to bring it beneath the temperature of the dew-point, vapour must be thrown out everywhere, and a fog or mist will be formed. In this manner are formed the dense fogs of the polar seas, the fogs found along the courses of rivers, upon the sides of mountains, and over shoals and headlands. The celebrated fogs of London originate in the same way; but their black and thick appearance is owing to the quantity of smoke which is suspended in them.

The formation of clouds, as well as their frequent disappearance, can, in most cases, be readily explained by the general principles regarding the atmosphere and its vapour already laid down. Thus, we often see a clear morning gradually become overcast with clouds. This arises from the sun's rays heating the earth, and causing currents of warm, moist air to ascend into regions where it is cooled by expansion below the dew-point, and part of its vapour is condensed into clouds. As the day declines, the process is reversed; the cloudy particles descend and are dissolved, and a cloudless evening ensues.

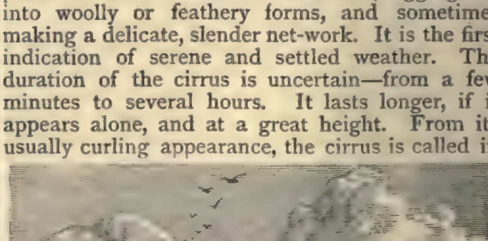
It is not uncommon to see the top of a hill wrapped in a stationary mist or cloud, even while a pretty rapid breeze is blowing over it. The explanation is simple. The current of air, in crossing the hill, rises into a region where the temperature is below its dew-point, and part of its vapour is there condensed into mist; but, as it descends the other side, it becomes warmer, and can again dissolve the watery particles. The substance of the cloud is thus really in motion over the summit; but it is constantly being shorn off on the lee-side, and as constantly receiving additions on the other side, so that it appears motionless as a whole.

A question often asked regarding clouds is thus answered by Mr Buchan in his valuable *Handy Book of Meteorology:* 'A very natural inquiry is: How are clouds suspended in the air? The example of a cloud appearing to rest on the top of a hill though a strong wind be blowing at the time, suggests an explanation. The cloud itself may appear stationary or suspended, but the particles of which it is composed are undergoing constant renewal or change. The particles are upheld by the force of the ascending current in which they are formed; but when that current ceases to rise, or when they become separated from it, they begin to fall through the air by their own weight, till they melt away and are dissolved in the higher temperature into which they fall. Hence, as Espy has reasoned, *every cloud is either a forming cloud or a dissolving cloud.* While it is connected with an ascending current, it increases in size, is dense at the top, and well defined in its outlines; but when the ascending current ceases, the cloud diminishes in size and density.'

The classification of clouds proposed by Luke Howard in 1803, is still universally followed. The three principal forms are the *cirrus*, or feather-cloud, the *cumulus*, or heaped-cloud, and the *stratus*, or stretched-cloud. The *cirrus* is com-

Cirrus.

posed of thin threads or filaments, aggregated into woolly or feathery forms, and sometimes making a delicate, slender net-work. It is the first indication of serene and settled weather. The duration of the cirrus is uncertain—from a few minutes to several hours. It lasts longer, if it appears alone, and at a great height. From its usually curling appearance, the cirrus is called in

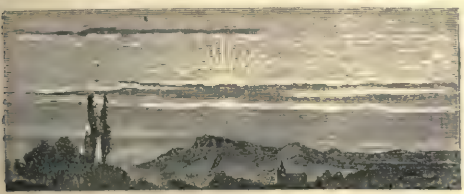


Cumulus.

England the *mare's-tail* cloud. The *cumulus* is the kind of cloud resembling mountains piled upon mountains, and generally ends above in rounded

* Besides the above, there are various instruments called *hygrometers*, depending on the principle of the shrinking and expanding of bodies in relation to the degree of humidity with which they are affected. Fibrous vegetable substances, such as ropes, contract by imbibing moisture; while, on the contrary, hairs and catgut (strings of violins) contract by drought. Hair has been found to be the most delicate in hygrometrical motions. Saussure accomplished the construction of a hygrometer from a single long hair, previously cleaned in a soda lye. Various philosophical toys, as ornaments for mantel-pieces, have also been constructed to indicate the dryness and moistness of the atmosphere, all on the similar principle of contraction and expansion of a hair, piece of catgut, or part of the beard of the wild oat.

masses, while it is horizontal below. The appearance, increase, and evanishing of cumulus, in fine weather, are often periodical, and correspondent to the degree of heat. Generally, it forms a few hours after sunrise, attains its highest degree in the hottest hours of the afternoon, and decreases and vanishes at sunset. If the upper region, with its drying power, predominates, the upper parts of the cumulus become cirrus; but if the lower region predominates, the basis of the cumulus sinks, and the cloud becomes *stratus*, which appears as a



Stratus.

long horizontal band of moderate density, with its lower surface resting upon the earth or the water. Combinations of the above forms have been discriminated under the names of *cirro-cumulus*, *cirro-stratus*, and *cumulo-stratus*. The black rain-cloud, which seems a general mixture and confusion of all the clouds in the heavens, has been called the *cumulo-cirro-stratus* or *nimbus*.

The *cirrus* clouds are the most elevated; and must be often made up of snow-particles, for even under the equator, water would be frozen at such a height. In general, we may say of the light fleecy masses that we see on a summer-day, that they are made up of snow-powder or frozen particles. The *cirro-cumulus* is formed from the cirrus by the fibres breaking and collapsing into small roundish masses. It is this which is known as a mackerel sky, and is attendant on dry and warm weather. The *cirro-stratus* clouds consist of horizontal masses, dense in the middle and thinned towards the edges, so that a group of them resemble a shoal of fishes. Their prevalence indicates a coming storm.

The *cumulus* clouds are evidently the precipitation of the ascending vapour in the cold upper regions; for they generally increase with the heat of the day, which disperses all superficial mists. The *stratus*, on the other hand, has more the character of a night-cloud: it is a result of the cooling of the air in the evening, and comes out in the lower regions of the atmosphere. All mists and fogs are of this species of cloud; which, in its lightest state, does not wet leaves or any objects with which it comes in contact. Sometimes it remains quiet, and accumulates in layers, till the atmosphere is incapable of sustaining its weight, when it assumes the condition of the heavy and dark *nimbus*, and falls in a shower of rain.

The extreme height to which clouds may reach has never been accurately determined; but from observations made in balloon ascents, it is probable that the cirrus cloud is often ten miles above the earth.

The average amount of the sky covered by clouds, is an important element in the climate of a country. It is usually measured by the scale of 0 to 10; 5 indicating that the sky is half-covered, 10 that it is wholly obscured. In Shetland, three-fourths of the sky is the average space covered with cloud; the mean for the whole of Scotland is less than two-thirds, being 6·7 in the west, and 6 in the east and interior.

Dew.—When moisture is precipitated at night in the form of wetness, and drops on the surface of the ground and on the leaves of plants, it receives the name of *dew*. This precipitation arises when the surface of any body is cooled below the dew-point temperature of the air at the time. Thus, if the dew-point were 45°, and if by any means a glass tumbler were cooled down to 40°, the film of air lying next to it would also be cooled down to 40°, and would therefore have to give out all the vapour which it could not hold at that temperature; but the precipitated surplus in this case would not appear as mist in the air, but would adhere to the surface of the glass. When cold glasses are brought into a warm room, they sometimes become dewed all over in this way. The bringing out of visible dew is, as we have seen, the means of determining the dew-point temperature in Daniell's hygrometer.

Night-dews are most copious when the sky is clear. The reason of this is, that the earth cools faster under a clear sky than when hung over with dense clouds, which prevent the radiation of the heat; just as bed-curtains make a bed warmer. Wind also prevents the deposition of dew; because the air in contact with the earth is constantly changed, so that the temperature does not fall sufficiently low. The surfaces which naturally radiate off their heat with most rapidity are the first to sink below the dew-point temperature and to become dewed. Thus, rough surfaces are wetted sooner than smooth, plants sooner than glass, and glass sooner than metals. Metals being good conductors of heat, as fast as their surface cools, heat flows to it from the interior, and consequently the temperature of the surface cannot sink till the whole mass throughout has parted with its heat. Woolly and fibrous substances cool very fast at the surface, and are therefore rapidly bedewed. No dew can fall on a surface till its temperature has fallen below the dew-point; hence, in the case of a very dry atmosphere, there may be no dew formed at the coldest time of the night. In arid deserts, and in the countries where dry winds prevail, dew is not often seen.

When the surface dewed is below the freezing temperature, the vapour is not only precipitated, but is also frozen; hence the origin of *hoar-frost*, or frozen night-dew. The occurrence of hoar-frost is a proof that the temperature of the ground has fallen below 32°, as well as below the dew-point temperature. As in the case of dew, everything that prevents the radiation of heat arrests the formation of hoar-frost. During the chilly nights of spring, plants that are sheltered by trees are less liable to be frozen than those which are fully exposed; and a slight covering of straw, or even of paper or netting, will often afford an effectual protection. Vineyards, it is said, have frequently been saved from the effects of frost by enveloping them during the night in a cloud of smoke.

Rain is the aggregation of the cloudy particles into masses or drops. The causes of the formation of clouds have been already explained. Every cloud does not end in rain; it is only when the whole mass of air between the cloud and the earth is saturated, that the watery particles fall down.

Snow.—When the temperature of the stratum of air from which the rain falls is under 32°, the

vapour or clouds must necessarily be frozen, and the descending particles will be *snow* instead of rain. Snow-flakes are the aggregation or union of frozen particles, just as rain-drops are the union of watery particles. They aggregate, according to the law of the crystallisation of water, into regular and symmetrical forms, of which the general character is a six-sided figure; as, for example, six needles branching from a centre, or six arms from a six-sided nucleus, each needle being three or six sided. Though single crystals always unite at angles of 30°, 60°, or 120°, they nevertheless form, by their different modes of union, about 1000 distinct

varieties of snow-flake, some of which are figured in the preceding engravings. Any agitation of the air, or an increase of moisture or temperature, destroys, of course, their delicate and beautiful structure.

Hard pieces of ice falling in showers are called *hail*. The mode of their formation is not clearly understood. The sudden ascent of moist air into the upper regions, where it encounters a cold current, is probably the common cause of hail. Hailstones vary in shape, and when cut across are found to be composed of alternate layers of clear and opaque ice, enveloping a white nucleus. Many of them seem to be agglomerations of several hailstones. They vary in size from the smallest shot to several inches in diameter.

Besides *nitrogen*, *oxygen*, and *watery vapour*, the atmosphere contains minute quantities of numerous other substances—carbonic acid, ammonia, ozone, exhalations of all kinds, dust, seeds or germs of plants and animalcules, &c. But, however important some of them may be in the economy of nature, the consideration of them does not properly belong to meteorology.

SURFACE OF THE EARTH IN RELATION TO THE ATMOSPHERE.

Mean Temperature—Trade-winds—Sea and Land Breezes—Hygrometric Changes—Fall of Rain—Fluctuations of the Barometer and Thermometer.

The changes and fluctuations of the atmosphere have all a relation to the peculiarities of the earth's surface, and especially to the unequal heating of its different parts, owing to the varied action of the sun, the distribution of sea and land, and the different elevations of the land.

By the *mean temperature* of a place is understood the average temperature for a whole year, or for a number of years. If observations were made of the temperature for every hour in the course of a day, the average of all these would be the mean temperature of the day; also the mean of the greatest and least temperatures would be pretty nearly the mean of the day. If the mean temperatures of 365 days are found in this way, and an average taken of the whole, this gives the average or mean temperature of the year. And if a great many years have been observed in the same manner, the average of the whole would be reckoned the general mean temperature of the place where the observations have been made.

The action of the sun is the chief source of the warmth possessed by the atmosphere and the ground, though not the only source (see GEOLOGY and PHYSICAL GEOGRAPHY).

The reason why the sun heats the equator and the regions adjoining more strongly than it heats the temperate and polar regions, is, that at the equator it rises higher in the heavens, and shines more directly downwards. The farther away a place is from the equator, the less is the average noonday height of the sun, and therefore the smaller the influence it exerts.

The mean temperature of the equator is about 80°. If the whole earth were a perfectly smooth globe of one uniform kind of surface—that is, if it were all sea, or all one kind of level land—the temperature would decrease steadily from the equatorial amount, according to the latitude; but the variations of the surface cause many important deviations.

The whole force of the sun's rays does not act directly on the solid surface of the earth; the atmosphere, especially when charged with vapour, arrests a certain portion of the heat, and is itself rendered warm by the portion arrested. This is one source of the warmth of the air. When clouds are spread out in the atmosphere, the resistance to the rays is still further increased, and a greater portion taken up by the air itself. The other sources of atmospheric heat are, contact with the surface of the earth, and the radiation of heat from the ground upwards.

The air exercises a very important influence in keeping up the mean temperature of the earth, by resisting the passage of heat outwards, on the same principle that our bodies are kept warm by clothing. The thinner the covering of air, the colder would the earth be; as we see in ascending to the tops of mountains, at which the temperature is always much lower than at the sea-level—the cold increasing with the height. These high places receive a more intense solar radiation through the thin covering of air that lies upon them; but such is the ease with which the heat can radiate off through a thin atmosphere, that they are always kept comparatively cold. If we had no atmosphere at all, the rays of the sun would be very intense where they actually struck, but so rapid would be the loss of heat by radiation, that the whole earth would be permanently kept far below freezing; no liquid material of any known kind could exist on its surface.

Trade-winds.—The first great effect on the atmosphere of the unequal temperature of the different parts of the earth, and especially of the steady decrease of heat from the equator to the poles, is to produce the two grand currents which we have already described: an upper-current from the equator to the poles, and an under-current from the poles to the equator. If the earth were at rest, these currents would blow exactly north and south, but the daily revolution of the globe has an effect in altering their directions. The equator, or thickest portion of the earth's body, considered as a ball revolving on an axis, moves with the greatest rapidity in the daily whirl; any place upon it is carried round at the rate of upwards of 1000 miles an hour. But the belts on each side of the equator being smaller in circumference, any point on one of them is moved with proportionably less rapidity. Thus the belt or zone at 60° of latitude has only half the circumference of the equatorial zone; so that a place upon it will move round only 500 miles an hour. Now the atmosphere revolves along with the earth, and every portion of it will have the same velocity as the place on which it lies. But if the equatorial air, with its high velocity, is carried away in the upper-current to a place with a lower velocity, the air will still persevere in its equatorial speed, and will consequently outrun the speed of the place upon which it has come, and be felt as a strong wind in the direction of the rotation.

A similar explanation serves to shew that the under-currents from the poles to the equator will not be due north and south, but will have, in addition, a direction towards the west.

According to this simple theory, the prevailing winds ought everywhere on the earth's surface to be easterly: in the northern hemisphere, they should blow from the north-east; in the southern hemisphere, from the south-east. And at sea within the tropics, and to some distance beyond them, this is in fact the case. The great polar currents are there known by the name of the *trade-winds*, because they are so constant that they can be calculated on by navigators. The trade-winds begin to be felt at about 30° of latitude on each side of the equator. Ships entering upon this belt begin to feel a steady easterly breeze, which continues, although with some variation, to within 2° of the equator. The two currents from north and south meet about the equator, and completely neutralise each other; and their meeting forms a belt varying from 150 to 550 miles in width, called the *region of calms and variables*. There is no steady wind in this region; its atmosphere is generally calm, having at certain seasons light southerly winds, interrupted by fearful storms and tornadoes.

Beyond the region of the trade-winds, the prevailing currents are in the opposite direction—in the northern hemisphere, for instance, from the south-west. To account for this, we must suppose that the two great currents change places, and that about the latitude of 30° the upper equatorial current descends to the surface of the earth.

The region of the south-east trade-winds is much larger than that of the north-east, the belt between them lying generally not at the equator, but several degrees north of it. The entire belt of the trades shifts in some degree northwards in summer, and southwards in winter, following the course of the sun.

Direct proofs have been furnished that in the regions of the trade-winds there are upper return-currents flowing in the contrary direction. The ashes of the volcano of St Vincent, on one occasion, were carried from west to east, to the astonishment of the inhabitants of Barbadoes, who were experiencing at the time the easterly wind.

Sea and Land Breezes.—The great polar and equatorial currents are modified by another class of currents, of a more local character, arising from the unequal susceptibility of the sea and the land to the sun's heat. If the sun shine with the same directness and force on two tracts of surface, the one water, and the other solid ground, the ground will be most rapidly heated, and at the end of the day it will be found much warmer than the water. On the other hand, in the absence of the sun, the land cools fastest, and at the end of the night it will be found below the temperature of the adjoining water. This difference causes an inequality in the temperature of the columns of air lying upon the two surfaces. When the land is hottest, the air resting upon it will be hotter and lighter than the air over the sea; hence the cold air from the sea will rush in upon the hot. Thus during the day, when the land is warmer than the sea, there will be a breeze from the sea to the land, and during the night, a breeze from the land to the sea. These *sea and land breezes* are felt regularly on all the sea-coasts when not overborne by other winds.

Monsoons.—Where a large tract of land joins a great expanse of sea, as on the coasts of America and the south of Asia, the sea and land breezes become very considerable. The easterly trade-winds are often reversed by them. But the most powerful effect of the sea and land winds is annual, or dependent on the seasons. The most remarkable example of this is furnished by what are called the *monsoons*—from the Arabic word *mausim*, a set time or season—experienced along the coasts of Africa, India, and China. When the sun is far north in midsummer, and shines with direct rays on the Asiatic peninsulas, the land in them is rendered very much hotter, both day and night, than the ocean, and a strong sea-wind sets in towards these coasts from the south-west—that is, in a direction opposite to the great current that causes the trade-winds. Hence an immense wide-spreading conflict arises, which begins about the month of April, or two months before the sun has reached his extreme north declination. The beginning of the conflict in April causes furious rain, wind, and thunder-storms; but in the course of two or three weeks the sea-breeze completely overcomes and suspends the trade-wind, and continues steadily to prevail from April to October; this is called the *south-west monsoon;* and it can be as much calculated on for navigation as the trade-winds in their most uninterrupted regions. The influence which sustains this wind becomes gradually weaker as the sun moves southward, and in October it becomes too weak to overcome the trade-wind, and the two meeting with equal force, cause a second violent tumult of rain and storms, till in a short time the trade-wind prevails; which then continues during the winter half-year, and forms what is called the *north-east monsoon.*

In the Atlantic, a similar action is perceived. In the summer-time, the land of North Africa is made so much hotter than the adjoining sea, that

a brisk south-west or south-south-west wind blows between the equator and the southern limit of the northern trade, which is then at about 10° or 12° north latitude. In America, also, similar breezes are experienced.

*Rainfall.**—The chief sources of evaporation are the seas, lakes, and rivers. Although there is three times as much sea as land, this is not more than enough to keep up a sufficient moisture for the habitable countries; for although some regions have rather more than is desirable, many large tracts of country remain desert and uninhabitable solely from the dryness of their air and the scarcity of rain.

The evaporation is necessarily greatest in the equatorial regions, where the temperature is greatest, and decreases steadily towards the poles. And although a great deal of the tropical evaporation is transported by air-currents into higher latitudes, the precipitation of vapour, or the rain, is also most abundant in the warmest climates, and in the neighbourhood of the tropical seas.

Rain is the most capricious of all the meteorological phenomena, both as regards its frequency and the amount which falls in a given time. It rarely or never falls in certain places, which are, on this account, designated the rainless regions of the globe—the coast of Peru, in South America; the great valleys of the rivers Columbia and Colorado, in North America; Sahara, in Africa; and the Desert of Gobi, in Asia, are examples; whilst, on the other hand, in such places as Patagonia, it rains almost every day. Again, the quantities which have been recorded at some places to have fallen at one time, are truly enormous. In Great Britain generally, if an inch fall in a day, it is considered a very heavy rain. In many parts of the Highlands of Scotland, three inches not unfrequently fall in one day. On the 5th of December 1863, there fell at Portree, in Skye, $12\frac{1}{2}$ inches in 13 hours. At Seathwaite, in Borrowdale, 6·62 inches fell on November 27, 1845. But it is in continental, and especially tropical countries where the heaviest single showers have been recorded. The following are a few of the most remarkable: At Joyeuse, in France, 31·17 inches fell in 22 hours; at Geneva, 30 inches in 24 hours; at Gibraltar, 33 inches in 26 hours; on the hills above Bombay, 24 inches in one night; and on the Khasia Hills, 30 inches on each of five successive days.

The heaviest annual rainfall on the globe is 600 inches on the Khasia Hills, about 500 inches of which falls in seven months during the south-west monsoons. This astonishing amount is due to the abruptness of the mountains which face the Bay of Bengal, from which they are separated by 200 miles of low swamps and marshes.

The following are some of the annual rainfalls in the tropics: Singapore, 97 inches; St Benoit (Isle of Bourbon), 163 inches; Sierra Leone, 87 inches; Caracas, 155 inches; Pernambuco, 106 inches; Rio Janeiro, 59 inches; Georgetown, 100 inches; Bahamas, 52 inches; and Vera Cruz, 183 inches.

In general, *when a mountain-chain crosses the course of an ocean wind, the weather-side is wet and the lee-side is dry.* The trade-winds of the Atlantic sweeping over the continent of South America become cooled as they ascend towards the Andes, and, depositing their vapour, feed the mighty streams of the Amazon and Orinoco. On the west side of the wall of the Andes, in Peru, rain is almost unknown.

Distribution of Atmospheric Pressure.—The varying pressure of the atmosphere, from place to place and from time to time, is the chief cause of all fluctuations of wind and weather. A knowledge, therefore, of the distribution of this pressure over the globe, and the laws of its changes, as indicated by the barometer, is the basis of meteorology. *Variations* of the barometer are of two kinds—periodical and irregular. Of the regularly recurring variations, the *daily* variation is of small amount, and of little direct importance. The phenomenon has its cause in the daily march of the sun round the globe. The *annual* variation follows the march of the sun from one side of the equator to the other. The greater power of the sun in the northern hemisphere in summer rarefies the air, and causes a transference of a part of it into the colder southern regions, thus diminishing the pressure. The presence of a greater proportion of vapour acts in the same direction, owing to vapour having less specific gravity than dry air. As a rule, then, the atmospheric pressure is least in the summer, and greatest in the winter, in each hemisphere. But this annual fluctuation is subject to much greater local differences and anomalies than is the daily. Thus, in Siberia, the pressure is $\frac{8}{10}$ths of an inch less in July than in January. The great heat of Siberia in summer causes the air to expand and flow away in all directions. In winter, on the other hand, the great cold and small rainfall of that region cause high pressures to prevail. In Iceland and Orkney, again, the reverse of all this holds: the pressure is least in winter, and greatest in summer. The summer temperature of the North Atlantic, in which these islands are situated, is cool as compared with the heated continents that enclose it, hence there is an overflow from these regions into the basin of the North Atlantic, and therefore increased pressure; while in winter, the temperature there is comparatively high, causing an overflow of air towards adjoining countries, and a diminished pressure.

The distribution of atmospheric pressure is best exhibited by means of *isobarometric charts;* that is, charts on which lines are drawn through all places where the height of the barometer is the same. Such a chart may represent the mean pressure for the year, or the mean for a portion of the year, such as a particular month; or the readings of the barometer at a specified moment, such as the beginning or middle of a storm. Owing to the immense labour of collecting and arranging the hundreds of thousands of observations necessary for such a purpose, it is only recently that the attempt has been made. Mr Alexander Buchan, Secretary of the Scottish Meteorological Society, has the merit of first undertaking

* The quantity of rain which falls at any station during a given time is ascertained by means of the *rain-gauge*—an instrument constructed in various ways. One of the simplest forms consists of a cylindrical copper vessel furnished with a float: the rain falling into the vessel raises the float, the stem of which is so graduated that an increase in depth, to the extent of one-hundredth of an inch, can be ascertained. It is observed that rain-gauges collect different quantities at different heights above the ground, the amount being always greater at the lower level. This remarkable fact has never been quite accounted for.

the task; and a chart for the year, and one for each of the two months of July and January, published in his *Handy Book* in 1868, are the first-fruits of his labours. Ten more charts are to follow, so as to exhibit the progress of the annual variation, with its anomalies, throughout the year. It is easy to conceive that such a system of lines must throw great light on all inquiries regarding prevailing winds, the varying temperature, and the rainfall over the world.

The insight into the causes of atmospheric changes afforded by these charts, may be judged of from what Mr Buchan says in describing that for January: 'Over the North Atlantic occurs an extensive diminution of pressure, which deepens northwards till the greatest depression, 29·5, is reached in Iceland, or perhaps in a slightly lower depression nearly midway between that island and Spitzbergen. The widening of the isobarometric curves of 29·6 and 29·7 inches to the westward over Greenland, and to the eastward over the north of Norway and Russia, is an interesting feature of this area of low pressure. The low pressure of this region is due to the saturated state of its atmosphere and to the copious rainfall resulting from it. The flow of the Gulf-stream north-eastwards through the Atlantic to at least beyond Spitzbergen, and the larger amount of vapour poured into the atmosphere from its warmer waters, tends still further to lower the pressure. It is this low pressure over the North Atlantic, together with the high pressure to the eastward over Asia, which forms the key to the explanation of the winter climate of Europe.'

Distribution of Terrestrial Temperature.—The temperature of the earth differs not only in different regions of its surface, but at different elevations above or below the surface. In ascending a mountain or into the air in a balloon, the thermometer, as a rule, falls. The rate generally allowed is 1° of Fahr. for every 300 feet.* The increase of cold at high elevations arises from several causes. One cause is the rarefaction of the atmosphere, which takes place on ascending (see No. 15). Under ordinary circumstances, when a gas is allowed to expand, its temperature falls. This used to be explained by saying, that a gas when rarefied has a greater capacity for heat, and therefore requires a greater absolute quantity to keep it at a certain temperature. There is really, however, no change of specific heat, for it is possible, under certain conditions, to rarefy a gas without any loss of temperature. The real cause is that the gas in expanding performs *work;* it puts itself in motion to occupy the wider space, and no motion can be caused without expending some form of energy. The temperature of the gas depends upon some kind of oscillating motion among its molecules; part of this molecular motion is converted into a motion of translation, and the energy or heat of the gas is diminished by the amount thus expended. Another cause is found in the fact, that the sun's rays have little effect on the atmosphere, especially when dry, and only give out their full heat when they strike solid objects. It is thus the lower strata of the air that are in contact with the warm earth that derive most heat from the sun's rays. In addition to all this, the radiation, or loss of heat, goes on more rapidly, there being no solid objects around to return it, and the rarer air opposing less obstacle to its escape. At considerable elevations, too, there is proportionally less vapour in the air; and as it is the chief obstructor of radiation, objects in high regions are exposed naked, as it were, to the cold of the outer universe. At a certain height over every place, water will freeze, and if a mountain rise to this height, it will be covered with snow. The height over any place where water must be frozen at all seasons is called the *snow-line*, the altitude of which is greatest at the equator, and diminishes as the latitude increases. At a certain high polar latitude, it reaches the mean sea-level; that is to say, the ground at that level is eternally clad with snow.*

The law, however, of loss of temperature by elevation is subject to important exceptions. In winter, the earth is losing more heat by radiation than it derives from the sun's rays; therefore, in a dry, calm, clear night, the surface rapidly loses heat, and the stratum of air in contact with it is thus chilled below the general temperature of the atmosphere. The effect is most marked at short heights above the surface. The air in contact with the ground is frequently 15° or 20° below the air four feet above the ground; above four feet the differences are comparatively small. It is evident from all this, that in comparing thermometers, it is important that they be placed at the same height above the surface.

The effect of this chilling of the lower stratum of the atmosphere is modified by the configuration of the surface. From off heights and slopes, the chilled air flows down into the low-lying grounds, and there accumulates.

'This explains,' says Mr Buchan, 'why vapour becomes visible so frequently in low places, whilst adjoining eminences are clear; and the same fact instinct has made known to cattle and sheep, which generally prefer to rest during night on knolls and other eminences. Along most of the water-courses of Great Britain, during the memorable frost of Christmas 1860, laurels, araucarias, and other trees growing below a certain height were destroyed, but above that height they escaped.'

The variations of temperature below the surface belong rather to Geology and Physical Geography.

We have now to consider how heat is distributed over the earth's surface horizontally. The causes of the varying quantities of heat enjoyed by different places have already been described in a general way. The results of these causes, as modified by the varying relations of land and water, are made visible to the eye by means of charts having lines drawn through all places having the same temperature. These lines are

* According to the experiments made by Mr Glaisher in balloons, the diminution of temperature is 7·2° F. for the first thousand feet, but only 5·3° F. between the first and second thousand. From 14,000 to 15,000, it is reduced to 2·1°.

* The *snow-line* is found at various heights, according to latitude, proximity to the sea, and other causes, which affect the general climate of the region. In the Himalaya and Andes, it is found at an elevation of about 17,000 feet; in the Swiss Alps, at 8500 feet; and in the Scandinavian range, at 3500 feet. Generally, in those countries which are near the equator, the snow-line is found about 16,000 feet, or three miles above the sea-level: about the 45th parallel in either hemisphere, it occurs at an elevation of 9000 feet; under 60° of latitude, at 5000 feet or thereby; under 70° latitude, at 1000 feet; and under 80°, the snow-line comes down to the mean sea-level; for countries which are 10° distant from the poles are covered with snow all the year round.

called *isothermals* (Gr *isos*, equal, *therme*, heat), when they mark mean annual temperature; *isotherals* (Gr. *theros*, summer), when they mark either the mean of the summer months or that of the hottest month, July; and *isocheimals*, or *isochimenals* (Gr. *cheima* or *chima*, winter), in regard to winter. Fig. 1 is such a chart, exhibiting the distribution of the mean annual temperature; while fig. 2 exhibits the hottest and coldest months; the dotted lines marking the mean

Fig. 1.

Fig. 2.

temperature of January, and the solid lines that for July.

The part of the globe having the highest mean annual temperature forms an irregularly shaped belt, lying along the equator, and comprised between the north and the south isothermals of 80°. On either side of this warm belt the temperature diminishes towards the poles; and the lines shewing successively this diminution are, speaking in a very loose sense, arranged parallel to the equator, thus shewing the all-predominating influence of the sun as the source of terrestrial heat. The coldest portion of the earth's surface is a small oval-shaped patch near to but not surrounding the north pole, its mean temperature being −4°. Its narrowest diameter lies north and south, nearly touching the pole on the one side, and extending on the other as far south as 72°·30 N. lat. in 130° W. long. Part of it is seen in the diagram.

While the decrease of temperature in advancing towards the poles corresponds in a general way to what may be called the solar climate, there are deviations brought about by disturbing causes too important to be overlooked. The chief of these disturbing causes are (1) the currents of the sea; and (2) the prevailing winds.

Of ocean-currents affecting temperature, the most marked and important is the Gulf-stream in the North Atlantic, which, by conveying warm water to the arctic regions, pushes the isothermals many degrees to the northward. There is a similar, though much feebler, current passing from the North Pacific to the Arctic Sea through Behring's Strait, and there, accordingly, the isothermals are pushed a little to the northward. An opposite effect is produced by two cold currents from the Antarctic Ocean, flowing, the one along the coast of Peru, the other along the west coast of Africa.

Since winds bring with them the temperature of the regions they have crossed, the equatorial current is a warm wind, and the polar a cold wind; also winds arriving from the ocean are not subject to such variation of temperature during the year as winds from a continent. As an atmosphere loaded with vapour obstructs both solar and nocturnal radiation, it follows that moist winds are accompanied with a warm temperature in winter, and a cool temperature in summer; and dry winds with cold winters and hot summers. The direction of mountain-ranges is also an important element to be taken into account in estimating the influence of winds on temperature. These considerations explain the position of the isothermals in the north temperate zone, where the prevailing wind is the south-west or anti-trade. In January, the western parts of each continent enjoy a comparatively high temperature, from their proximity to the ocean, whose high temperature the winds waft thither; and they are further protected from extreme cold by their moist atmosphere and clouded skies. But in the interior of the continents it is otherwise; for the winds getting colder as they advance, and being deprived of their moisture as they cross the mountains in the west, the soil is exposed to the full effects of radiation during the long winter nights, and as a consequence, the temperature rapidly falls. In the centre of Siberia, the January temperature falls to −40°, which is 9° colder than the coldest part of the American continent; and this centre of greatest cold lies near the eastern part of the continent of Asia. On the other hand, in July, the interior of continents is much warmer than their western parts. Hence the interior and eastern parts of Asia and America are characterised by extreme climates, and the western parts by equable climates. Thus, at Yakutsk, in Siberia, the July temperature is 62°·2, and the January −43°·8, the difference being 106°·0; whilst at Dublin these are respectively 60°·8 and 38°·5, the difference being only 22°·3. This constitutes the most important distinction of climates, both as respects vegetable and animal life. On man especially the effect is very great—the severity of the strain of extreme climates on his system being shewn by the rapidly increasing death-rate as the difference between the July and January temperatures increases.

Winds and Storms.—Winds are classed as *Constant*, *Periodical*, and *Variable*. The Trade-winds and Return Trades constitute the first class; Sea and Land breezes, and Monsoons form the periodical class, and both have been considered under the general movements of the atmosphere.

Variable winds depend on purely local or temporary causes, such as the nature of the ground, covered with vegetation or bare; the physical configuration of the surface, level or mountainous; the vicinity of the sea or lakes; and the passage of storms. The hot, suffocating wind peculiar to Africa and Western Asia is known by the name of the Simoom; on the coast of Guinea it is called the Harmattan. A similar wind in Sicily and Italy is called the Sirocco, and in Spain the Solano. The *East Winds* which prevail in the British Islands in spring are part of the great polar current which at that season descends over Europe through Russia. Their origin explains their dryness and unhealthiness. It is a prevalent notion that the east winds in this country are damp. It is quite true that many easterly winds are peculiarly damp; all that prevail in the front part of storms are very damp and rainy, and soon shift round to some westerly point. But the genuine east wind, which is the dread of the nervous and of invalids, does not shift to the west, and is specially and intolerably dry. Deaths from brain-diseases and consumption reach the maximum in Great Britain during the prevalence of east winds. The *Etesian Winds* are northerly winds which prevail in summer over the Mediterranean Sea. They are caused by the great heat of North Africa at this season, and consist in a general flow of the air of the cooler Mediterranean to the south, to take the place of the heated air which rises from the sandy deserts. The *Mistral* is a steady, violent north-west wind, felt particularly at Marseille and the south-east of France, blowing down on the Gulf of Lyons.

Lord Bacon remarked that the wind most frequently veers with the sun's motion, or passes round the compass in the direction of N., N.E., E., S.E., S., S.W., W., and N.W., to N. This follows in consequence of the influence of the earth's rotation in changing the direction of the wind. Professor Dové of Berlin has the merit of having first propounded the *Law of the Rotation of the Winds*, and proved that the whole system of atmospheric currents—the constant, the periodical, and the variable winds—obey the influence of the earth's rotation.

The force of the wind is measured by *Anemometers*, of which some measure the velocity, by the revolution of vanes, and others the pressure. Of the latter kind is Lind's Wind-gauge, represented in the figure. When the instrument is used, water is poured into the tubes until the level in both stands at the middle of the scale. When no disturbing force acts upon either column of liquid, the level of both is accurately the same; but when the mouth of the tube AB is turned towards the wind, the column in AB is pressed downwards, and that in CD rises proportionably, and the difference of the heights of the two columns gives the column of water which the force of the wind sustains, and from this the pressure on a square foot is readily calculated.

Dr Lind's Anemometer.

The following are a few velocities of wind, translated into popular language: 7 miles an hour is a gentle air; 14 miles, a light breeze; 21 miles, a good steady breeze; 40 miles, a gale; 60 miles, a heavy storm; and 80 to 100 miles, a hurricane sweeping everything before it. We also add a few comparisons of velocity and pressure: 5 miles an hour is a pressure of 2 oz. on the square foot; 10 miles, ½ lb.; 20 miles, 2 lbs.; 30 miles, 4½ lbs.; 40 miles, 8 lbs.; 51 miles, 13 lbs.; 60 miles, 18 lbs.; 70 miles, 24 lbs.; 80 miles, 32 lbs.; and 100 miles, 50 lbs. During the storm in which the Tay Bridge was destroyed (Dec. 1879), the rate of velocity varied from 40 to 70 miles per hour, and the maximum velocity during the heaviest gusts was said to have reached 96 miles at Aberdeen. Wind is most frequently measured by estimation.

The estimate of the wind's force by the scale 0 to 12, means that 0 represents a calm, and 12 a hurricane. If such estimations be divided by 2, and the quotient squared, the result will be the pressure in pounds, approximately.

Storms are violent commotions of the atmosphere, occurring in all climates, particularly in the tropics, and differing from other atmospheric disturbances in the extent over which they spread themselves, their destructive power, and the sudden changes which take place in the direction of the wind. Numerous attempts have been made to reduce the phenomena of storms to general laws; but it is only quite recently that observations have been sufficiently numerous and accurate to furnish

the necessary grounds. The foregoing chart of Europe shews, from actual observations made at upwards of 100 localities scattered over that continent, the barometric pressure, and direction and force of the wind, at 8 A.M. of the 2d of November 1863, during part of the course of two storms which passed over Europe at that time. At the same hour of the previous day, the centre of the first storm (I.) was near Christiansund, and that of the second was approaching the west coast of Ireland. The isobarometric lines, or lines shewing where, at the above hour, the height of the barometer was the same, are given for every two-tenths in the difference of the pressure. Hence, where these lines approach near each other, or crowd together, the difference of pressure, or the atmospheric disturbance, was the greatest; and the least where they are most apart—a distinction of the utmost importance in determining where the storm may be expected to rage in greatest fury. The arrows shew the direction of the wind, being represented flying with it. The force of the wind is shewn (1) by plain arrows, ⟶, which represent light and moderate winds; (2) by arrows feathered on one side only, ⟶, which represent high winds; (3) by arrows feathered on both sides, ⟶, which represent strong gales, storms, or hurricanes.

Form and Extent of Storm Areas.—The circular isobarometric lines on the chart represent very accurately the general shape storms assume. The area of almost every storm is either circular or slightly elliptical. The outline is occasionally very irregular. The extent over which storms spread themselves is very variable, being seldom less than 600 miles in diameter, but often two or three times that amount, or even more.

Direction in which Storms advance.—It may be premised that by the direction of a storm is meant, not the direction of the wind, but the path followed by the centre of disturbance. The direction in which this progressive motion takes place differs in different parts of the world—being determined by the prevailing winds. Thus, about half the storms of Middle and Northern Europe travel from the south-west toward the north-east, and 19 out of every 20, at least, travel toward some point in the quadrant from the north-east to the south-east. Observation shews that the longer axis of the storm is almost always coincident with the direction in which the storm appears to be moving at the time. The storms of the Mediterranean follow a different course. Many of them proceed from the north to the south, influenced probably by the heated air rising from the Sahara. By far the greater number of the storms of North America take their rise in the vast plain which lies immediately to the east of the Rocky Mountains, and thence advance in an eastern direction over the United States; some of them, crossing the Atlantic, burst on the western shores of Europe. But the relation of the American to the European storms is not yet established. The storms of the West Indies generally take their rise from near the region of calms, and tracing out a parabolic course, proceed first towards the north-west, and then turn to the north-east about 30° N. lat., many of them traversing the east coasts of North America as far as Nova Scotia. South of the equator they follow an opposite course. The hurricanes of Hindustan usually pursue a parabolic path, first traversing the eastern coast towards Calcutta, and then turning to the north-west up the valley of the Ganges. The typhoons of the Chinese seas resemble, in the course they take, the hurricanes of the West Indies. Observations are wanting from other parts of the world to determine the course of storms.

Everywhere, the course tracked out by storms is determined by the general system of winds which prevail, modified by the unequal distribution of land and water on the surface of the globe. Facts seem at present to point to this general conclusion, viz., *Storms follow the course of the atmospheric current in which the condensation of the vapour into the rain which accompanies them takes place.*

The Rate at which Storms travel, varies from 15 or 17 miles an hour in Europe, to 30 or 40 miles in tropical countries.

Relations of Temperature, Rain, and Cloud to Storms.—The temperature increases a few degrees at places toward which and over which the front part of the storm is advancing, and falls at those places over which the front part of the storm has already passed. In other words, the temperature rises as the barometer falls, and falls as the barometer rises. When the barometer has been falling for some time, clouds begin to overspread the sky, and rain to fall at intervals; and as the central depression approaches, the rain becomes more general, heavy, and continuous. After the centre of the storm has passed, or when the barometer has begun to rise, the rain becomes less heavy, falling more in showers than continuously; the clouds break up, and fine weather ushered in with cold breezes ultimately prevails. It should be here remarked, that if the temperature begins to rise soon and markedly after the storm has passed, a second storm may be expected shortly. The rainfall is generally proportioned to the suddenness and extent of the barometric depression at the place where it falls.

Direction and Force of the Wind in Storms.—If the winds in Storm II. on the 2d November be attentively examined, they will be observed whirling round the area of low barometer in a circular manner, and in a direction contrary to the motion of the hands of a watch, with—and be this particularly noted—a constant tendency to turn inwards towards the centre of lowest barometer. The wind in storms neither blows round the centre of lowest pressure in circles, nor does it blow directly towards that centre, but takes a direction nearly intermediate. In other words, the whole atmospheric system flows in upon the centre in a spiral course. This rotatory peculiarity is common to all storms in the northern hemisphere that have yet been examined. In the southern hemisphere, a rotatory motion is also observed round the centre of storms, but it takes place in a contrary direction, or in the direction of the motion of the hands of a watch.

Professor Taylor has the merit of having first applied Dové's law of rotation to explain the direction of the rotation of storms round their centre. The cause may be seen by referring to Storm II. on the 2d November. On that morning, the pressure over England being much less than in surrounding countries, if the earth had been at rest, air-currents would have flowed

from all directions to England, to fill up the deficiency, in straight lines. The earth, however, is not at rest, but revolves from west to east; and as the velocity of rotation diminishes as the latitude increases, it is evident that the current which set out, say from Lyon to the north, would, on account of its greater initial velocity when it arrived at Paris, blow no longer directly to the north, but to a point a little to the east of north; in other words, it would no longer be a south, but a south-west wind. Again, since the current from the north of Scotland had a less velocity than those parts of the earth's surface on which it advanced, it lagged behind, and consequently, by the time it arrived at Silloth in the north of England, had changed from a north to a north-east wind. Similarly, the north-west current changed to a north, the south-west to a west, &c. Hence in a storm the whole system of winds rotates round the centre. It follows in the northern hemisphere that as storms advance, the general veering of the wind at places lying north of the path of their centre is from north-east by north to west; and at places south of their centre, from north-east by east and south to north-west; and conversely in the southern hemisphere.

Next, as to the force of the wind: The rule is simple, and without exception—viz., the wind blows from a high to a low barometer, and with a force proportioned to the difference of the barometric pressures. Hence, where the isobarometric lines crowd together, the violence of the storm is most felt, and where they are far asunder, the winds are moderate and light. We have stated that the progressive motion of storms varies from 15 to 40 miles per hour, which measures the time taken in passing from one place to another, but this gives no indication of the violence of the storm. This is determined by the rotatory velocity of the wind round the centre of the storm, which in Europe and America frequently amounts to 60 or 70 miles an hour continuously for some time. At Liverpool, on the 3d of December 1863, it blew in intermittent gusts with a speed of 93 miles an hour —a velocity frequently surpassed by storms within the tropics.

Of the different theories of storms hitherto proposed, we need only refer to the rotatory and the centripetal theories. The rotatory, or, as it is commonly called, the cyclonic theory, was first proposed by Piddington, and has since been elaborated by Redfield, Reid, Dové, and others. By this theory storms are considered as revolving round an axis either upright or inclined to the horizon, while at the same time the body of the storm has a progressive motion over the surface of the globe; the barometric depression, as caused by the centrifugal force, driving the air from the centre to the circumference of the storm. A fatal objection to this theory is, that observation conclusively shews that the wind does *not* rotate in a circle returning into itself, but constantly tends in a spiral towards the centre. Besides, the centrifugal force engendered by such a motion, even if it were a fact, would not be sufficient to depress the barometer at the centre to the hundredth part of the extent that actually takes place.

'The spiral rotation,' says Mr Buchan, 'instead of the purely circular rotation, of the winds in storms, completely alters the whole complexion of the question of the theory of storms. For since it follows from it that enormous quantities of air are constantly being poured all around into the area of the storm, and since, notwithstanding these accessions tending to increase the pressure, observation shews that the pressure is not thereby increased, but on the contrary sometimes diminished, *we are forced to the conclusion, that from a large area within and about the centre of the storm a vast ascending current must arise into the upper regions of the atmosphere; and arriving there must flow away over into neighbouring regions.* The physical cause of the ascending currents is to be found in the moist and warm, and therefore light, air which all observation shews to prevail in the front and in the central part of storms. And since most of the rain which accompanies storms falls in those parts of the storm, the barometer will be still further reduced by the removal of the elastic aqueous vapour which is condensed into rain-drops, and by the latent heat set free in the condensation of the vapour.'

An important point is to be able to tell in what direction the centre of a storm is from the place at which we are, and the rule is easy: 'Standing back to the wind, the centre lies to the left hand of the direction in which the wind is blowing. This holds in all places north of the equator, and it furnishes the rule which must be observed by ships in steering out of the course of the storm. From this relation of the winds to the pressure is also deduced the rule for predicting the direction of the wind at particular sea-ports during storms. Thus, suppose at 9 A.M. it be required to know the direction in which the wind will blow in London at 9 P.M., a storm being observed advancing from Ireland towards the east. Information being had through the telegraph of the course the storm is taking, and an inference being drawn from that observed course that at 9 P.M. its centre will be near Liverpool, then at that hour the gale may be expected at London from S.S.W.

Typhoons are violent storms that blow on the coasts of Tonquin, China, and Japan. They resemble the storms of Western Europe in their general characteristics, but the main features are more strongly marked. The central depression of the barometer is not unusually as much as 28·3 inches, and, on rarer occasions, even 27 inches.

Whirlwinds and Waterspouts.—Whirlwinds differ in many respects from storms or typhoons. They seldom continue longer than a minute at any place, and sometimes only a few seconds; their breadth varies from a few yards to nearly a quarter of a mile; during their short continuance, the changes of the wind are sudden and violent; and the barometer is not observed to fall. They are caused by two air-currents coming in contact and causing an eddy. The direction of the eddy of the whirlwinds, especially when the diameter is very small, differs from the rotation of winds in a storm, in that it may take place either way—right to left, or left to right—according to the direction of the stronger of the two winds which give rise to the whirlwind. In the sandy deserts of the tropics, these eddies draw up with them large clouds of dust, and the whole is borne forward by the wind that may happen to be blowing at the time.

Waterspouts are whirlwinds occurring on the sea or on lakes. When fully formed, they appear

as tall pillars of cloud stretching from the sea to the sky, whirling round their axes, and exhibiting the progressive movement of the whole mass precisely as in the case of the dust whirlwind. The sea at the base of the whirling vortex is thrown into the most violent commotion, resembling the surface of water in rapid ebullition. It is a popular fallacy that the water of the sea is sucked up in a solid mass by waterspouts, it being only the spray from the broken waves which is carried up.

What are sometimes called *waterspouts on land* are quite distinct from these phenomena. They are merely heavy falls of rain of a very local character, and may or may not be accompanied with whirling winds.

Weather-forecasts.—From the direct bearing weather-changes have on human interests, they have from the earliest times been closely watched, so that the causes by which they are brought about being discovered, their approach might be predicted with some degree of confidence. The craving in the popular mind for this knowledge is strongly attested by the prognostics of the weather current in every language, which, amid much that is shrewd and of considerable practical value, embrace more that is vague, and not a little that is positively absurd.

It may be laid down as a well established truth, that *no prediction of the weather can be made, in the British Islands at least, for more than three, or perhaps only two days beforehand.* Yet a belief in the prognostications of almanac-makers was once nearly universal, and is still prevalent.

The Moon and the Weather.—The belief is almost universal, that the weather is influenced by the phases of the moon. A *change* of the weather, either from foul to fair, or from fair to foul, may be specially looked for, it is thought, at the times of new and full moon, or even at the quarters, though these last are not considered so influential. This belief is found to be altogether without foundation.

The only predictions of the weather to be relied on are of the kind described in speaking of storms, where the telegraph comes into play. Almost all the weather-changes of Europe begin from the south-west, and pass over Great Britain to the north-east. Unsettled or bad weather is accompanied with a low barometer; elsewhere, the barometer is higher. Thus, then, suppose that, from weather-telegrams received, it is seen that everywhere in Europe barometers are high, we may be sure that no storm need be dreaded for two days at least. But if, on the following morning, barometers begin to fall a little in the west of Ireland, and an easterly wind begins to blow generally over Great Britain and Norway, and a south-east wind over France; then, since the winds blow towards the lowest barometer, or rather a little towards the right of it, the presumption is that a storm of greater or less severity is coming up, the centre of which is likely to pass over England. This ought, therefore, to be closely watched by the telegraph, and the indications announced from time to time.

It is our proximity to the Atlantic that makes it impossible to predict the weather beyond three days at the utmost. In Norway and the Baltic, and places towards the east of Europe, the weather may be predicted for a longer time, since each storm as it appears in the west may be followed in its course by the telegraph, and the places which it threatens be warned of the coming danger. In America also, where storms chiefly advance from west to east, gales and unsettled weather are predicted at the sea-board in the east some days before.

But the collecting of this information by the telegraph is a work which, owing to the expense, governments only can accomplish; and from its importance, it is an incumbent duty which they should discharge for the benefit of the seafaring population.

From all that precedes, it will be clear enough that the mere height of the barometer, at a particular place, taken by itself, affords no sure indication of what weather is coming; so that the terms Rain, Fair, Set Fair, marked on the common weather-glass, are delusive. The quantity of vapour in the air, the temperature, and the direction of the wind, are all to be taken into account. And with regard to the barometer itself, it is not so much the actual height that is of consequence, as whether it is rising or falling, and whether the rise or fall has been of long duration. A slow rise continued for some days gives promise of settled weather; a steady and long-continued fall indicates that a tract of unsettled and stormy weather may be expected. A sudden and great fall of the barometer is the sure forerunner of a violent storm.

CLIMATE.

The climate of a place depends on its distance from the equator, its height above the sea-level, its position in reference to oceans, seas, and continents, the form of its surface, and the character of its soil. The points to be stated in reference to climate are, the mean temperature, the extreme winter and summer temperatures, the range of temperature daily, and from day to day, the humidity, the total fall of rain, the frequency of the falls, the relation of the amount fallen to the ordinary amount of vapour in the air, the prevailing winds, and the degree of variability of the weather. In general, the southern hemisphere of the globe is colder than the northern.

The causes which determine most of these elements of climate have been already described; and the general results over the globe, as regards the most important element, temperature, are exhibited in the isothermal charts (page 42).

Under the geography of Great Britain and other countries, the peculiarities of their several climates will be noticed.

ELECTRICITY OF THE ATMOSPHERE.

Thunder and Lightning—Aurora Borealis.

The electric phenomena of the atmosphere possess great interest, but are as yet imperfectly understood (see ELECTRICITY). The discharges of the excitement are well known under the terms *thunder* and *lightning*, and they generally accompany storms and hurricanes, but rather as effects than causes.

The *aurora borealis*, one of the most beautiful of meteoric phenomena, is now believed to be connected with the *magnetism* of the earth.

LUMINOUS METEORS.

Rainbows—Halos—Parhelia—Coronæ, &c.

The various luminous appearances of the heavens, apart from the ordinary phenomena of sun, moon, and star light, are usually treated of under Meteorology.

The *rainbow* is owing to a complicated reflection and decomposition of the rays of the sun in passing through drops of rain. It appears when the sun is unclouded, and rain is falling in the opposite quarter of the heavens. The mode of its formation is more particularly explained under OPTICS. A morning rainbow is an unfavourable prognostic of the weather; a rainbow in the evening is favourable.

Halos are coloured rings occasionally seen surrounding the sun or the moon. There are often several circles, some concentric, others intersecting or touching one another. They arise from the minute snow crystals of the cirrus cloud, and are due partly to refraction and partly to reflection. It can be shewn by the well-known principles of prismatic refraction, that the common halo of 22° radius is owing to refraction by the faces of the crystals that are inclined to one another at an angle of 60°; while the wider circle of 46° radius is produced by faces at an angle of 90°. At certain points of the circles, other effects conspire to produce luminous knots called *parhelia* (mock-suns), or *paraselenæ* (mock-moons).

The true halos are to be distinguished from the *coronæ* that surround the sun or moon when a thin cloud passes over them. These depend on a different optical principle. The same appearances may be seen by looking at a candle through steam or through the dust of a room. The smaller the size of the particles, the greater is the diameter of the corona. A narrowing corona round the moon shews that the cloud particles are enlarging, and indicates coming rain. Coronas are less often seen round the sun, owing to the strength of his light.

One marked distinction between coronas and halos is, that in halos the red prismatic colour is next the centre; in coronas, the blue.

IGNEOUS METEORS.

Shooting-stars—Fire-balls—Aërolites.

Shooting-stars are observed during serene nights. A luminous point like a star bursts into view, shoots a certain way through space, and then disappears. Sometimes it leaves a luminous train behind it; in other cases it gives forth sparks. These meteors have been noticed to occur in great numbers at once; and the interest of such appearances has been very much increased by the fact of their being in some measure periodical. On several years they have been found to occur in the month of November. They also occur with some degree of frequency in August. Shooting-stars and *fire-balls* break out occasionally at every period of the year.

It is now agreed that these bodies are nothing else than small planets, and, therefore, the consideration of them properly belongs to astronomy. There is every reason to believe that the planets, satellites, and comets are not the only bodies which move round the sun, and lie within the solar system—they are merely the large conspicuous masses; while millions of others may exist, too small to be descried on ordinary occasions, and making themselves known by coming within the earth's atmosphere. The friction against the air, caused by their immense velocity, develops enormous heat, which melts the surface of the body, and this outer liquid portion is thrown off in a long flaming stream forming the train, which, after losing its velocity, is precipitated to the earth as a fine dust or volcanic ash, while the meteor, thus rapidly diminishing, either becomes wholly dissipated into tail, or falls to the earth, or makes its way out of the atmosphere, and continues its course. The periodic meteors are small bodies: they have been calculated to range from 30 grains to 7 or 8 pounds, and none of them have been known to fall to the earth. These smaller bodies, that are for the most part dissipated in the air, are the *shooting-stars*, properly so called. The irregular or sporadic meteors frequently come to the earth in large masses, and often burst in falling, owing to the outside being suddenly and intensely heated, while the interior remains cold. These *aërolites* (Gr. *aër*, air, and *lithos*, a stone) are found to consist of iron and stony matter in various proportions, the iron in some largely predominating. To account for the periodicity of the November meteors, it is imagined that a great number of them may move in a continuous ring or common orbit round the sun, so situated that the earth, in its annual course, brushes, as it were, with the outskirts of its atmosphere this ring of planetary fragments once a year. If the bodies were all round the ring, there ought to be a shower of them every November; but the great displays occur only once in about 33 years; and therefore it is inferred that the great mass of them are grouped at one part, and that the time of revolution of the ring being 33 years, that length of time must elapse between each concurrence of the earth and the dense part of the group.

One of the most familiar of luminous meteors is the *ignis-fatuus*, or 'Will-o'-the-wisp,' which appears at night on marshy grounds, places of sepulture, or wherever putrefaction and decomposition are going on. The appearance is that of a small flickering light, straggling in an irregular manner at the height of one or two feet from the ground, and sometimes standing for a few moments over a particular spot. When approached or pursued, the lights are agitated by the motion of the air, and seem to elude investigation. The cause of this species of meteor has never been satisfactorily explained.

Until recently, meteorological observations had been mostly casual and without any uniform plan; hence the vagueness and uncertainty that hang over so much of the subject. But since 1840, the earth has been covered with a net-work of meteorological observatories, maintained by the several European governments. Above all, the use of the telegraph in meteorology is proving a powerful means both of advancing the science and of turning it to practical account. It is not unreasonable to anticipate that, with the agents and apparatus now at work in this field, the next half-century may see light and order arising out of many things that now seem nothing but chaos.

PHYSICAL GEOGRAPHY.

GEOGRAPHY—from *gé*, the earth, and *grapho*, I write—in its simple and literal signification, is that science which describes the superficial appearance and conditions of our globe. It naturally divides itself into two great branches—1. *Physical Geography*, which treats of the earth as a superficies composed of land and water; considers the position, extent, altitude, and general character of the former; and the position, extent, depth, currents, and other motions of the latter: in short, all that relates to the distribution of land and water, variations of surface, temperature and climate, and distribution of plants and animals as dependent thereon, are the legitimate objects of this species of geography. 2. *Political Geography*, which treats merely of the division of the earth's surface by man into territories and states, describing their boundaries, the history of their occupation, their produce, commerce, population, laws, religion, and other topics which constitute the fundamental features of human polity. The latter of these branches will form the subject of several subsequent treatises; to an exposition of the former—dwelling more on principles than on mere descriptive details—we intend to devote the present number. Before doing so, however, it will be necessary to advert briefly to the cosmical relations and constitution of our planet, as determined by astronomy, geology, chemistry, and meteorology.

GENERAL CONSTITUTION OF THE GLOBE.

Astronomy informs us that the earth we inhabit is one of a number of *planets* which revolve round the sun as a common centre, constituting what is usually denominated the SOLAR SYSTEM. These planets are situated at different distances from the central orb, and differ also in their magnitudes, their densities, and in their periods of revolution. They are nearly spherical in form, are opaque, have no light of their own, but merely reflect that of the sun; and all move from west to east in nearly circular orbits. Several of them serve in turn as centres for other bodies of revolution, which are known by the name of *satellites*—as the moon, for example, which is the satellite or attendant of the earth. Besides the planets and their satellites, there is a third and numerous class of bodies belonging to the solar system—namely, *comets*, which revolve round the sun in regular periods, but in orbits so elliptical, that in parts of their course they approach nearer to the great orb than any of the planets, and in others recede so far into the regions of space, as to be entirely beyond the reach of our most powerful telescopes. The *stars* belong to other systems of revolution, and have, so far as has yet been determined, no perceptible effect upon the conditions of our globe, though undoubtedly bearing, like everything in nature, a universal harmonious relationship.

The earth, as an individual planet, is situated at the mean distance of 91,350,000 miles from the sun; has a mean diameter of 7912 miles; performs a revolution round the sun in 365 days 5 hours 48 minutes and 49 seconds, which constitutes the space of time called a year; rotates on its own axis once in 24 hours—that is, in one day; and in these movements is attended by the moon, which is distant 237,000 miles, is 2160 miles in diameter, and which completes her synodic revolution in 29 days 12 hours and 44 minutes, or in one lunar month. We have spoken here of the *mean* diameter of the earth, because, upon accurate measurement, it has been found to be not a perfect sphere, but an *oblate spheroid*, whose greater diameter is 7925, and whose lesser is only 7899 miles. This gives a difference of 26 miles between the two diameters, or a flattening at each pole of about thirteen miles—a result that may be artificially illustrated by twirling with rapidity a ball of any yielding material, such as putty, round a spit thrust through it as an axis, when a bulging at the outer circumference will take place, causing the ball to lose its original spherical form. This bulging takes place through what is called the law of centrifugal force; and from what we know of this law, it is concluded that the earth was in a soft or yielding state at the time when it assumed its present form. Besides the bulk, revolutions, and configuration of our globe, science has also determined its *density* with considerable accuracy. By weighing the most prevalent rocks, it has been found that the solid crust composed of them is about two and a half times heavier than water; but from experiments made on the attraction of mountains of known bulk, compared with the attraction and bulk of the globe, and by other means, it has been inferred that the density of the whole mass is five or six times that of water: in other words, the earth, as at present constituted, is five or six times heavier than a globe of water of similar dimensions, and more than twice the weight of one composed of such rocky substances as those with which we are acquainted. In addition to what may be called its own proper material, the earth is surrounded by a gaseous envelope or atmosphere. This *atmosphere* or air is peculiar to, and inseparable from, our globe—it rotates with the solid mass upon its axis, and does not, as may at first be supposed, occupy the space in which the rest of the heavenly bodies revolve. Like all aëriform and liquid masses whose particles press upon each other equally in every direction, the portions or strata next the earth are more pressed upon than those in higher regions; and continuing this conception, a height must be arrived at where the air becomes so attenuated as to be inappreciable. That limit used to be assumed at 45 to 50 miles; but there is evidence to shew that there is an atmosphere of some kind even at the height of 400 or 500 miles.

From its planetary relations, as a part of the solar system, the earth derives its figure and motions, its light and heat, and consequently the changes of season, and the alternation of day and night; the phases of the moon, and the rising and falling of the tides; the vicissitudes of wind and weather, and all the varied results and phenomena

that flow therefrom. Thus, while its figure is preserved by the laws of centripetal and centrifugal force, its motions are determined and influenced by the attraction and gravitation of the sun and other planets. From its situation with respect to the sun, it necessarily follows that only one-half of its surface can be exposed at a time to the light and heat diffused from that orb, thereby causing day in the one part, and night in the other. The *seasons*, again, are caused chiefly by the fact, that in performing its path round the sun, the earth preserves its axis in a slanting or oblique position, as has been more particularly explained in ASTRONOMY and in METEOROLOGY.

The solar system, however, vast as it seems, is but a unit in space, which is peopled with other systems and orbs circling beyond the bounds of human conception. What we term *fixed stars* are but suns and centres of revolution; and the solar system, as a whole, may revolve in space round some vast centre, just as its individual planets have their motions round the sun. From such a revolution may arise cycles of heat or cold, life or death, exuberance of certain living forms, and annihilation of others—cycles which meet with a faint analogy in the recurrences of our summers and winters. Even in the known relations of the earth to the sun, astronomers find causes of vicissitudes of temperature sufficient to account for those alternate periods of equatorial heat and glacial cold which geology shews our earth to have already passed through.

The materials of which the earth is composed present a history not less curious than that of its planetary relations. Superficially speaking, the globe consists of land and water—the water occupying the extreme depressions of the land, and this land composed of solid or rocky materials. Our direct knowledge of these materials extends only to a small depth—a mere rind of the globe; regarding the interior portions, we can only infer certain things. One of those inferences is that already noticed—namely, that the interior, as a whole, is more than twice as dense as the superficial matter. But whether this arises from the materials being different, or from their being more compressed, we have no means of knowing. It used to be held that the earth was a molten mass enclosed in a solid shell or cooled *crust*, through which the agitations of the liquid below produce the phenomena of volcanoes and earthquakes. From considerations, however, regarding the tides, and other astronomical data, it is inferred with certainty that this is not the case; and it is most likely that at least half the distance from the surface to the centre is solid and more rigid than the rocks we know. The solid earth to which we have access consists of rocks, differing not only in their appearance and arrangement, but in their mineral and chemical characters; some being compact and crystalline, as marble, others soft and dull, as chalk; some lying in layers or strata, others occurring in huge irregular masses; while, mineralogically and chemically speaking, we have such rocks as granite, quartz, slate, lime, coal, rock-salt, chalk, and clay. But the crust so composed, compact and solid as it may seem, is far from being permanent and stable; in other words, the dry land which now appears, with all its irregularities of hill and valley, plain and ravine, lake and river, is not the dry land which existed many thousands of years ago. Strictly speaking, indeed, the aspect of the globe is ever changing. Here the sea encroaches on the land, there the débris borne down by rivers silts up bays and estuaries; here earthquakes sink, and volcanoes elevate the surface; lakes are dried up, and rivers change their course; and, greater than all of these, vast regions gradually subside, and are covered by the ocean, while others as gradually emerge from the waters, and become dry land. All these changes, past and present, form the subject of geological consideration.

Geology, in its aim to decipher the physical history of our globe, has determined that all the known rocks may be ranked under two great sections—the *stratified* and the *unstratified*. The former appear in layers or beds, and have evidently been deposited in water, hence said to be *aqueous* or *sedimentary;* the latter appear in vast irregular masses, generally disrupting the stratified rocks,

and have all the appearance of having been formed like the lavas of the present day; hence they are called *igneous* or *volcanic*. Of the sedimentary rocks, sandstone, limestone, slate, and coal may be taken as illustrative examples; of the igneous, granite, basalt, greenstone, and lava are the most familiar. As at present, so in all time past, the surface of the earth has been subjected to atmospheric, aqueous, and other influences, the effects of which are to wear down the exposed material; and this, borne away by floods and rivers, is deposited in the ocean, where, consolidated by pressure, heat, and chemical agency, it forms new strata of rocks, which in time are brought to the surface by volcanic and other elevating forces. Thus, then, one set of agencies degrade, and another reconstruct and elevate; and in proportion as either of these preponderate, so will any portion of the earth be low and level, or high and precipitous. Such, then, is the origin of the stratified and unstratified rocks—the one but the reconsolidated matter of pre-existing rocks, which have been worn and battered down by rains, frosts, waves, and rivers; the other the cooled and hardened material sent forth from the interior of the earth by volcanic agency. But while rivers and floods bear down mud, sand, and the like, they also carry such vegetable and animal remains as lie in their course; and in this manner plants and animals are entombed in the newly formed layers or strata. As at present, so in former eras, such remains have been enclosed in the stratified rocks, where, subjected to certain chemical agencies, they have become petrified, and are thus preserved as records of the former Flora and Fauna which peopled the globe. Geologists have, accordingly, found that the earth has not always been occupied by the same kinds of plants and animals that now exist; but that different eras in its onward history have had very different Flora and Fauna, and that not one, perhaps, of the genera at one time in existence now survives.

By long-continued and widely extended observations in various parts of the globe, based on

numberless data of composition, structure, inclination, and fossil contents, geologists have been able to form a definite list of the various rock-formations from the earliest to the most recent, arranged in the order of time. They have divided the whole of the rocks composing the crust of the earth into sections called 'systems,' and have subdivided these again into 'groups,' in a certain well-defined order. So that when a rock is presented to their observation in any part of the globe, they can state, with more or less certainty, the system to which it belongs, and the period in the past history of the earth at which it was deposited. See GEOLOGY.

The constituents of all these rocks or strata, as well as those of plants and animals, are compounded of about sixty-three elementary substances; of which, at the ordinary pressure and temperature of the atmosphere, five are *gaseous*, and the rest mostly solid, by far the greater number being metals. See CHEMISTRY.

Of the constitution of the ocean, or watery portion of the earth's superficies, chemical research affords us precise data. When pure, water is composed of 1 part of hydrogen and 8 oxygen by weight, or of 2 hydrogen and 1 oxygen by volume. In nature, however, water is generally found to contain many impurities—such as clay, sand, animal and vegetable matter, &c.—which, if left at rest, by their own weight soon fall to the bottom. Such substances are said to be *mechanically suspended*, and when deposited at the bottom, form sediment. Besides impurities of this description, water may contain matter which will not fall down, and which is said to be held in *chemical solution*. The saline matter in sea-water amounts to about 3½ per cent. of its weight, or nearly half an ounce to the pound. It consists chiefly of common salt, sulphate of soda, carbonate of lime, chloride of magnesia, and silica, although more than twenty other substances have been detected in minute quantity. The saltness of the sea, however, is not quite uniform. In general, it is greater in the trade-wind regions than in extra-tropical; or wherever evaporation exceeds precipitation. A rainless sea, like the Red Sea, is considerably salter than the ocean generally; the Baltic, again, which receives a great many rivers, and is besides shallow, contains only half as much salt as the Atlantic. It is often found that while a comparatively fresh current is flowing one way on the surface, a salter undercurrent is setting in the opposite direction. A knowledge of the constitution of the ocean is necessary to the explanation of numerous facts in geology and biology.

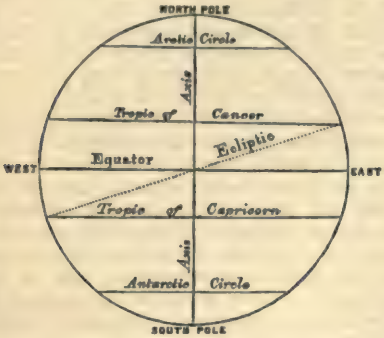
The *atmosphere*, the next great constituent of the globe, plays an equally important part in the organic and inorganic economy. As it presses with a weight of about fifteen pounds upon every square inch at the ordinary sea-level, and diminishes in density upwards in geometrical progression, it is evident that animals and plants fitted to live at small elevations will die if removed to great heights—a circumstance corroborated by the fact, that travellers experience difficulty in respiration on very high mountains. Notwithstanding its transparency, the air intercepts and reflects the sun's rays, and propagates them by an infinity of repercussions; and were it not for this property, objects would never be illuminated unless exposed to the direct light of the sun. The air—and more especially the watery vapour forming a part—is also the recipient and retainer of the heat radiated from the earth; and were it not so constituted, the heat derived from the sun's rays would be returned to space, and an excessive cold continually prevail. See METEOROLOGY. Chemically speaking, the atmosphere is a mixture of two gases, nitrogen and oxygen, in the proportion of 77 of the former to 23 of the latter, with about one part in 2000 of carbonic acid. In addition to these, which are its permanent constituents, there are always traces of ammonia and a certain amount of aqueous vapour, amounting from 1 to 1·8 per cent.; in certain localities, also minute quantities of other ingredients are to be occasionally detected. The atmosphere may therefore be regarded as the laboratory in which clouds, rain, snow, and other vapours are formed—the medium through which the light and heat of the sun are diffused and equalised—an element without which animal and vegetable life could not exist, for both incessantly inhale and exhale its elements; and an agent indispensable to those innumerable physical operations which constitute the progressive history of our planet.

Thus assisted by the determinations of astronomy, geology, chemistry, and meteorology, as regards the general constitution of the globe, physical geography proceeds to describe and explain its superficial appearance and conditions, and those, again, as influencing the life and distribution of the plants and animals by which it is peopled. Before entering, however, upon these interesting but complicated details, it will be necessary to explain the principal terms and technicalities usually employed by geographers.

GEOGRAPHICAL TERMS.

The direction from which the earth moves in its daily rotation is called the *West;* that towards which it moves, the *East;* the point which is on the right hand of one standing with his back to the east is called the *North;* that on the left hand, the *South.* The imaginary line on which the earth turns is called the *Axis;* its termination towards the north is known as the *North Pole;* that towards the south, the *South Pole.* The early cultivators of geography, dwelling on a part of the earth nearer the north than the south pole, supposed the former to be uppermost, though, in reality, such ideas as upper and under do not belong to astronomy; and it is for this reason that in globes and maps the northern part is always placed at the top, the east being towards the right, and the west towards the left hand, with the south at the bottom. Hence also the term *high latitudes*, applied to places lying far north. Exactly between the two poles, and consequently dividing the earth into two equal portions, is a line called the *Equator;* all north and south of which are respectively called Northern and Southern Hemispheres or Half-spheres. In the same way, an encircling line, at right angles to the equator, divides it into Eastern and Western Hemispheres. The circuit of the earth, both in its girth between east and west, and between north and south, is divided into 360 parts, called *degrees*, each degree being equal to about 69½ British miles. At the distance of 23½ of these degrees from the equator, in both directions, are two parallel lines called the

Tropics, because at these distances from the equator the sun *turns* in his annual path; they are known respectively as that of *Cancer* and that of *Capricorn*, from constellations situated in a corresponding part of the sky. At the same distance from each pole is a parallel line—that on the north being styled the *Arctic*, and that on the south, the *Antarctic Circle*. The space between the tropics



is called the *Torrid Zone*, because the sun, being always vertical in some part of that space, produces a greater degree of heat than is felt in regions where his rays strike more obliquely. The spaces between the tropics and the Arctic and Antarctic Circles are styled the *Temperate*, and the spaces within these latter circles, the *Frigid Zones*. Lastly, a line, which cuts the equator obliquely, touching upon opposite points of the tropics, is called the *Ecliptic;* it properly belongs to the sphere of the heavens. A series of lines drawn from pole to pole over the earth's surface, and cutting the equator at right angles, are called *Meridians*, from the Latin *meridies*, mid-day. Every place upon the earth is supposed to have one of these passing through it, although it is usual to describe only twenty-four upon the surface of the terrestrial globe. When any of these is opposite the sun, it is then mid-day, or twelve o'clock, with all the places situated on that meridian; and consequently midnight with those on the opposite meridian, on the other side of the earth.

The exact situation of a place upon the earth, or its latitude and longitude, is determined by means of these circles. They are all divided, as already stated, into 360 parts, which parts are called *degrees;* these degrees again into 60 equal parts, called *minutes;* the minute into 60 others, called *seconds;* and so on. They are usually indicated by certain signs—thus, $8^\circ\ 5'\ 7''$, is 8 degrees 5 minutes 7 seconds. The *latitude* of a place is its distance measured in that manner from the equator. If it lies north of that line, it is in north latitude; if south of it, in south latitude. There being only 360 degrees in the circumference of the earth, and the distance from the equator to either of the poles being only a fourth part of it, a place can never have more than 90 degrees of north or south latitude. The *longitude* of a place is the distance of its meridian from another, which is called the *first meridian*. The first meridian is quite arbitrary, and it is a matter of indifference through what point we draw it, provided it be settled and well known which one we adopt, so as to prevent mistakes. In Germany, the island of Ferro is generally adopted; in France, the observatory of Paris; and in England, that of Greenwich. Longitude is reckoned either east or west of the first meridian; and 180 is therefore the utmost degree of longitude. Some geographers, however, reckon longitude all the way round the globe. From the meridians all tending to a point at either pole, the degrees of longitude necessarily decrease as we approach these points from the equator.

Besides these terms and technicalities, which refer to the earth as a whole, there are others employed to designate its separate portions of land and water. Thus of the land, a *continent* is any vast region uninterrupted by seas; an *island*, any smaller portion surrounded by water; a *peninsula*, a portion nearly surrounded by water; an *isthmus*, the narrow neck which connects a peninsula with the mainland; a *cape*, *promontory*, or *headland*, a point of land jutting out into the sea. As to the water, a large uninterrupted extent of sea is called an *ocean;* smaller portions are known as *seas;* a bend of the sea into the land, a *bay;* a deeper indentation, a *gulf;* a narrow strip of sea, a *strait* or *channel;* and where the sea stretches inland to receive the waters of some large river, it is termed a *firth* or *estuary*. Referring to the surface of the land, without any reference to water, extensive flats are known as *plains*, *steppes*, *pampas*, &c.; smaller ones as *valleys*, *straths*, and *dales;* elevated land is spoken of as rising into *hills*, or, still higher, into *mountains;* and level elevated tracts are known by the name of *table-lands* or *plateaux*. Running water makes its appearance in *springs*, many of which conjoined form *streams*, and streams *rivers;* and where these become stagnant, and spread out into inland sheets, they take the name of *lakes*. The bounding-line of land and water is termed the *shore*, and the land bordering on the sea in any place is generally spoken of as the *coast* or *sea-board*.

DISTRIBUTION OF LAND AND WATER.

To exhibit the earth's surface at one view, it is usual to map it into two halves or hemispheres—the Eastern comprehending the one great continent of the *Old* World, or that known to the ancients; and the Western, or *New* World, discovered and explored since the close of the fifteenth century. To these, modern geographers add a third—namely, *Oceania*, or the Maritime World, partly situated in both hemispheres, and comprising Australia and the vast groups of islands which stud the Pacific Ocean. It will be seen at one glance that the sea and land are very unequally distributed—that they preserve no regularity of outline or form—and that either is placed indifferently as to position, on the earth's surface. Many fanciful conjectures have been offered to account for the configuration of the existing continents, but none of them seem to have any foundation in fact.

Though we are thus unable to account for the present relative arrangement of sea and land, there is one determining principle sufficiently clear—namely, that so long as the same quantity of water remains on the globe, a fixed amount of cubic space will be required to contain it. If the difference between the elevations and depressions of the solid crust be small—in other words, if the

hollows in which lakes and seas are spread out be shallow—their waters must extend over a greater superficial space; and if these hollows be deep, the waters will occupy less extensive areas. The operation of this principle should be borne in mind; for, if the inequalities of the land were generally less, the waters would occupy larger spaces, and this more extended area of shallow water would act in various ways. It would render the climate more genial and uniform; and, extending a greater surface to the evaporating power of the sun, rains and atmospheric moisture would be more prevalent. These, again, would influence the amount and kind of animal and vegetable life on dry land; while the shallow waters themselves would be more productive of life—it being a well-known fact that marine plants and animals flourish only at limited depths.

The proportion of dry land to water, as at present known, is about one to three—that is, nearly three-fourths of the whole surface of the globe may be assigned to water. Reckoning the entire area of the globe at 197 million square miles, the land is computed to occupy about 52 millions, leaving 145 millions for sea. The land is far from equally distributed over the globe; the greater part of it lies north of the equator. 'If,' says Professor Ansted, 'a person, stationed vertically over the town of Falmouth in England, could see half the globe, he would see more than 49 out of the 52 millions of square miles of land, or about an equal surface of land and water. If, however, he were perched equally high above New Zealand, he would see 96½ millions of square miles of water, and less than two millions of square miles of land.' To render this unsymmetrical protuberance of the land consistent with the right balancing of the globe, it has been assumed that the rocks in the water hemisphere may be heavier than those in the other, arising either from their containing more metal or being more compact.

CONTINENTS AND ISLANDS.

The continuous masses of land large enough to deserve the name of continents are only three in number—the Eastern Continent, or Old World; the Western Continent, or New World; and the Southern Continent, or Australia. By much the largest is the Eastern Continent; Europe, Asia, and Africa are, strictly speaking, not separate continents, but divisions or lobes of this vast tract. North and South America, in like manner, are the two divisions of the Western Continent. The areas of the three continents, with the adjacent islands, in round numbers of millions of miles, are as follows:

Old World, or Eastern Continent		31,230,000
Europe	3,724,000	
Asia	16,152,000	
Africa	11,354,000	
New World, or Western Continent		15,000,000
North America	8,200,000	
South America	6,800,000	
Southern Continent, or Australia		4,632,000

The outline and disposition of the three continents are as diverse as can well be conceived. The great mass of the Old World lies north of the equator, with its main axis ranging from north-east to south-west. The western continent runs, in its longest direction, nearly from north to south, and has considerably more of its area, in proportion, to the south of the equator than is the case in the other continent. Australia, again, is wholly in the southern hemisphere, has its greatest length from east to west, and is of a compact oblong shape, while the other two continents are excessively irregular and deeply indented. The Old and New Worlds agree in one remarkable circumstance; nearly all the projecting portions point southwards, and are mostiy of a triangular shape. This is seen, in the Old World, in Kamtchatka, Corea, Malacca, Hindustan, Arabia, Southern Africa, Italy, Greece, Spain, Scandinavia; and in the New, in Greenland, Alaska, California, Florida, and South America. Retaining the generally acknowledged divisions, let us glance at their respective positions and superficial characteristics as influencing the vitality of our planet.

Europe—lying almost wholly within the northern

temperate zone, diversified by a happy blending of mountain and plain, marked by no geographical feature on a scale so large as to give to its surface the character of monotony, and surrounded and intersected by seas which greatly influence its climate—affords, in proportion to its area, a habitat to a more varied and highly developed existence than any other quarter. Asia, situated partly within the torrid, temperate, and frozen zones, and presenting an area almost five times that of Europe, exhibits every species of geographical diversity. With such a variety of character, it is impossible to treat of it as a whole, and consequently geographers divide it into five well-marked regions—namely, *Central* Asia, consisting of a series of ascending plateaux, diversified by mountain-ridges of stupendous height, and intersected by narrow valleys; *Northern*, including the whole of the continent north of the Altaï Mountains—a flattish region traversed by large rivers, bleak and barren, suffering under an intense cold, thinly peopled, and almost physically incapable of improvement; *Eastern*—upon the whole a low-lying and somewhat arid region, though traversed by several of the largest rivers in the world, and occasionally diversified by spurs from the central table-heights; *Southern*, including the two peninsular projections of India within and without the Ganges—decidedly the finest region of the continent, diversified by minor hill-ranges and well-watered valleys, enjoying a high, though not an oppressive temperature, having only a rainy season for its winter, and, except during long drought, presenting in every district an unfailing verdure; and, lastly, *Western* Asia—from the Indus westward and north to the Caspian—which, with a few minor exceptions, may be said to consist of high sandy plains, studded with salt-lakes, very inadequately watered by rivers, and on the whole a hot and arid region. A continent marked by such a diversity of surface and climate, presents an appropriate field for the exhibition of almost every form of vitality known in the other continents; and thus has belief ever pointed to it as the cradle of organic existence. Africa, the next great division of the Old World, is almost entirely insular, the isthmus connecting it with Asia being only seventy-two miles across, of no great elevation above the sea-level, and even in part occupied by lakes and salt-marshes. It is only a few years ago that little was known regarding the physical construction of Africa beyond a limited strip around the coast, and a few tracks across the Great Desert of the north. Thanks to the adventurous explorations of recent travellers, we now have a tolerable notion of its general features. One of these features is an almost continuous range of mountains girdling the continent round, leaving a belt of lowlands of from 50 to 300 miles broad between them and the coast. In the triangular part of the continent, south of Cape Guardafui and the Gulf of Guinea, the interior consists of an elevated plateau variegated by mountain tracks, river-valleys, and depressions containing great lakes; the whole abounding in multiform vegetable and animal life. North of this plateau the interior consists of the comparatively low-lying and fertile track known as Nigritia and the Great Desert or Sahara. The isolation of Africa, its intertropical position, and its general configuration, must stamp it with *vital* peculiarities; and yet its connection with Asia on the one hand, and its proximity to Europe on the other, offer numerous facilities to the interchange of vegetable and animal species. Thus the southern and northern sea-board of the Mediterranean present many similar forms; and the Flora and Fauna of Egypt and Nubia are identical in many instances with those of the adjoining tracts of Arabia.

Turning now to the New World, we find also the two Americas so slenderly attached by the narrow rocky Isthmus of Panama, which at one part is little more than eighteen miles across, that they may safely be regarded as separate and distinct continents. This separation is rendered still more decided by the irregular character of the isthmus and the adjoining high table-land of Mexico, which form an almost impassable barrier to the migration either of animal or of vegetable races. South America lies chiefly within the tropics, a third part or less stretching southward into the temperate zone; its superficies is broadly marked by mountain and plain, exhibiting along the entire western coast a flat arid region, from 50 to 100 miles in breadth; then rising boldly up into the Andes, which stretch along its whole length, and present a rugged irregular region of variable breadth; and ultimately falling away to the north and east in the *llanos* of the Orinoco, the *plains* of the Amazon, and the *pampas* of La Plata. Nor are its physical features more broadly marked than the plants and animals by which it is peopled, these exhibiting typical peculiarities only next in degree above those of the somewhat anomalous continent of Australia. The problem of the north-west passage being now solved, Greenland and a number of islands lying west of it might be conveniently erected into a new geographical division. Following, however, the usual course of including these regions, the area of the known continent of North America may be stated at 8,200,000 square miles—the great mass of which lies within the northern temperate zone. The general physical characteristics of the continent are remarkable for the magnitude of the scale upon which they are presented—the plains, lakes, and rivers being superior to those of all other countries. Though lying chiefly within the temperate zone, its southern and northern regions are respectively placed under tropical and arctic influences; and thus it presents in some measure the threefold variety of Fauna and Flora which characterises the greater continent of Asia. This greater diversity of climate renders it less peculiar in its living forms than the sister continent, at the same time that its proximity to Asia—being separated by Behring's Strait, which is only thirty-six miles broad—renders the immigration of Old-World species by no means improbable.

In estimating the comparative adaptability of a land as the habitation for man, an important element is the extent of its coast-line compared with its area. The more irregular the shape of the land, and the more it is broken into by gulfs and bays, the more are the inland parts brought into proximity to the great highway of intercourse and civilisation. Europe is so indented with seas and gulfs, that it has a coast-line of 20,000 miles, while the same area might be contained in a regular figure of 6000 miles' circuit. Had it had an outline of this kind, it would hardly have been, as it is,

the habitat of the most advanced races. The following table exhibits the number of square miles of area to one mile of coast in the several large divisions of land, thus affording a measure of the comparative accessibility of the interior:

Europe	157 sq. miles of area to 1 mile of coast.		
Asia	528	"	"
Africa	738	"	"
North America	266	"	"
South America	440	"	"
Australia	340	"	"

The *insular portions* of the globe are not less worthy of notice than the continents themselves. We find them sometimes solitary, oftener collected into groups or *archipelagoes:* in some cases they are little more than low sand-banks, ledges of rocks, or coral reefs; and in others—rising to a considerable elevation above the surface of the water, and spreading to a considerable extent—they present in miniature all the features of the continents to which they belong. They are often the summits of submarine mountain-chains, and, as such, are intimately connected with each other and with the neighbouring mainland. Many of them are evidently the production of volcanic forces—the dawn of new continents emerging from the waters, as others are the gradually submerging relics of former terrestrial regions. The most important island-groups are the British, Japan, Philippine, and East Indian in the eastern hemisphere; and the West Indian and Polynesian in the western. The largest individual islands (regarding Australia as a continent) are—Borneo, with an area of about 280,000 square miles; Madagascar, 234,000; New Guinea, whose outline is yet imperfectly known; Sumatra, 177,000; Niphon, 109,000; Great Britain, 90,000; Nova Zembla, 25,000; Newfoundland, 40,000; Cuba, 43,400; and Iceland, 40,000 square miles.

Islands, we have said, are either connected with existing continents, are portions of former continents now submerged, or are new and independent elevations. Thus, if an island is of the same geological formation with the adjoining mainland, we must regard it either as a portion separated by depression, or as a belated portion only rising into dry land. In either case, we are bound to consider it in all its relations—vital as well as physical—as belonging to the adjacent continent. Again, islands of totally different formation from that of the nearest continent may in most cases be regarded either as relics of former lands, or as new lands rising into day; and we are not to be startled at the fact of their exhibiting—like Australia—races of plants and animals altogether peculiar.

Such is a brief glance at the partition of the dry land (so far as it is known) into continents and islands—a partition which exercises an all-important influence over organic existence, and which, after all, is dependent on very minute geological operations. A general elevation of the solid crust in the eastern hemisphere, for example, would connect Britain with the continent of Europe, the Lofoden Islands with the Scandinavian peninsula, enlarge the connection between Asia and Africa, elevate the Sunderbunds of the Ganges into a vast plain, the Laccadive and Maldive reefs into extensive islands, and the bed of the Yellow Sea into an alluvial plain. Equally important results depend upon the relative positions of the continents and islands. Had South America, unaltered in a single square yard, lain parallel with, instead of crossing, the equator, or had Africa been intersected by seas, as Europe is, it requires no stretch of imagination to conceive the radical difference which their Flora and Fauna would have presented. As regards man, and the highest aim of creation—the civilisation of man—the present arrangement is of the first importance. The theatre of his operations all arctic, and he would never have risen above the condition of the Laplander or Esquimaux; all antarctic, and behold his condition in that of the miserable Fuegian; all tropical, and see him in a state of languid, enervated, semi-civilisation; while balanced as conditions are, see his progress mainly in one broad zone, where Chinese, Indian, Persian, Chaldean, Syrian, Egyptian, Greek, Roman, Frank, and Anglo-Saxon have successively or simultaneously figured in the march of improvement.

MOUNTAINS AND TABLE-LANDS.

As elevation above the waters of the ocean is the origin of the dry land, so its most prominent features are those peculiar upheavals known by the name of *hills* and *mountains.* The theory of their upheaval belongs to Geology; but according to their character, so is that of the regions to which they belong, generally speaking, determined. They subserve numerous and important purposes in nature. Rising into regions of perpetual ice, they serve, in hot climates, to temper the air with the breezes generated around their heights; they are the reservoirs of rivers, supplying the shrinking streams, in the dry seasons of the lower countries, with copious torrents from their melting snows; they are in most instances the storehouses of the richest minerals; they increase and diversify the surface of the earth; and, by presenting impassable barriers between opposite regions, they give variety and richness to animal and vegetable life: we say impassable barriers, for the broadest seas are not half so effective in obstructing the dispersion of vegetable and animal life as lofty snow-clad mountains.

Isolated mountains of great height are of rare occurrence, and when they do appear, are usually active or recent volcanoes. Hills and mountains, whether rising to the height of 1000 or 20,000 feet, generally appear in chains or ranges, consisting either of one central chain, with branches running off at right angles, or of several chains or ridges running parallel to each other; and in both cases often accompanied by subordinate chains of minor elevation. Several chains constitute what is called a *group;* and several groups, a *system.* The relative ages of mountain-chains appertain more especially to the province of the geologist; but with their epochs is connected their physiognomy or contour, a subject eminently interesting to the geographer. So persistent is the contour of mountains, whether associated with the older or more recent formations, that the practised eye of the geologist can generally determine at a glance the era of their upheaval. The bold, but bald and massive heights of a granitic mountain differ widely in aspect from the abrupt and splintery crags and pinnacles of the older stratified formations; while the rounded, undulating, and terraced outline of the secondary trap-hills distinguishes them at once from the conical crateriform heights of the

tertiary era. Nor is it in appearance alone that these distinctions are interesting; the cold barren subsoil of a granitic district, altogether independent of elevation, differs as widely in its vegetable exhibitions from those of a fertile and congenial trap, as a cultured garden does from a moorland wild.

Respecting the classification of mountains, various plans have been adopted by continental writers; but most of them are objectionable, as involving geological theories: we shall adhere to that simpler arrangement which takes into account merely their geographical position and connection. Those of Europe have been classified into a number of systems, some of which are continental, others insular. Laying aside minutiæ, the following seem to be distinct and natural: 1. The *Hesperian*, embracing the mountain-ridges of the Spanish peninsula—all of which maintain a wonderful parallelism in position, as well as unity of character, and whose extreme culminating point is Maladetta, in the Pyrenees, 11,168 feet. 2. The *Gallic* system, including all the hilly eminences in France which lie to the north of the Garonne, west of the Rhone, and south of the Rhine. None of these are of great age, or of great elevation, the highest being a peak of the Plomb de Cantal, in Auvergne, 6113 feet. 3. The *Alpine* system, embracing all those ridges and branches which radiate from the great Alpine range of Switzerland, such as the Maritime, Cottian, Pennine, Rhetian, Noric, and other Alps; the Apennines in Italy, and the Balkan or Hæmus group in Turkey. The highest or culminating point is Mont Blanc, in Switzerland, 15,732 feet. 4. The *Hercynio-Carpathian* system, including all the mountains and eminences comprehended between the Rhine, Dnieper, and Danube, the plains of Northern Germany and Western Poland. The highest point in this system is Lomnitz, in the Central Carpathians, upwards of 8000 feet. 5. The *Scandinavian*, a system of the highest antiquity, embracing the well-defined chains of Norway, Sweden, and Lapland, the extreme height of which does not much exceed 8000 feet. 6. The *Ural* system or chain, which forms the boundary-line between Europe and Asia, and rises in its highest part to between 5000 and 6000 feet. Lastly, the *Britannic* system, consisting of a number of detached chains, as the Grampians, Cheviots, and Welsh mountains, the highest point of which is Ben Nevis, in Inverness-shire, 4406 feet. All of these systems, as axes of elevation, have long ago become fixed and permanent; none of them has for the last two thousand years shewn symptoms of volcanic activity: Hecla, Vesuvius, and Etna, the only active volcanoes in Europe, seem to point to future upheavals.

The mountains of Asia may be all traced from that vast central plateau already adverted to, which forms, as it were, the nucleus of the continent. Omitting ranges of minor altitude, we may enumerate—the *Altaï*, an Alpine girdle (greatest height 12,790 feet), running along the 50th parallel of latitude from the 84° of longitude to Lake Baikal, and continued eastward in the Daurian system and Stannovoi mountains, which are supposed to stretch to Behring's Strait; the *Khin-gan* range, bounding the Desert of Gobi on the east, but of unknown altitude; the *Thian-shan* and *Kuen-lun*, two ranges beginning in the west of Chinese Tartary, and running eastward—the former about the parallel of 42°, the latter about 36°—into China; attaining in some summits a height of upwards of 20,000 feet, and remarkable as containing active volcanoes at a distance of 1500 miles from the sea; the great *Himalaya* mass, extending about 1500 miles in length, and from 100 to 160 across, rising from the Indian side by stages of 4000, 8000, and 11,000 feet to a mean elevation of 18,000 or 20,000 feet, attains in several peaks the height of about 25,000, in Dhawalagiri 26,826, in Kinchinjunga 28,156, and in Mount Everest 29,000—probably the greatest elevation on the globe; the *Hindu Kush*, with their southern ramifications, which may be regarded as prolongations of the Himalaya; and, lastly, the *Tauro-Caucasian* system, diversifying the west of Asia with numerous ridges and peaks, the highest of which are Elburz, 18,493 feet, and Demavend, 21,000. In connection with these systems and ridges are active volcanoes, as in Kamtchatka, Japan, the Thian-shan ranges, &c.

The mountain-systems of Africa are as yet only partially known. The hills of Cape Colony rise from Table Mount, 3582 feet, to the summits of the Nieuveldt and Snieuveldt mountains, in the north of the colony, which are estimated at 7000–10,000 feet; the spaces between the ranges being broad elevated terraces or *karoos*, connected by shrubby *kloofs* or valleys. Beginning with Cape Colony, one vast table-land, the greatest on the globe, occupies the south of the African continent, stretching on the east as far north as Nubia. The mountain-ranges seen running parallel with the east coast form the border of this table-land; the highest of them yet seen is Kilima-Njaro, between 3° and 4° south latitude, estimated at 20,000 feet. The Abyssinian mountains form a terminating cluster to the range, reaching in the Abba Jared, at the extremity of the table-land, the height of 15,000 feet. The Cameroons, on the west, are above 13,000 feet; some of the summits around the great equatorial lakes in the interior rise to 10,000, but none of them, apparently, into the region of snow. On the north, between the Sahara and the Mediterranean, the *Atlas* system is well defined, and here an elevation of 11,400 feet has been ascertained.

The mountains which traverse South America may be ranked under two systems—the *Cordillera of the Andes*, and the *Mountains of Brazil.* The former, in several parallel chains, extend along the western edge of the continent from the Strait of Magellan to the Caribbean Sea, in many places spreading out over a breadth of several hundred miles, embracing lofty table-lands, containing mountain lakes, and everywhere intersected by steep narrow ravines and passes. A remarkable feature of the Andes is that the parallel ranges frequently come together, forming lofty table-lands called *knots.* At Popayan, the main chain divides into three ridges, one of which, shooting off to the north-west, passes into the Isthmus of Panama; a second separates the valleys of the Cauca and Magdalena; and a third, passing off to the north-east, separates the valley of the Magdalena from the plains of the Meta. The most elevated portion of the system is the Bolivian Andes, from south lat. 21° to 14°, numerous summits of which rise to 13,000–22,000 feet. The highest peak of the

system is in Chili, where Aconcagua is 22,300 feet—perhaps the highest volcano in the world; Chimborazo, in the equatorial Andes, is 21,424. Altogether, the Andes present a most magnificent spectacle to the voyager on the Pacific; the snow which permanently covers their lofty summits, even under the burning sun of the equator, contrasting beautifully with the deep blue of the sky beyond; while occasionally another contrast is exhibited in vast volumes of smoke and fire, emitted from some of the numerous volcanoes which stud the entire range. The Brazilian mountains occupy a great breadth of country, but seldom exceed an elevation of 6000 feet.

The chief mountain-system of Central and North America may be considered as a continuation of the Andes of the south, the whole forming, as it were, the backbone of the New World, and extending from Cape Horn to the Arctic Ocean, a distance of nearly 10,000 miles. The Cordilleras of Central America, or Mexican Andes, as they are sometimes called, extend from the Isthmus of Panama to the north of Mexico. They spread themselves, for the most part, from sea to sea. At Panama, where the range is crossed by a railway, the elevation is under 300 feet; but it increases towards the north. The greater part of Mexico consists of magnificent table-lands from 5000 to 9000 feet high, girt and intersected by mountain-ranges, with peaks—several of them volcanic—rising above 17,000 feet. Within the United States and British America, the system is known by the general name of the Rocky Mountains. It consists of several parallel ranges running in the general direction of the Pacific coast, and between that coast and the head-waters of the streams that flow into the Mississippi, and extending over a tract 1000 miles broad from east to west. The eastern range or axis, which forms the main water-shed between the basin of the Mississippi and the Pacific, rises in Fremont's Peak to 13,570, and farther north, in Mount Brown, in British America, to 16,000. The western or Maritime range attains, in the Sierra Nevada of California, a height of 14,000; and in Mount St Elias, on the coast, in lat. 61°, a height of 17,800. The Alleghanies or Appalachians, on the east side of the continent, extend in parallel ranges, with valleys between, from Alabama to Main; the highest summit of the system is Mount Washington, in New Hampshire, 6634 feet.

In Oceania we have several minor groups and ranges; but the principal elevations are in detached volcanic heights, the index-fingers, as it were, to future mountain-systems. In Malaysia, the highest known point is Mount Ophir, in Sumatra, 13,850 feet. The east coast of Australia is bordered by a range of no great elevation; but a backbone runs through the islands of New Zealand, near the west coast, attaining a height in some peaks of 10,000 to 12,000 feet. The highest points in Polynesia are the active volcanoes of Mauna Kea and Mauna Loa, in Hawaii, each about 14,000 feet.

Such are the more prominent mountain-systems as known to geography. Those who regard them as mere ridges, rising on one side, and descending as abruptly on the other, and at most intersected by a few narrow passes, gorges, and ravines, form a very erroneous conception of the physical contour of the globe; for, so far from this being the case, most of these systems are but the escarpments or ramparts of elevated expanses known as *plateaux* or *table-lands*, which form in some instances the nucleus of continents, and the source from which the rivers of such continents flow. Thus, on examining the map of Asia, it will be seen that all the rivers flow—north, east, south, and west—from the central region, which in reality forms a succession of remarkable plateaux. These plateaux may be termed the Persian, which ranges from 3000 to 6000 feet above the sea; the Mongolian, at an elevation of from 8000 to 12,000 feet; and that of Tibet, which reaches 17,000. There are some masses of this kind in Europe, but of comparatively small extent—as the central part of Spain, which is about 2200 feet in height; and the Swiss table-land, between 3000 and 4000 feet. The elevation of the great South-African plateau seems to be highest towards the east side. In South America, the city of Potosi, in Bolivia, is situated in the elevated valley of Desaguadero, at 13,600 feet above the sea-level; and the plateau on which Quito stands has an elevation of 9000 feet. One of the most noted table-lands is that of Mexico, not less remarkable for its elevation than for its extent.

EARTHQUAKES AND VOLCANOES.

These are rather agents than effects—rather the cause of geographical diversity than geographical features themselves; and in this respect belong more properly to the province of geology: still, as much of the superficial irregularity is the direct result of their operations, and as it is often impossible to separate cause from effect, it will be necessary here to give them some further consideration.

Volcanoes affect the external features of the earth chiefly by the matter they eject from its interior. By the discharge of lava, loose stones, scoriæ, fine dust or volcanic ash, and other materials from these vents, multitudes of isolated conical mountains have been formed; valleys have been filled up by the lava-streams, and woods, villages, and cattle have been buried. The immense volumes of steam generally discharged during an eruption condense into rain, and mixing with the ashes, form torrents of mud, little less destructive than the rivers of lava. A mud avalanche from Vesuvius overwhelmed the ancient Roman cities of Pompeii and Herculaneum in 79 A.D. As an example of the enormous masses of material thus poured out from the interior of the earth, we may cite Etna in Sicily. It reaches a height of nearly 11,000 feet, with a circumference of about ninety miles, and is composed entirely of lava and ashes thrown out from many different points around the central cone. There are several hundreds of volcanoes now in activity, and there is evidence that they once existed in many places where they have long been extinct. In Auvergne, in the centre of France, there are lofty mountains of lava, and numerous cones of loose cinders rise into conspicuous hills, each with its crater, while congealed streams of lava can be traced down the plateau into the valleys. Yet all is cold and still, and has been so for unknown ages. Sheets of lava are still conspicuous in the British Islands; but they have

been so long exposed to the wasting of the elements, that no actual crater can now be traced. Volcanoes for the most part occur in lines, and not far from the sea; partly along the margins of the great continents, partly in chains of oceanic islands. The most remarkable example of the marginal arrangement is seen in the long chain of volcanic vents that studs the western border of America from Tierra del Fuego to Mexico. Of insular volcanoes the most numerous and energetic occur in the Indian Archipelago—Sumatra, Java, and the adjacent islands. Along the island of Java there runs a band of not less than forty-five volcanoes, most of which have been seen in eruption.

But the forces, whatever they are, that produce volcanoes and earthquakes do not always act in this violent paroxysmal way. They are constantly producing movements and changes on a vastly greater scale than anything resulting from earthquakes and volcanoes, but so gently and insensibly, that it is only by the results which they bring about in a long course of years that we can detect their operation. Without shaking or rending the earth, they succeed, in the end, in elevating vast tracts of land above the sea, or in depressing them beneath it. The *raised beaches* which form so marked a feature in the scenery of many parts of the coasts of the British Islands, are evident proof of such a gradual upheaval. The Scandinavian peninsula, except a part of its southern end, is even now slowly rising; in some districts, at the rate of two or three feet in a century. But the most marked elevation of a continuous kind is that which is taking place along the western coasts of South America. Evidences of the opposite movement—a gradual sinking of the land—are also abundant. The extreme south of Sweden is undergoing sensible depression; and submerged forests on several parts of the British coasts point to a like operation. The most striking proof, however, of subsidence of the earth's crust is furnished by the coral islands of the Indian and Pacific Oceans. The characteristic form of the coral island is a ring of white rock enclosing a lagoon of still water, the walls of the ring rising for the most part perpendicularly from immeasurable depths. Now the polypes that form these rocks can only live at a moderate depth, and it has been satisfactorily established that these ring-islands had their beginning in *fringing reefs* of coral such as are now seen off the shores of existing land. Let us suppose that one of these fringing reefs encircles some oceanic island, and that the sea-floor in that region is being slowly depressed. As the downward movement continues, the corals keep building up the reef to about the level of the waves. In this way the space of water between the island and the coral ring is greatly increased, while, of course, the area of the island itself is correspondingly lessened. The downward movement continues—the island grows less and less, until its last mountain-top sinks beneath the sea. Over the submerged island there now stretches a smooth sheet of green water known as a *lagoon*. Encircling it is the circular reef of coral, or *atoll*, along the outer margin of which the restless waves of the ocean are ever surging. Soil gradually forms on the reef, seeds borne to it by the waves or carried by birds take root, and the ring of coral reef becomes a habitable spot for man. Such is the history of the growth of the coral islands. They have been built round the summits of a sinking continent, over whose mountains and valleys the great ocean now rolls.

What may be the nature of the force which produces these upheavals and subsidences, those quakings and eruptions, how it originated and how it is kept up, are questions to which, as yet, no very definite answer can be given. It is clear, indeed, that heat plays a large part in producing these changes. The temperature of the earth is found always to increase as we descend into the crust; and if the rate of increase which has been observed were to continue without any modification, we should reach the melting-point of even the most refractory substances at the depth of a few miles. But, for reasons already given, the old notion that there is still a central liquid part in an incandescent state, with a thin crust over it liable to be shaken and broken through by the commotions of the fluid interior, cannot now be held.

That the interior of the earth, however, whatever be its composition, is intensely hot, is indicated by all the evidence we can gather on the subject. Some portions must be liquid, as is shewn by the discharge of fluid lava at a white heat from volcanic vents. There seems, indeed, to be good reason to believe that though the main mass of the interior may now be solid, there nevertheless exist within it large lakes or reservoirs of melted rock, and that volcanoes serve as the orifices of communication between these areas and the surface. When the water which is everywhere traversing the upper layers of the crust reaches these heated spaces, it is converted into steam, which exerts an enormous expansive force. The abundance with which steam is given off during volcanic eruptions has long been familiar, and serves to indicate that steam may be the agent more immediately employed in forcing melted lava to the surface. During the changes which are in progress underneath, a mass of water will sometimes be suddenly precipitated into an area of intensely heated rock, and its instant expansion will produce a sensible concussion or earthquake above ground.

The constant transference of materials from the interior to the surface, whether by the action of volcanoes or by that of springs, must necessarily produce cavities within the crust. When, for example, we contemplate such a mountain as Etna, and reflect that all its vast piles of lava, scoriæ, and ashes have been abstracted from the interior of the earth, we see how real and important is this transference of material, and how easy it is to conceive of the formation of large hollow spaces beneath the surface. Again, the amount of solid material removed by springs, though it does not stand up before us as an enduring monument like Etna, is probably in reality greater in any one year over the whole globe, than all the lava and ashes which have been erupted by volcanic action during the same period. By some springs, such as those of a thermal kind, the quantity of these materials carried off in a single year would, if collected and rendered visible, make huge mounds or even small hills. Alike, therefore, by the action of volcanoes and the subterranean circulation of water, cavities must be

produced within the interior of the earth. As these become enlarged, their roofs, from failure of support, will sometimes give way with a sudden collapse. Such is not impossibly the origin of many earthquake shocks. When we know that even on the surface the explosion of a powder-magazine sometimes gives rise to a tremor of the ground, which is felt at a distance of several miles, we may conceive how the collapse of one of these underground cavities, and the consequent rushing together of thousands of tons of rock, may send a pulsation for many miles through the elastic crust of the earth.

The slow rising of some parts of the surface is accounted for by supposing that among the internal movements of the earth a great mass of rock may gradually have its temperature raised, and thus be expanded so as to push up the crust lying above it. In like manner, if the rock cools down, a slow depression of the overlying region will be the result. But without supposing an actual increase of temperature in any part, both upheaval and subsidence may be accounted for by the gradual cooling of the earth as a whole. As the nucleus shrinks in dimensions, the outer coat becomes too large for it, as it were, and has to accommodate itself by going into frumples, bending inwards in one part, and outwards in another. The inequalities on the surface of the globe have thus a similar origin to those on a shrivelled apple; or, to vary the figure, continents and sea-beds, mountains and valleys, are the wrinkles that mark the aging of mother earth.

PLAINS, VALLEYS, AND OTHER DEPRESSIONS.

The plains, or level portions of the earth's surface, form a feature in its physical aspect equally important with that presented by its mountain-systems. The name is given to extensive tracts whose surface in the main is level, or but slightly broken by elevations and depressions. They are found at all elevations above the sea, and of every degree of fertility; from the exuberant tropical delta just emerging from the water, to the irreclaimable sterility of the desert of ever-shifting sand.

The noblest of these expanses are the river-plains of the New World, drained by such waters as the Mississippi, the Amazon, and La Plata. Much of the Mississippi plain is rolling or undulating in its surface, well watered by minor rivers, exhibiting broad grassy *prairies* and extensive pine-forests. In South America we have first the low belt of country skirting the shores of the Pacific, from 50 to 100 miles in width, and about 4000 in length, fertile at its extremities, but in the middle sandy and arid; next, the basin of the Orinoco, consisting of extensive plains called *llanos*, either destitute of wood, or merely dotted with trees, but covered during part of the year with tall herbage; then the basin of the Amazon, a vast plain, embracing a surface of nearly 2,000,000 square miles, possessing a rich soil and humid climate, and almost entirely covered with dense forests and impenetrable jungle-marshes by the river-sides; and, lastly, the great Valley of the Plata, occupied chiefly by open plains called *pampas*, in some parts saline and barren, but in general clothed with weeds, thistles, and tall grasses. Next, in order of importance, is that section of Europe extending from the German Sea, through North Germany and Russia, towards the Ural Mountains, presenting indifferently tracts of heath, sand, and open pasture, and regarded by geographers as one vast plain. So flat is the general profile of this region, that it has been remarked, 'it is possible to draw a line from London to Moscow, which would not perceptibly vary from a dead level!' Passing the Ural ridge, a plain of still greater dimensions stretches onward through Siberia, towards the shores of the Pacific. This region is of no great elevation, and, though diversified by occasional heights, consists chiefly of gravelly steppes, covered with coarse herbage, lakes, and morasses. In Africa, the northern and central portion, so far as explored, appears to be a vast expanse of Sahara, or sandy desert, broken at scanty intervals by oases of life and verdure.

Certain minor tracts in these wide expanses receive distinctive designations. These are the verdant *prairies* of North America, already noticed, the *pampas* and *llanos* of South America, the *steppes* of Asia and Northern Europe, the *tundras* or bog-marshes of Siberia, the grassy *karoos* of Southern Africa, the tangled *jungles* of India, the alluvial *straths* or *dales* of our island, and the low muddy, but gradually increasing *deltas* of such rivers as the Ganges, Nile, Niger, and Mississippi. To lesser flats and depressions—as valleys, glens, ravines, &c.—which give character to the landscape of particular districts, our space will not permit us to refer.

THE OCEAN.

The ocean, though in fact a single mass of fluid resting in the hollows of the solid crust, surrounding the dry land on all sides, and indenting it with numerous bays and gulfs, is generally divided by geographers into the following great basins: The *Pacific* Ocean, 11,000 miles in length from east to west, and 8000 in breadth, covering an area of 50,000,000 square miles; the *Atlantic*, 8600 miles in length from north to south, and from 1800 to 5400 in breadth, covering about 25,000,000 square miles; the *Indian* Ocean, lying between 40° south, and 25° north latitude, is about 4500 miles in length, and as many in breadth, covering a surface of 17,000,000 square miles; the *Antarctic* Ocean, lying round the south pole, and joining the Indian Ocean in the latitude of 40° south, and the Pacific in 50°, embraces an area—inclusive of whatever land it may contain—of 30,000,000 square miles; and the *Arctic* Ocean, which surrounds the north pole, and lies to the north of Asia and America, having a circuit of about 8400 miles. Besides these great basins, there are other *seas* of considerable extent, as the Mediterranean, covering an area of 1,000,000 square miles; the German Ocean, 153,700; the Baltic, 134,900; the Black Sea, with its subordinate gulfs and branches, 181,000; but these and other minor sections will be more appropriately described when we come to treat of the respective countries (Volume II.) with which they are politically as well as physically associated.

Respecting the depth of the ocean, our knowledge has recently become much more definite and certain, owing to improvements in deep-sea sounding. The floor of the North Atlantic, in particular, is nearly as well known as the most of

terra firma. Proceeding west from Ireland, the bottom descends in a succession of steps or terraces, sometimes of immense extent. The descent from one plateau to another is sometimes by steep cliffs 9000 feet deep. The greatest depth is some distance south of the great bank of Newfoundland, where there is a basin-shaped depression 1000 miles in length, with soundings of about 30,000 feet, or above five miles and a half. The bottom of the Pacific is less known: soundings of 40,000 feet have been obtained.

The temperature of the sea, where it is not affected by currents from a warmer or colder region, necessarily corresponds to that of the air above it; but this is true only of the water at and near the surface. In the Mediterranean, for example, the surface temperature ranges from 80° in summer to 54° or 55° in winter. But this excess of summer heating does not extend beyond a depth of 100 fathoms: below this, the temperature of 54° or 55° is maintained constantly at all depths; and this temperature is that of the crust of the earth in that region. In the Atlantic, in the same latitude, the temperature of the upper stratum of 100 fathoms does not essentially differ from that in the Mediterranean; but at greater depths, the temperature sinks to 49°, 40°, 38°, 36°, and in some places to the freezing-point of fresh water, and even below it (29·6°). Recent observations tend to shew that an almost glacial coldness prevails over the whole deep-sea bed in both hemispheres, extending even to the tropics. The cause of this phenomenon will be explained when we come to speak of the currents of the ocean.

The sea consists of salt water, as already adverted to, and from its continual motion, under the influence of currents and waves, preserves, generally speaking, uniform saltness. Under special circumstances, however, we find the saltness increased, as by the excess of evaporation over the fresh-water influx in the Mediterranean and Red Seas, and about the northern and southern limits of the tropical belt; and decreased, by the contrary cause, in the Sea of Azof, Black Sea, Baltic Sea, and in the polar regions. The origin of the saltness of the sea is sufficiently accounted for when we consider that the chloride of sodium and other soluble salts which form constituent ingredients of the globe, are being constantly washed out of the soil and rocks by rain and springs, and carried down by the rivers; and as the evaporation which feeds the rivers carries none of the dissolved matter back to the land, the tendency is to accumulate in the sea. The principal ingredients found in sea-water are chloride of sodium, or common salt, together with salts of magnesia and lime. The mean quantity of salts of all kinds in the ocean is 34·4 parts in 1000. In some parts of the Mediterranean the salinity is as high as 39·26, and of the Red Sea 43; while in the Baltic and Black Seas, it varies from 18 to 12. Of the mean of 34·4 parts, about 24 are due to chloride of sodium, 4 to chloride of magnesium, nearly as much to sulphate of soda, one part to carbonate of lime, and ·25 or one part in 4000 to silica. Upwards of thirty different elementary substances have been already detected in sea-water, and spectrum analysis may yet reveal more; but, except those named above, they exist mostly in exceedingly minute proportions, so that it is only in the analysis of sea-weeds, marine animals, and the stony matters deposited in marine boilers, that their presence can be detected. But when we consider the vastness of the ocean, the absolute quantity of even the minutest ingredient must be enormous. The silver dissolved in the sea would far transcend 'the wealth of Ind.'

The specific gravity of the water of the ocean varies, of course, with the salinity; the average is 1·0272. Another effect of the salinity is that, while fresh water freezes at 32° F., the water of the ocean requires to be reduced to 28°; and the ice then formed is porous and full of a briny fluid —the solid ice in fact is fresh.

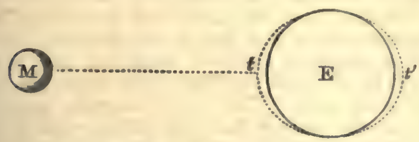
The *colour* and *phosphorescence* of the ocean are the next sensible properties requiring attention. When examined in small quantities, sea-water is colourless; but when viewed in the mass in the wide ocean, it appears to be of an azure or blue tint. The cause of this generally blue colour has not been as yet clearly explained; it would seem that the blue rays of light are more readily reflected from masses of a transparent fluid. While there can be no doubt that the ocean is generally of a blue colour, it is equally certain that there are many portions of sea in which a different hue appears. The causes of these exceptions from the rule seem to be of various kinds. Frequently the ordinary colour of the sea is affected by the admixture of foreign substances, these being sometimes of a living and organic nature, and sometimes not. Another class of cases in which the ocean appears to be tinged with a peculiar colour, is referable to the reflection of rays of light from the bed or bottom; and hence, in shallow and clear seas, the colour of the ground is a main cause of any particular tint which the water may there assume.

The phosphorescence of the ocean, described in such glowing terms by almost every voyager in tropical seas, is now satisfactorily ascertained to arise sometimes from the presence of infusorial animalcules, and at others from the decomposition of vegetable and animal matter. Similar phenomena, arising from similar causes, exist on land—the glowworm, fire-fly, certain fungi, putrid fish, &c.—and their appearance in the one element need not excite greater surprise than their exhibition in the other.

TIDES—CURRENTS—WAVES.

The waters of the ocean are subject to various motions and fluctuations, such as tides, currents, whirlpools, waves. That regular ebb and flow known by the name of *tides*, and which confers on the ocean one of its most interesting features, is caused by the attraction of the sun and moon. By the universal law of gravitation, all masses of matter have a tendency to be attracted or drawn towards each other. The moon, therefore, as a mass of matter, in passing round the earth, has a tendency to draw the earth after it, or out of its natural relative position; and it really does so to a small extent. As it passes round, it draws up the waters in a protuberance, or, in common language, draws a huge wave after it. But it also draws the whole solid globe—though to a less extent than the water immediately under it—and so causes the opposite side of the globe to be drawn away from the ocean, leaving the waters

there to form a similar protuberance or high wave. In the one case, the water is drawn directly up or towards the moon (M); in the other, the water is



in some shape left behind by the land being pulled away from it. In both a similar effect is produced: two tides (t, t') are caused at opposite extremities of the earth. Where the higher part of either of these great billows strikes our coasts, we have the phenomenon of high-water; and when the lower touches us, it is low-water. Each of the waves is brought over any given place in the circumference of the earth in twenty-four hours, so as to cause high-water twice a day. The sun exerts a far greater attractive influence on the earth than the moon does; but from the great distance of that luminary, the *difference* of that attractive force on different parts of the globe is much less, and therefore the effect in raising tides is comparatively small. But when this minor influence of the sun coincides with that of the moon, or acts in the same line of attraction (Mt), we perceive a marked increase in the tides; on such occasions we have what are called *spring* or *large* tides. When the solar and lunar attractions act in opposition, we have *neap* or *small* tides. The spring-tides happen twice a month, when the moon is at full and change; and the neap when the moon is in the middle of its orbit between those two points. A tide requires six hours to rise—which it does by small impulses or ripplings of the water on the shore—and six hours to ebb or fall; but every successive high-water is from twenty to twenty-seven minutes later than the preceding, or, on an average, about fifty minutes for two tides, in consequence of the earth requiring that time above the twenty-four hours to bring any given point again beneath the moon. The tides are thus retarded by the same reason that makes the moon rise fifty minutes later every day. It is evident that the tides will be greatest at that point of the earth's surface which is nearest to the moon, or where the latter is vertical. She is so between the tropics; and accordingly the tides are there greatest, and they diminish as we approach either pole. It is further to be remarked that the moon does not anywhere draw up the tides immediately. In consequence of the law of inertia and of fluid friction, the tidal wave lags behind the moon. Moreover, in consequence of all the great seas and oceans forming, as we have seen, only one sheet of water variously distributed, the ebb and flow in each depend not on its own proper tide, but are the result of the combination of that tide with currents mingling with it from tides of other seas—a result depending upon inequalities of sea-bottom, the configuration of its coasts, their inclination under water, the size and direction of the channel which connects it with other seas, and occasionally upon winds and currents which are not tidal. So much do these circumstances affect the astronomical or *primary* tidal wave, that while it rises in the expanse of the Pacific to one or two feet only, the *derived* wave often rises in confined or obstructed seas to elevations of thirty, fifty, or even a hundred feet! Inland expanses of water, like the Baltic, Mediterranean, and Caspian Seas, and the lakes of North America, have no perceptible tides.

Besides being affected by the regular motion of the tides, the ocean is pervaded by a system of *currents*, mostly constant, which has been compared to the circulation of the blood. These currents play a most important part in modifying the climates of different regions. As respects the causes of oceanic currents, much remains to be cleared up; but some of the leading causes seem well established. The two prime movers are differences of temperature and prevalent winds. Sea-water does not freeze until it is cooled down to about 28°; and, unlike fresh water, it continues to grow heavier down to that point. The effect of the intense cold of the polar regions is thus to cause a constant sinking down of the surface, and to establish a current of ice-cold water along the bottom towards the equator; while, to supply the place of what sinks down, an in-draught or northward flow takes place on the surface, which brings the warm water of the temperate and tropical regions towards the poles. This is the general theory of the *vertical* circulation of the ocean—a circulation which might almost be assumed from the well-known laws of the flow of liquids, and which recent observations have established as a fact. The general prevalence of cold currents along the bed of the ocean from the poles to the equator is now beyond dispute. Motion once thus begun, however, is differently modified in each locality by the shape of the coasts, by prevalent winds, and other circumstances. But one cause which modifies all currents that tend either north or south, is the daily rotation of the earth. At the equator, any spot on the surface is moving eastward at the rate of 1000 miles an hour; at 60° north latitude, the velocity is only one half. Thus, the water of a current starting from the equator northward, is constantly coming to places where the bottom under it has less and less eastward velocity. But, by the law of inertia, the water tends to retain the same velocity eastward with which it started, and thus it moves to the east of north—shooting ahead, as it were, of the bottom over which it is flowing, as a rider does whose horse slackens his pace. The contrary happens to a stream flowing from north to south. In this case, the eastward motion or motal inertia of the water is too slow for the parts of the bottom to which it successively comes; the bottom slips in a manner from under it, and it falls to west of south. This, in combination with the action of opposing coasts, accounts for the circular sweep which many of the currents make, returning partly into themselves.

Different in origin from this vertical circulation, though partly mixed up with it, is the *horizontal* circulation caused by prevalent winds. The best example of this is the Equatorial Current, which sets from the west coast of Africa to the east coast of Brazil, and which is owing to the action of the trade-winds. Currents caused by winds are always shallow, and their rate of motion seldom exceeds half a mile an hour: they are called 'drift-currents,' in opposition to the deeper-seated 'stream-currents.' In order to feed this westerly equatorial current, there spring up two *in-draught* currents—the one from the north along the west coast of Portugal and Morocco,

the other from the Cape of Good Hope along the west coast of Africa as far as the Gulf of Guinea. When the equatorial current reaches the coast of Brazil, it divides into two branches. One proceeds southwards, turning gradually eastwards across the Atlantic until it falls in with the northern in-draught from the Cape of Good Hope. The other branch is deflected northwards into the Caribbean Sea and the Gulf of Mexico. The water thus driven into this pent-up sea now rushes with accumulated momentum through the strait or gulf between Florida and the Bahamas, and forms the famous Gulf Stream.

The Gulf Stream, after issuing from the Florida Strait, proceeds at first northward, parallel to the American coast; but between the parallels of 35° and 37°, it turns gradually eastward, passing over the southern extremity of the Bank of Newfoundland, and all the while expanding in breadth and becoming shallower. The temperature of the stream, when it starts, is from 83° in summer to 77° in winter, and even after travelling 3000 miles to the north, as high as the Banks, there is a difference in a winter day between its water and that of the surrounding ocean of 20° to 30°. Along its whole course a cold arctic current underlies it; and this arctic current intervenes between the western border of the stream and the coasts of Florida, Georgia, and the Carolinas, the line of demarcation between the two being so abrupt that it is known as the 'cold wall.' At the bow of a ship entering the Gulf Stream the temperature has been found to be 70°, while it was only 40° at the stern. The velocity of the stream, at its outset, is from 50 to 60 miles a day; but this velocity becomes greatly reduced as it proceeds.

It has usually been held that the Gulf Stream extends across the Atlantic to the shores of Northern Europe, and is the cause of the mild and moist climate enjoyed by the western parts of that continent. The opinion, however, is beginning to prevail that, as a distinct current, the Gulf Stream ceases in the middle of the North Atlantic, its waters being by this time thinned out to a mere film, and its initial velocity and distinctive heat having been dissipated. That warm waters from tropical seas are brought to the coasts of Britain, and even into the polar seas beyond, is proved by drift-wood, seeds, and fruits from the West Indies being frequently cast ashore on the Hebrides, the north of Norway, and Spitzbergen. But this is accounted for by the general flow of the surface-water towards the poles, forming part of the vertical oceanic circulation; a flow which receives an eastward deflection as it proceeds northwards in the way above explained. This general set of the surface-water is further promoted by the prevalence of south-westerly winds or return-trades, which maintain a pretty constant north-east *drift* over the whole surface of the north-eastern portion of the Atlantic. In this way, although the Gulf Stream may have lost its original impetus, a large portion of the superheated water which it brings into the centre of the Atlantic, must be carried to the shores of Europe and into the Arctic Sea. Before, however, the Gulf Stream loses its force as a distinct current, it sends off a branch southwards by the Azores which re-enters the equatorial current before described.

While the climate of the west of Europe is thus ameliorated by having its shores washed by waters from warm seas, and by the moist and warm south-westerly winds that predominate, the corresponding coast of America is, at least, as much depressed by a current from the Greenland seas which flows southward along the shores of Labrador, carrying with it immense fields of polar ice, and accompanied by dry and piercing winds from the north and north-west. This arctic current intervenes between the coast of America and the Gulf Stream, as already mentioned, and flows under it into the Gulf of Mexico.

The currents of the Pacific Ocean are little known; but the Indian Ocean, exposed to a tropical sun and hemmed in on the north, sends out several large currents of warm water. One is the Mozambique current; another escapes through the Strait of Malacca, and flows past China and Japan into the Pacific, making for the north-west coast of America. This current resembles in many respects the Gulf Stream.

Two currents of equal force, but of different directions, meeting in a narrow passage or gut, will cause a *whirlpool*, a phenomenon which has ignorantly been said to be produced by subterranean rivers, gulfs, chasms, &c., but essentially is only an eddy. Charybdis, in the Strait of Sicily, and the Maëlstrom, on the coast of Norway, are eddies of this kind, alternately absorbing and casting up again whatever approaches them.

Being an elastic and mobile fluid, water is readily acted upon by winds; and thus *waves* are produced, varying in height and velocity according to the force and continuity of the wind, extent of uninterrupted surface, depth of the ocean, contending currents, and the like. The common cause of waves is the friction of the wind upon the surface of the water. Little ridges or elevations first appear, which, by continuance of the force, gradually increase until they become the rolling mountains seen where the winds sweep over a great extent of water. The velocity of waves is in proportion to the square root of their length. The large waves just spoken of proceed at the rate of from thirty to forty miles an hour. It is a vulgar belief that the water itself advances with the speed of the wave; but in fact the *form* only advances, while the *substance*, except a little spray above, remains rising and falling almost in the same place with the regularity of a pendulum. A wave of water, in this respect, is imitated by the wave running along a stretched rope when one end is shaken. But when a wave reaches a shallow bank or beach, the water becomes really progressive; for then, as it cannot sink directly downward, it falls over and forward, seeking the level. Sailors and others speak of waves running 'mountains high;' but, according to Scoresby, 43 feet is about the utmost difference of level between crest and trough in ocean-waves.

LAKES AND RIVERS.

Lakes are inland bodies of water not connected with the ocean or any of its branches: they are generally fresh, but are occasionally brackish, or even decidedly salt. They are classified according as they are fresh or saline, and according to the manner in which they receive and discharge their waters—namely, those that both receive and discharge running water; those that receive waters,

but have no visible outlet, as the Caspian Sea; those which receive no running water (being fed by springs), but have an outlet; and such as neither receive nor discharge running water. Lakes are distributed over the globe according to the inequalities of surface; and all tend to annihilation, partly by silting up their basins, and partly by deepening their outlets, thereby effecting an entire drainage of their waters. The most gigantic are those of North America—such as Superior, Huron, Michigan, Erie, and Ontario, which respectively occupy 32,000, 20,000, 16,000, 10,000, and 7200 square miles. Next in order are the lakes of Africa, three of which—Victoria Nyanza, Albert Nyanza, and Tanganyika—are estimated at 29,900, 25,400, and 10,400 respectively. The largest lakes in Asia are Aral and Baikal; the surface of the former is estimated at 23,000, and the latter at 15,000 square miles. Europe can boast of a vast number, which, though generally small, give beauty and diversity to her landscapes. Those of Ladoga and Onega, in Russia, are the largest; the former having a surface of 6330, and the latter of 3280 square miles. A comparative estimate of the extent of these vast sheets may be formed when we mention that the area of Lake Geneva does not exceed 340 square miles.

Lakes subserve important purposes in the economy of nature. They serve as reservoirs for the waters which rivers would too speedily carry away from the land; they are the tanks, as it were, in which the impurities of streams subside; they refresh and enliven the landscape; and as they all tend to silt up their own sites, these sites become in time tracts of fertile alluvium, and such has been the origin of some of our finest plains.

Rivers, streams, springs—whether flowing with a volume several miles in breadth, or trickling in a tiny rill which a child's hand might obstruct—constitute a class of the most valuable agencies in the physical history of our globe. They are the irrigators of its surface, adding alike to the beauty of the landscape and the fertility of the soil; they carry off impurities and every sort of waste débris, to be deposited in the ocean as the strata of future continents; and when of sufficient volume, they form the most available of all channels of communication with the interior of continents. Rivers originate in the rain and snow which descend from the sky (see METEOROLOGY). Falling on the surface, the water percolates the soil, finds its way through the rents, fissures, and pores of the rocky strata, and ultimately escapes at some lower level in the form of *springs*. Some of these springs are perennial, others temporary or intermittent: some are limpid, and almost absolutely pure; others are impregnated with metallic, earthy, and saline ingredients, according to the nature of the strata through which they have percolated: some are cold, others tepid; while many issue, with bubbling and steam, near the ordinary boiling-point of water. Springs, naturally tending to lower levels, unite and form *streams;* and these, again, falling still lower, conjoin in valleys, and form *rivers*—creating in their course rapids, cataracts, and waterfalls, ravines and dells, lakes, swamps, and marshes, alluvial plains, and low terminating deltas. The valley in which a river flows is usually termed its *basin;* and its *drainage* is that portion of country drained by its streams or tributaries; the terms are often used synonymously. To compare merely the lengths of rivers is far from conveying a correct idea either of their physical or economical importance; the extent of their basins is an equally important item. The following is a comparative view of the length and drainage of some of the principal rivers on the globe, headed by the Thames as a standard of comparison.

PRINCIPAL RIVERS.	Length in Miles.	Drainage in Square Miles.
EUROPE—		
Thames	250	600
Vistula	530	75,000
Loire	530	45,250
Rhine	800	86,000
Elbe	600	58,800
Don	900	224,000
Dnieper	1000	226,000
Danube	1750	250,000
Volga	2320	500,000
ASIA—		
Euphrates	1800	260,000
Indus	1800	250,000
Ganges	1500	300,000
Yang-tze-kiang	3600	700,000
Amoor	2700	780,000
Obi	2000	1,350,000
AFRICA—		
Nile	5000(?)	(?)
AMERICA—		
St Lawrence	2000	297,000
Mississippi—Missouri	4400	1,244,000
La Plata	2000	1,250,000
Amazon	4000	2,000,000

CLIMATOLOGY.

The climatology of the globe relates to the degree of heat and cold to which its respective countries are subject, the dryness and moisture of the air, and its salubrity or insalubrity as influenced by these and other causes. As yet the minutiæ of climate are but imperfectly determined; the following general causes, however, have been sufficiently ascertained: 1. The action of the sun upon the soil and atmosphere; 2. The internal heat of the globe; 3. The height of the place above the sea; 4. The general exposure of the region; 5. The direction of its mountains relatively to the cardinal points; 6. The neighbourhood of the sea, and its relative position; 7. The geological character of the soil; 8. The degree of cultivation which it has received; and 9. The prevalent winds. These causes, acting together or separately, determine the character of a climate as moist and warm, moist and cold, dry and warm, dry and cold, &c.; and this climatic character is the main influence which determines the nature and amount of vegetable and animal development. The several subjects belonging to this section are treated in detail in the number on METEOROLOGY.

DISTRIBUTION OF PLANTS AND ANIMALS.

The *life* of the globe—that is, its vegetable and animal productions—constitutes its most important and exalted feature as a creation. All the

varied materials of which it is composed, all the complicated actions, reactions, and mutations to which they are subject, are humble phenomena compared with the production of the lowliest organism. This life is everywhere: the waters teem with it, the dry land from pole to pole is clad with it; nay, there is life within life, and perhaps there exists not a single plant or animal but becomes in turn an abode for others of more diminutive dimensions. Speculations as to the origin and generic classification of vegetable and animal life belong not to our subject. Geography views them simply as they exist, and endeavours to determine the laws which regulate their distribution.

Vegetables are regulated in their terrestrial distribution by conditions of soil, heat, moisture, light, height of situation, and various other causes; *in the waters*, by depth, heat, light, nature of bottom, and the presence of mineral and saline ingredients. Were it not for these causes, there is no reason why the tribes and genera of one region should not be identical with those of another—why the palms of India should not flourish alongside the oaks of England, the oaks of England with the pines of Norway, or these again with the dwarf birches of the arctic regions. As it is, the tropics have genera unknown to the temperate zone, and every advance poleward brings us in contact with new and peculiar species. Temperature in this case seems to be the grand regulating condition; and as this is effected by elevation, as well as by increase of latitude, we find the mountain-ranges near the equator presenting all the features of a tropical, temperate, and even arctic vegetation. Thus palms and plantains may luxuriate at their bases; then appear oranges and limes; next succeed fields of maize and wheat; and still higher, commences the series of plants peculiar to temperate regions. In temperate latitudes, though the variety of vegetation be less, similar phenomena present themselves. Besides these great climatic effects, there are others depending on soil, moisture, light, &c., which, though limited, are not less imperative. Thus, the southern slope of a hill is generally clothed with species distinct from those on the north; a limestone district presents a carpet of vegetation widely different from that of the clayey moorland: some tribes flourish in the moist valley, which would die on the open plain; some tribes thrive in the marsh, others on the dry upland; some luxuriate under the influence of the sea-spray, which would be instant destruction to others. But whilst most species are subject to these laws, there exists in the constitution of many a certain degree of elasticity which admits of their adaptation to a wider range—a beneficent arrangement, which permits man to extend through cultivation those grains and fruits upon which his subsistence so essentially depends. (For further and more minute information respecting the laws which regulate the dispersion and distribution of plants, see VEGETABLE PHYSIOLOGY.)

The animals which people the globe are subjected to somewhat similar laws of distribution. Some are strictly tropical, others confined to the temperate zone; while not a few are destined to find their subsistence wholly within the polar circles. Besides this general distribution, we find a more particular restriction to certain continents and tracts where peculiarities of soil, climate, and food seem to be the governing conditions. Thus, the elephant roams only in India, Burmah, and Africa; the ostrich in Africa; the rhea in the pampas of South America; the kangaroo in Australia; the reindeer within the arctic circle; the polar bear amid the snows of Greenland and Labrador; and so on, as will be more minutely shewn under ZOOLOGY. Similar laws are impressed on the life of the ocean. The 'right' whale, as it is termed, of the northern hemisphere, is a different animal from that of the southern; for 'the tropical regions of the ocean are to him as a sea of fire, through which he cannot pass, and into which he never enters;' while the sperm whale delights in warm water. The herring finds its chosen habitat in the Northern Sea; the oyster clings to a peculiar bottom, at a certain depth; the cod inhabits the same banks and shoals for ages; and a few fathoms of greater or less depth would be more fatal to many species of shell-fish than the dredge of the fisherman. As on plants, so on animals, altitude exerts a very decided influence; and we do not exaggerate when we affirm that a lofty mountain-range presents a more impassable barrier to vital distribution than the widest expanse of ocean. Though presenting a close analogy in the manner of their distribution, plants and animals differ in this respect, that many tribes of the latter—birds, fishes, and mammalia—make periodical migrations of vast extent; food and proper breeding-places being the objects of their search. These migrations must not be confounded with that adaptability of constitution which fits the horse, the dog, the ox, the sheep, the pig, and other domestic animals, to be the companions and supports of man in his onward possession of the globe. The one is but a change of place in search of food, under a congenial temperature; the other amounts to a constitutional change, irrespective of climatic influence.

Man, of all animals, has the widest geographical distribution. This he enjoys not only from the greater adaptability of his constitution, but from that superior intelligence which enables him to counteract the effects of climate by clothing, houses, fire, and the storing of provisions. It may be justly affirmed, therefore, that there is no region where man may not exist and carry on the purposes of life in a higher or lower degree of civilisation. Though generally regarded as a single species of a single genus, naturalists have divided mankind into several varieties, according to their more prominent physical features; and ethnologists, extending the subject according to minor features, language, and so forth, have subdivided these varieties into branches, tribes, and families. See ETHNOLOGY.

VEGETABLE PHYSIOLOGY.

THE science which embraces the study and investigation of the vegetable kingdom, is known by the name of BOTANY, from the Greek word *botané*, meaning an herb or grass. That department of the subject which explains the organisation and vital functions of plants, is called *Vegetable Physiology;* and that which recognises their arrangement into orders, tribes, genera, and species, according to their respective forms and qualities, *Systematic Botany.* The one relates to functions which are common to all vegetables, the other takes notice only of those structural peculiarities which serve to distinguish one species from another, and to enable the botanist to form these into natural and artificial groups. It is to the former of these departments that we now direct attention.

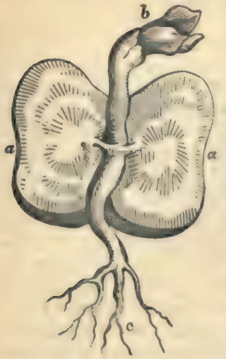
GENERAL ECONOMY OF VEGETATION.

Nature and Functions of Plants.—The simplest forms of life are observable in certain plants and animals, whose economy is limited to the absorption and assimilation of nutriment, and the power of reproduction; and the difference between these inferior forms is so trifling, that in them the animal and vegetable kingdoms seem to pass into each other. The absolute differences between plants and animals are indeed difficult to define, when they are to be applied to all plants and to all animals. In many cases, form and structure afford no decisive characters whereby we may separate the two kingdoms from each other; while phenomena usually regarded as pertaining to the animal kingdom are prevalent in the lower forms of plants, and indicate that no reliance can be placed upon their mode of life. In like manner, the chemical distinctions upon which much dependence has hitherto been placed, give way before increased knowledge; for cellulose and starch, long considered as peculiarly vegetable products, are now known to occur in animal structures. The locomotive power of many of the lower algæ is greater than that of many animal organisms; and even the spores, or seeds, of some algæ of more complex organisation, move about when freed from their parent, with an activity which appears truly animal, by means of the cilia with which they are provided. When the spore finds a suitable resting-place, its movements cease; and having thus exchanged its animal-like mode of life for one of a less erratic character, it becomes developed into a beautiful alga in all respects resembling its parent. The two classes, plants and animals, seem, as it were, to start from a common point at the base, the inferior forms bearing a certain similarity in structure and functions, which gradually disappears as we ascend in the scale of development.

Plants derive their food partly from the soil and partly from the air; and whatever they take must either be reduced to a liquid or to a gaseous state. The ultimate elements of which plants are composed are—carbon, oxygen, hydrogen, and nitrogen. Of these, carbon, which is a solid substance, is the principal; and as it is insoluble in water, it must be combined with oxygen, so as to form *carbonic acid gas*, before it can be taken up by plants. Oxygen is the next in abundance, and it is absorbed principally when combined with nitrogen, in the form of atmospheric air. Hydrogen is not found in a free state in the atmosphere, and therefore it can only be taken up by plants when combined with oxygen, in the form of water, or with nitrogen, as ammonia, in which last form it exists in animal manure. Nitrogen, though found in very small quantities in plants, is an important element, as it constitutes the principal ingredient in the *gluten*, which is the most nutritive part of corn and other seeds, and which is essential to the germination and nourishment of young seedling plants. Nitrogen also appears to be a principal agent in the production of colour in leaves and flowers, especially when they first expand. As oxygen is imbibed by plants in combination with all the other elements of which they are composed, it is not surprising that the plant takes up more of this gas than it requires; and, consequently, it has been furnished with a remarkable apparatus in the leaves, to enable it to decompose the carbonic acid and other gases which it has absorbed, and to part with the superfluous oxygen. Plants are thus found to improve the air by the removal of carbonic acid, which is injurious to animal life, and by the restoration of oxygen, which is favourable to it; and so to maintain a necessary equilibrium in the atmosphere, as animals are continually absorbing oxygen, and giving out carbonic acid. Light being essential to the decomposition of carbonic acid gas in the leaves, oxygen is not exhaled by plants during the night; but, on the contrary, a small quantity of carbonic acid gas escapes, and oxygen is absorbed. These processes have been called the *respiration of plants;* but they are very different from the respiration of animals.

Development of Vegetable Life.—This depends upon the concurrence of certain agents, the principal of which are—heat, air, moisture, light, and soil. No seed can germinate without the concurrence of the three agents of heat, air, and moisture; but in the *growth* of most plants, the agency of soil and light is also necessary. Every perfect seed contains the germ or embryo of a new plant of the same kind as the parent, and a portion of concentrated carbon and nitrogen, in the form of starch and gluten, laid up to serve as nutriment for the young plant, till its organs are sufficiently developed to enable it to seek food for itself. This nutrient matter is either contained in the tissues of the embryo's cotyledons, or laid up beside it in the seed, in the form of separate albumen. The seed is generally furnished with a hardened covering, in order to preserve it in an inert state as long as may be necessary. The common bean will afford a familiar example of the process of germination. As soon as it is put into the ground, it is acted upon by the influence of heat and moisture, which distend its tissues, so as to burst the external integument. The agency of the air is next required to

combine with the store of nutriment laid up in the seed, and to fit it for the purposes of vegetation.



The first organ which expands in the embryo of a young plant is the radicle, or root *c*. There is a small opening (foramen) in the covering of the seed, towards which the point of the root is always turned, in order that it may be protruded without injuring its soft and delicate texture. The radicle takes up water and air, and transmits the liquid thus formed to the other tissues. The nutritive substances laid up in the cotyledons, or seed-lobes (*a a*), become quite changed during the process of germination. The starch, which is insoluble in water, is rendered soluble by the action of a peculiar substance called ***diastase***, derived from the gluten, which acts as a ferment. This substance has so powerful an effect upon the starch as to render it instantly soluble, and thus nutriment is prepared for the use of the infant plant. The starch is changed into sugar; and when the store of starch and gluten has been exhausted, the plant is able to subsist by its own assimilating powers, at the expense of the air and the soil.

Heat, though essential to germination, is injurious, unless it be combined with moisture. A high degree of dry heat will parch seeds, and destroy their vitality; hence, when they are to be kept for food, it is not unusual to dry them in an oven, to prevent them from germinating. When combined with moisture, a very high temperature is not injurious to many kinds of plants, especially those of low organisation; for example, various species of plants inhabit the hot springs of Italy and the hot-water pools around the geysers in Iceland; while, on the other hand, certain lichens and mosses grow in the region of perpetual snow, where the temperature seldom rises to 32° Fahrenheit. Warmth is not only necessary for the germination of the seed, but also for the growth and after-development of the plant. In flowering plants the sap will not rise without a certain degree of heat. Cold will also check the development of the flowers and fruit, and even of the leaves, and will prevent the full flavour being attained by the fruit. The secretions of plants are diminished by cold.

Moisture must be combined with heat and air to render it useful to vegetation. An excess of moisture without heat, and combined with air, induces decay in seeds, instead of exciting them to germinate; and an excess of moisture is injurious even to growing plants, as it destroys the delicate tissue of the root spongioles.

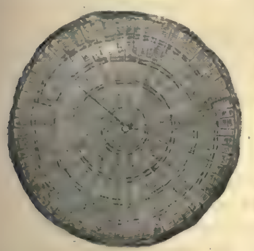
Air is essential both to the germination of the seed and the development of the plant. Without oxygen from the atmosphere, the carbon laid up in the seed cannot be made available for the use of the infant plant, as carbon in its concentrated state is insoluble in water, and requires to be combined with oxygen to convert it into carbonic acid gas. In like manner, air is essential through all the processes of vegetation; no wood can be formed, no seed ripened, and no secretions produced, without abundance of carbon; and this cannot enter the plant, even from the soil, without a constant supply of oxygen from the air.

Light is not required for the germination of seeds, but it is essential to the development of plants, as it occasions the decomposition of the carbonic acid contained in the parts exposed to its influence; without which the plant could not assimilate the carbon. Colour also appears to depend partly on light. Plants grown in darkness are of a sickly aspect, and are said to be ***etiolated***, or blanched.

In addition to the elements of which plants are principally composed, there is also found in their substance a quantity of inorganic matter, which differs according to the nature of the plant, and which appears to be derived solely from the soil. Plants require different kinds of inorganic food, according to their nature, and appear to possess the power of selection, as they only take the kind they need, though it may form but a very small portion of the soil in which they grow. Thus it is evident that any particular crop must in time exhaust the soil in which it grows of the requisite inorganic matters, unless they should be renewed by the addition of what are called mineral manures (see AGRICULTURE); and it is also clear that crops requiring another kind of earth may succeed in the same soil after it has become unproductive for the first kind of crop. Hence the necessity for what is called ***the rotation of crops***—that is, for letting crops of a different nature succeed each other in fields and gardens. Wheat, barley, rye, and oats are silica plants; pease, beans, and clover, lime plants; and turnips and potatoes, potash plants. Thus, these crops, from the difference in their predominant inorganic ingredients, are generally made to alternate with each other. In some soils containing a large amount of phosphates and other organic matters, the same plants may be cultivated successfully for a number of years.

Term of Vegetable Existence.—The longevity of plants differs according to their nature and the circumstances in which they are placed: thus, plants are ***annuals***, which grow only one season, and die as soon as they have ripened their seed—***biennials***, which generally last for two years—or ***perennials***, which last for several years. Trees and shrubs, which have ligneous or woody stems, are destined to remain undecayed for years. The term ***shrub*** is applied to those woody plants which branch out from near the root, and seldom attain a great height; while ***trees*** have, generally speaking, only one stem or trunk proceeding from the root to a considerable height before it divides into branches. The length of time which trees live depends in a great measure on the situations in which they grow. The age of trees was formerly calculated by their diameter, or by the number of concentric circles or layers in the trunk; but both these modes are now found to be often fallacious. According to the first, it was supposed that if a tree attained the diameter of a foot in fifty years, fifty years should be counted for every foot it measured in diameter; and thus it was supposed that the great baobab tree, found by Adanson on the banks of the Senegal, which measured nearly thirty feet in diameter, must have been about 6000 years old, or coeval with the world itself. It is found, however, that the

baobab, like all soft-wooded trees, grows rapidly, and attains an enormous diameter in less than a hundred years. The mode of counting by concentric circles only applies to exogenous trees, and even with them is very uncertain. A warm spring, which sets the sap early in motion, followed by weather cold enough to check vegetation, will give the appearance of two layers in one year, as the recommencement of vegetation will have the same appearance as a new layer in spring. In many trees, such as the oak, for example, a second growth often takes place after midsummer; so that even a third layer is occasionally formed in the course of six months. On the other hand, it is possible that a moist warm winter, by keeping an evergreen tree growing the whole year without any check to vegetation, might give the appearance of only one layer to the growth of two years. Notwithstanding these anomalies, practical men find counting the concentric circles of a tree the best mode which has yet been discovered of ascertaining its age, as in northern countries only one growth is made in the course of a year. The accompanying figure represents a section of an exogenous or outside-growing stem five years old, having the pith in the centre, a cylindrical layer for every year of the growth, the bark on the outside, and the medullary rays passing from the centre to the circumference.



DISTRIBUTION OF PLANTS.

The geographical arrangement of the vegetable world is influenced by conditions of soil, heat, moisture, light, altitude of situation, and various other causes; for, did they flourish independently of these conditions, then there were no reason why the vegetation of one part of the globe should differ from that of another. The flowers, shrubs, and trees which adorn the plains of India, are not the same as those which clothe the valleys of Britain; and these, again, are totally different from the scanty vegetation of Iceland or Spitzbergen. Each species is, nevertheless, perfectly adapted to the conditions under which it exists, and finds in its native situation all the elements required for its growth.

In a state of domestication, however, many species exist in regions far beyond the limits of their original distribution. Our cultivated useful plants are of this kind; as, for example, the potato, which is a native of tropical America, and is of the highest utility in Northern Europe. In South America, the warm climate enables it to propagate by the seed; hence in that region its tubers are small and insignificant; but in Europe, where the climate is unfavourable to the production of the plant from seed, it propagates by the tubers, which are consequently enlarged, so as to contain a store of nutriment for the young plant, before its stem and leaves be sufficiently developed.

The *habitats* of plants—that is, the situations in which they naturally thrive best—are generally distinguished as follows: *Marine*, when the plants float upon, or are immersed in, salt water, such as sea-weeds; and *maritime*, when they grow by the sea-shore, or in places exposed to the influence of the sea-breeze. *Aquatic* is the general term for fresh-water habitats; and these may be *lacustrine*, that is, growing in lakes—*fluviatile*, in rivers—or *palustrine*, when in marshes or wet meadow-lands. Plants are also distinguished as growing in open pastures, in cultivated lands, woods, mountainous parts, and in caves, mines, and other underground excavations. The term *epiphyte* indicates that the species grows upon others without deriving from them the elements of nutrition; and *parasite*, that it adheres to their surface, enters their tissue, and directly extracts its nourishment. Examples of epiphytes are seen in numerous species of tropical orchids, and parasites in such plants as the mistleto, dodder, and Broom-rapes. The range of habitat is that extent of the earth's surface over which a plant is distributed by nature. The terms maritime and alpine, for example, are general in their application, and refer to all plants which grow by the sea-side or on mountains; but the plants which flourish on the sea-shores of Great Britain are not the same with those on the coast of Africa; nor are these, again, identical with the maritime vegetation of Chili. The geographical range of any plant conveys a more special idea, and embraces only that particular tract over which the species extends. This range is circumscribed by conditions of temperature, light, and elevation above the sea, and does not, as might be supposed, depend very closely upon belts of longitude, by which temperature is generally indicated. Thus, nearly all the beautiful Pelargoniums and Mesembryanthemums which adorn our green-houses are natives of a limited space near the Cape of Good Hope, as are also many of our most beautiful bulbs. The curious Stapelias, that smell so much like carrion, are found wild only in South Africa. The different kinds of Eucalyptus and Epacris are restricted to Australia. The Umbelliferous and Cruciferous plants spread across Europe and Asia; the Cacti are found in tropical America; and the Labiatæ and Caryophyllaceæ are seldom found beyond Europe. The peculiar ranges and centres of vegetation, as they are termed, cannot be sufficiently understood, however, without a knowledge of the different tribes and classes of plants, the consideration of which forms the subject of next paper—SYSTEMATIC BOTANY.

Soil exercises less influence on the distribution of plants than is usually ascribed to it, though there can be no doubt that on its power of absorbing and retaining heat and moisture much of the luxurious growth of vegetables depends. They will grow to some degree in almost any soil, as the bulkier ingredients—clay, lime, and sand—always predominate; but a proper proportion of these earths is necessary to perfect vegetation, and many plants will not continue healthy and propagate unless supplied with other elements, such as potash, soda, and various metallic salts. For this reason, the natural vegetation of a limestone country differs from that of a retentive clay; while the plants which cover sandy downs are different from those of the alluvial valley. Moisture, which is indispensable to the existence of vegetation, also exercises great influence in its natural distribution. Very dry regions are deficient in vegetable forms, while their luxuriance in tropical countries is connected with great heat and moisture. The plant

which roots in the parched sand is furnished with leaf-organs to absorb moisture from the atmosphere, and retain it; while in a wet situation these organs would become diseased, and rot away; so, in like manner, a marsh-plant, whose spongioles are its main organs of sustenance, would perish were it removed to an arid soil. The organic structure of such plants forms a limit to their distribution; and the same may be said of the Salicornia, Salsola, *Lepigonum marinum*, &c., which live only when exposed to the salt spray of the ocean.

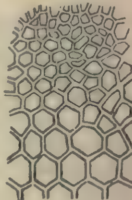
Heat and light are perhaps the most manifest agents in the distribution of vegetable life. The luxurious growth of the tropical jungle is the direct result of warmth and moisture, just as the barrenness of Nova Zembla is the effect of piercing cold; yet both situations are inhabited by plants which enjoy the conditions peculiar to their existence. No conditions of mere soil, or light, or moisture, could make the palms, tree-ferns, and jungle-flowers of India flourish in Great Britain; so neither would our oaks or pines flourish in Iceland, unless we could provide for them that temperature and seasonal influence necessary to their healthy existence. Light, though it acts most powerfully on the colours and blossoms of plants, is in some measure an element in their geographical arrangement. The northern side of a hill may sometimes be as green, but it never will be so flowery as the southern. The more free the exposure, the more readily will most plants also blossom, and yield a rich fruit. So well is this understood in the grape-countries on the Rhine, that the right bank of that river, which faces the sun, is reckoned to be much more valuable than the left, and commands a higher price for its wines.

Altitude, or elevation above the ordinary sea-level, also exerts an obvious influence on the distribution of vegetable life: it is equivalent to removal from a tropical to a temperate region, or from temperate latitudes to the arctic circle. For every hundred feet of ascent, there is a proportional fall of the thermometer; so that, at the height of 5000 feet in the latitude of Britain, and 16,000 at the equator, we arrive at the region of perpetual snow. This intimate relation between altitude and decrease of temperature accounts for the fact, why the base of a mountain may be clothed with the vegetation of tropical India, the sides with that of temperate England, and the summit with the mosses and lichens of icy Labrador. 'We may begin the ascent of the Alps, for instance, in the midst of warm vineyards, and pass through a succession of oaks, sweet chestnuts, and beeches, till we gain the elevation of the more hardy pines and stunted birches, and tread on pastures fringed by borders of perpetual snow. At the elevation of 1950 feet, the vine disappears; and at 1000 feet higher, the sweet chestnuts cease to thrive; 1000 feet farther, and the oak is unable to maintain itself; the birch ceases to grow at an elevation of 4680; and the spruce-fir at the height of 5900 feet, beyond which no tree appears. The *Rhododendron ferrugineum* then covers immense tracts to the height of 7800 feet; and the herbaceous willow creeps 200 or 300 feet higher, accompanied by a few saxifrages, gentians, and grasses; while mosses and lichens struggle up to the imperishable barrier of eternal snow.'

The circumstances which facilitate the dispersion or migration of plants, are not unconnected with the causes which limit their geographical distribution. Many seeds drop from the parent stalk, spring up into new series of stems, which in turn give birth to another race of seeds, and these again to another circle of vegetation. Thus, any species of plant would spread from a common centre till arrested by the influences which limit its range of habitat; and this mode of dispersion no doubt frequently occurs. In most plants, however, the seeds are small and light, and easily borne about by the winds: some are downy, and furnished with wings or hairs, while others are ejected from their carpels with considerable force. All these appendages and peculiarities are evidently intended to facilitate their dispersion, which is further assisted by rivers, lakes, and tidal currents, by the wool of animals, the droppings of birds, and the economical pursuits of man, whether accidental or intentional.

STRUCTURE OF PLANTS.

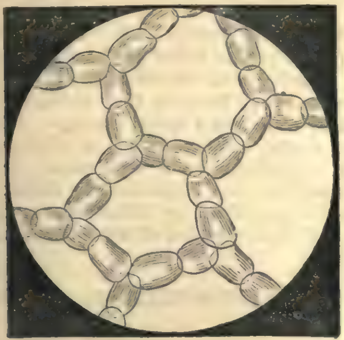
In order to explain the varied phenomena of plant-life, we must revert to the elementary tissues of which the various organs are composed. It is in these tissues that the processes of growth and multiplication, of individual development and of reproduction, can alone be accurately traced. Vegetable Histology limits itself to such investigations. If we cut a thin slice from the leaf or succulent stem of a plant, and place it under the object-glass of a microscope, we shall find it to present the general appearance of a web or tissue, more or less of a honeycomb form, as represented in the wood-cut (*a*). If more carefully examined, it will be found that the apparent meshes of the network are not hollow spaces in a homogeneous mass or membrane, but that each has its own envelope—is, in fact, a minute bladder or vesicle, or elongated tube, as the case may be; and that the whole mass of tissue is formed by the aggregation of such vesicular or tubular bodies held together by means of an imperceptible layer of intercellular matter, which causes the contiguous cell-membranes to cohere. In the tissues of plants there is an infinite variety, both as regards the form and arrangement of their elementary bodies, but all may be reduced to three distinct types of structure, to one or other of which every modification can be referred. These are distinguished as the *cellular*, *woody*, and *vascular* tissues.



a, Cellular tissue.

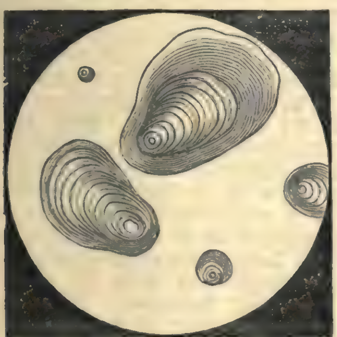
Cellular tissue (*Parenchyma*) may be said, in general terms, to form the soft and succulent parts of plants—as, for example, the pith of trees, the delicate central tissue of Papyrus, shewn in the following figure (*b*), and the soft parts of our esculent vegetables and fruits. It is composed of minute bladders or vesicles, which are called *cells*, which have their walls composed of a chemical substance called cellulose. Cells are seldom so large as to be visible to the naked eye, but are readily seen under a compound microscope. They usually consist of a pellucid membrane, and contain a formative protoplasm in their interior, with nuclei and nucleoli, which give origin to new cells.

Starch, gum, sugar, oil, resin, colouring matter, air, crystals, and other nitrogenous substances, are



b, Papyrus: pith-like tissue, composed of cells arranged in form of a network, so as to leave large intercellular spaces (*ad nat.*).

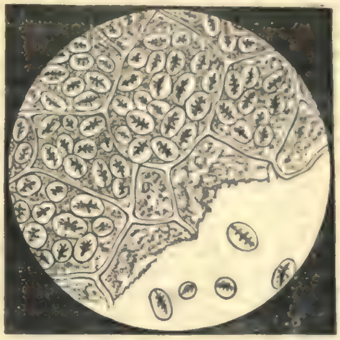
also found in the cells of plants. Starch is a very abundant substance in cells, serving purposes of nutrition, and may be readily seen by placing under the microscope a thin slice of potato upon which a drop of tincture of iodine has fallen; this induces a beautiful blue colour in the starch-granule, and is a constant test for the occurrence of starch. Starch usually occurs in the form of minute grains, many of which are contained in each cell. Their form is often constant and characteristic in certain plants—for example, the very minute angular starch-granules of rice are quite different from those of the other cereal grains, which, again, are easily distinguished from those



c, Starch-grains of Potato (*ad nat.*).

of the potato, shewn in the above figure (*c*); while those of leguminous plants have a somewhat common character (*d*). The peculiarities of starch-granules have been successfully employed in detecting adulterations of food and drugs, and for other purposes of practical utility.

The cell in many cases displays a thickened opaque wall and an empty cavity within. This arises from the deposit of woody matter on the interior surface of the cell-wall, which is seen in the hard stone of the cherry and in the shell of the coco-nut, both of which consist of cellular tissue equally with the softest parts of their respective fruits, and owe their solidity to the indurated woody matter. Instead of having the whole inner surface of the cell covered in this way, the deposited matter may be so arranged as to cover



d, Lentil: cells of seed containing Starch-grains (*ad nat.*).

certain parts only: it is often deposited in the form of rings or spiral coils; and in the latter case gives rise to the beautiful spiral cells seen in the

e, Spiral tissue from the root of an Epiphytal Orchid (*ad nat.*).

leaves and roots of epiphytal orchids (*e*), and in the leaves of bog-mosses (*Sphagnæ*).

With respect to their general form, cells are exceedingly variable, and are usually greatly modified according to the position in the plant which they occupy. They very commonly present the hexagonal appearance represented in the woodcut (*a*); but in the bark and young stems, as well as in roots and other parts, they often assume an oblong form (fig. *e*); sometimes resembling the bricks of a wall set on end, and thus indicating the manner in which plant-structure is built up, as it were, by separate cells cemented together.

The rounded or spherical form may be regarded as the normal form of the cell, the two modifications to which we have alluded arising from the pressure of spherical or oval cells in contiguity, or special modifications intended to fit them for their place in the structure. In many cases, however, we find cells of a very different form, whose modifications obviously arise from certain special functions which they are designed to perform. The pith-like substance of the rush, used as wick for 'rush-lights,' consists of cells of a most beautiful stellate form; the free cells or spores of certain

algæ are covered with cilia, which give them locomotive power; the cells of hairs are elongated, and often much branched; and the cells of unicellular algæ, such as the Desmideæ and Diatomaceæ, often display the most exquisite symmetry, both in outline and in the elaborate sculpture of their surface. The cotton hair, which is a cell in peculiar condition, presents the form of a flat twisted band with a thickened margin, a character which is retained by it after it is dressed, spun, and woven into cloth, and even after that cloth has been worn to rags, reduced to pulp, and remanufactured into paper.

In the pulp of leaves and fruit, and in the cellular tissue of the bark, there are frequently cavities found among the cells, which are of several kinds. Those called *receptacles of secretion* are formed for the reception of the oils and other fluids secreted by plants; as, for example, the fragrant oil in the myrtle and the orange, and the turpentine in the pine and fir tribe. Other similar cavities, called *air-cells*, contain oxygen nearly in a pure state, and are called *intercellular spaces*. All these cavities have no distinct membrane to inclose them, but are surrounded by what may be called a wall of cells, which form part of the cellular tissue. If the stem of the common *Hippuris*, or mare's-tail, or the leaf-stalk of a water-lily, be cut across, a beautiful arrangement of these intercellular spaces will be displayed, and the manner in which they are formed by the peculiar arrangement of the plant's cells is shewn in wood-cut *b* (page 69).

Cellular tissue readily decays when the parts composed of it fall from the plant. In leaves, the pulpy parts disappear first, leaving behind the outer cuticle and the nerves or veins, which are of firmer texture; the latter, indeed, being composed principally of woody tissue, the tubes of which have been filled with earthy matter during the process of vegetation, decay very slowly. Those parts of a plant which nature seems to have intended not to be of long duration—such as the fleshy parts of the leaves, the flowers, and the fruit—are composed entirely of cellular tissue of loose texture.

Woody Tissue (*Pleurenchyma*).—The stems of trees and of flowering-plants in general possess a tenacity not found in the leaves and flowers. This is mainly due to the presence of woody tissue, which consists of minute spindle-shaped tubes lying closely together, and overlapping each other at the ends. The strength of these tubes is mainly due to the deposit of ligneous matter on their inner surface. The value of many plants employed in the arts depends upon the abundance of this tissue: when separated from the softer tissues of the stem and leaves by maceration, it forms the fibre of flax, hemp, jute, Chinese grass, and other textile substances well known in commerce. In cone-bearing plants, such as the Scotch fir, the woody tissue is very peculiar, each tube exhibiting a series of round discs with a central dot. By carefully studying the peculiarities in such tissues, the sources of unknown timbers may often be determined. In most pines there is a single row of discs on each tube, while in others a double row of opposite discs is observed. In the Araucarias of the southern hemisphere, the discs are angular, and are arranged alternately in several rows; and in the yew, the tube has beautiful spiral markings as well as minute discs. Such characters are invaluable to the student of vegetable palæontology.

Vascular tissue has been divided by modern botanists into three kinds—namely, *vascular proper*, *pitted*, and *laticiferous*. Vascular tissue consists of cylindrical tubes of great delicacy and thinness, called *spiral vessels* and *ducts*. *Spiral vessels* are so called because they contain delicate fibres coiled round in a spiral manner. They are of a light elastic nature, and their fibres, though coiled up naturally like a cork-screw (see fig.), may be unrolled to a considerable extent. If a leaf-stalk of a geranium or strawberry be cut half through, and then doubled down first on one side,

Spiral Vessel.

and then on the other, and the two pieces be then carefully and gently drawn asunder, the transparent membrane will break, and the spirals will unroll so as to appear, when seen with the naked eye, like fine hairs between the two portions of the leaf-stalk. Spiral vessels prevail in leaves and flowers, and are found, though more sparingly, in the young greenwood of trees and shrubs; but rarely in the old solid wood, roots, or bark. They are few in coniferous trees; but abundant in palms and their allies. In ferns and the club-mosses they occur occasionally, but are usually replaced by a peculiar kind of vascular tissue, called the *scalariform* tissue, from the ladder-like appearance on the angular vessels, caused by bars of fibre in their interior; the other cryptogamous or flowerless plants have no vascular tissue.

Pitted tissue, sometimes called *dotted ducts*, consists of tubes which, when viewed by transmitted light, appear full of holes. This depends on the incrusting matter or cellulose inside being unequally deposited over the surface of the membrane, and thus leaving uncovered spots at various intervals. The dotted ducts are larger than the vessels of the other tissues. They frequently exhibit contractions at intervals, which give them a jointed or bead-like appearance. In such cases, they seem to be formed of dotted cells placed end to end, with the partitions between them obliterated, so as to form continuous cylindrical tubes. Laticiferous tissue consists of tubes which are distinguished from all other kinds of tissue by being branched. They are filled with a fluid called *latex*, of a granular nature, often milky or coloured, and exhibiting movements. This milky fluid abounds in the India-rubber and gutta-percha plants, and is seen to exude in abundance from the dandelion when its leaves or stalks are wounded. The fluid, in many plants, contains a large quantity of caoutchouc; it is bland and nutritious in the cow-tree of the Caracas, but in many other plants narcotic and acrid.

Multifarious as are the modifications of the tissues of plants, and the cells and vessels of which they are composed, all have a common origin, all are modifications of the *cell*. The plant begins its existence as a cell, and its whole course of development may be said to be the evolution of cells. The process of cell-development, or cytogenesis, thus explains the whole phenomena of plant growth and reproduction. To the investigation of this subject,

therefore, the attention of vegetable histologists has of late years been specially directed, and the results have appeared in the form of certain theories which have given rise to much angry discussion. There appear to be four modes in which vegetable cells are multiplied—namely, by nuclei, by division, by gemmation, and by conjugation.

GENERAL INTEGUMENT AND ITS APPENDAGES.

Submerged plants have the cells of their leaf-tissue directly exposed to the action of the surrounding water; but land-plants usually have all their organs invested in an epidermis or skin, which regulates transpiration, and prevents their tissues becoming dried up. The surface of this epidermis, again, is covered by a very thin structureless layer, called the cuticle. The epidermis is composed of cellular tissue; but the cells are pressed closely together, and flattened, and they are often filled with air instead of water. The use of the epidermis is to retain a sufficiency of moisture in plants; for should the delicate membrane of which the cells of their tissue are composed become so dry as to lose its elasticity, the different organs would be unable to perform their proper functions. On this account, its thickness is curiously adapted to the conditions under which a plant grows. Plants of very hot countries are supplied with three or even four layers of dense external tissue, in order that the moisture may be retained, notwithstanding the excessive heat and dryness of the climate. But it is necessary that the tissues of plants should not be shut out from the free action of the atmosphere, whence a large proportion of their food is derived. They are therefore provided with peculiar breathing-pores, or *stomata*, by which air and fluid enter, and from which fluid transpires. In mosses, where the leaves usually consist of a single layer of cells, stomata are confined to the fleshy base of the fruit; but in flowering-plants they chiefly occur on the under surface of the leaf; and this is especially the case in many evergreen shrubs, which are thereby enabled to benefit by the moist exhalations from the soil and herbage beneath, without suffering from a scorching sun. This law is reversed where the habits of the plant require such an adaptation. Water-lilies and other plants whose leaves float on the surface of the water or lie flat on the soil, have no stomata on their under surface, but are supplied with an increased number on their upper surface, which alone is exposed to the action of the atmosphere. The following calculation of the number of stomata in the leaf of the royal water-lily, will serve to indicate the extremely minute size of these bodies and the great numbers of them required by plants: each stomate measures the $\frac{1}{300}$th part of an inch in diameter; one square inch of surface contains 139,843 stomata; so that one ordinary sized leaf of this plant, with a surface of 1850·08 square inches, contains upwards of twenty-five millions of stomata (25,720,937).

Hairs are minute prolongations from the epidermis, and are found upon almost every part of plants. Sometimes they cover the whole of the leaf, and at others they are only found on one surface. They are described in general terms as downy, silky, hirsute, bristly, ciliate, &c. according to their aspect and mode of arrangement. The hairs of plants are exceedingly variable in size and form, and are either unicellular or multicellular—consisting of one or of many cells. In either case, they may be simple or branched. There are branched unicellular hairs in Cruciferæ, and beautiful stellate hairs in many plants. The sting of the nettle is a modification of the hair, being a conical tube with a basal bulb, filled with irritant fluid, which shews singular movements under the microscope. The tube is sharp-pointed, and surmounted by a little curved knob; when the plant comes in contact with the hand, this knob is knocked off; the sharp point which it protected now penetrates the skin; and the pressure upon the conical sting causes the irritant fluid which it contains to be poured out into the wound. The whole phenomenon is strikingly similar to the mode of action of the animal sting.

Glands.—Although some have stated that there is no true process of secretion in plants analogous to that of animals, still the latest researches seem to indicate that such a process does exist, and that it is performed by special organs—usually modifications of the epidermis itself or of its appendages. Thus, in the Cinchonas of South America, we have conical glands, which pour out a gum-resinous matter on their free surface. The same kind of glands are found in the bedstraws of our hedgerows. The honey of many flowers also appears to be a true secretion, poured out upon a free surface of the tissue by special cells, which are not analogous to the fat-cells of animals, to which the so-called vegetable secretions have been likened.

Besides the above-mentioned organs, there are prickles, thorns, and spines. *Prickles* may be called hardened hairs, as they are merely indurated expansions of the epidermis, without any woody fibre; and they may be detached from the branch which bears them without laceration. Examples of prickles are well seen in the rose and bramble. *Thorns* differ from prickles in being formed partly of woody fibre; and they cannot be detached from the branch which bears them without lacerating its vessels. They have their origin in buds, and are the result of an arrestment of development, being formed instead of leaves and branches. Examples in hawthorn and sloe. *Spines* resemble thorns in every respect, except in being found on the leaves and stems of herbaceous plants; while thorns only grow on the trunk and branches of woody plants. When spines grow on leaves, they are always found on the veins which are extensions of the woody fibre. Example, holly.

ORGANS OF NUTRITION.

The organs of nutrition are the root, the stem and its branches, and the leaves; and of these organs, the root and the leaves, or some modification of them, exist in every flowering-plant, as the vital functions cannot be carried on without them.

The root (*radix* in Latin) is commonly defined to be that part of a plant which attaches itself to the soil where it grows, or to the substance on which it feeds, and is the principal organ of nutrition. Exceptions to this definition occur, as in the case of some plants which grow floating loosely in water, as duck-weed, as well as in the case of others having no root at all. As the nourishment of a plant is derived from the earth, the root is that part which grows in an opposite direction to the stem, and is buried in the ground. It is the

descending axis, while the stem is the *ascending*. The more common form is the fibrous root as seen in grasses, the fibres being terminated by loose cells or spongioles, which are the absorbent points. But the main root is often thickened into a tap-root, giving off secondary fibres—globe-shaped, in the turnip—conical, or tapering gradually from the collar to the attenuated fibre, in the carrot—fusiform, or tapering at both ends, in the radish—abrupt, where the lower end appears as if cut off, in the devil's bit scabious. In the dahlia, the roots branch off in a fasciculate manner; while in the orchis (*O. mascula*) they are tuberous, being in the form of globe-shaped bodies filled with starchy matter. The so-called tuberous roots of the potato are merely underground stems, from the circumstance of their having eyes or buds from which branches will spring.

The crown, collar, or life-knot, as it is variously called, is that part which lies between the stem and the root. It is the most essential portion of the whole; for if it be removed, or seriously injured, the plant will die; whilst the small fibres or rootlets, although an essential part of a plant, may be destroyed at pleasure, so long as the crown remains, for it readily reproduces them. When it is of a slender make, it dries up as the seeds ripen, and the plant soon dies, as seen in the corn-poppy, mignonette, and other annuals.

Roots have a remarkable tendency to grow downwards, or in the direction of the earth's centre; and from experiments, it seems not unlikely that this tendency is to some extent an effect of gravitation. The precise direction, however, is very much influenced by the condition of the soil. Both root and rootlets extend as if in quest of food, and will penetrate sidewise or obliquely to great distances. Though the root and stem differ in many respects, yet there are cases where it becomes difficult to distinguish between them. Some species of palms send down aërial roots for the purpose of strengthening their stems, and the same are seen very remarkably in the screw-pines and banyans. Many herbaceous plants send out roots in a similar manner when they are earthed up; and trees which grow in unnatural situations, as on a wall or bare rock, send down roots in quest of soil and moisture, which afterwards take the appearance of stems. The willow, maple, gooseberry, and some other plants, may have their roots converted into stems by reversing the plants, and burying the tips of the shoots in the earth, so as to leave the roots in the air. In this case, the branches will soon send out fibrous roots from the joints which have been buried in the earth, and the fibrous part of the old roots withering, the roots themselves will gradually assume the character of branches.

The Stem.—When a plant shews itself above the ground, it evidently manifests a strong tendency to the light. Light, in fact, is essential in bringing it to maturity, and in giving the green colour to its leaves. The stem, with a few exceptions, is always above ground. It is divided from the root by the part called the crown or collar. The space between the collar and the first branch is termed the bole or trunk. The stem of grasses, corn, and reeds, receives the name of culm; the stem of such flowers as the primrose, dodecatheon (see fig.), and the daisy is undeveloped;

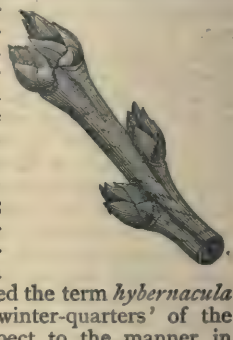
hence they are called stemless (acaulescent); the stalk upon which the flowers are borne being termed the scape, or flower-stalk; the running-stem, as in the strawberry and cinquefoil, is termed a runner; a shorter runner that does not root, as in the house-leek, is termed an offset; and a small stem proceeding laterally from a root or stool, a sucker.

The stem assumes many forms and characters as to bulk, structure, position, place, and duration. It appears as a corm (sword-lily, 1); a

1 2 3 4

bulb (the onion, 2); a culm (reed, 3); or as a woody trunk (the oak, 4). When a trunk bears permanent or perennial branches, the plant is termed a tree; when permanent branches arise, not from a distinct trunk, but from near the root, the plant is termed a shrub; and when the whole stem is not woody, and dies down every year, at least as far as the crown of the root, the plant is termed a herb. Trunks which increase by successive layers of new wood on the outside of the old, as the ash and beech, are termed *exogenous;* those which increase by the addition of fibrous matter in the centre, as the palms, are styled *endogenous;* and those which do not sensibly increase in thickness, and are formed by the adhesion of the leaf-stalks as they spring from the growing point, as the tree-ferns, are said to be *acrogenous.* (See SYSTEMATIC BOTANY, p. 108, figs. *b*, *a*.)

Buds, which have various forms, consist of the young shoots, leaves, or flowers, and proceed from what is called the *axil* of a leaf. They are usually formed either early in summer or in autumn, and are so contrived as to preserve from injury the delicate structure within. The outside is composed of tough scales, which are frequently covered with a gummy resin; and they are internally protected by a downy substance interposed between



the leaves. Linnæus applied the term *hybernacula* to leaf-buds, being the 'winter-quarters' of the young branch. With respect to the manner in which the leaves are arranged and folded in the bud, which is termed *vernation*, they may be simply placed in apposition, as in the mistleto; plaited, as in the palm and birch; doubled, as in the rose and oak; embracing, as in the iris and the sage; double embracing, as in valerian and teasel; rolled inwards, as in grasses; rolled outwards, as in rosemary, primrose, &c.; rolled lengthwise, breadthwise, rolled from the tip to the base, or wrapped round the stalk.

Leaves.—Leaves, from their number, position, and delicacy of organisation, are designed to effect an important office in the vegetable economy. Springing from the branches, and exposed in profusion to the atmosphere, they perform the functions of a breathing-apparatus analogous to that of the lungs or gills of animals. A similar purpose at least is designed; for the sap of plants, like the blood of animals, requires to be exposed to the atmospheric influence, in order that it may be suitable for nutrition. This purpose is accomplished by the agency of the leaves, to which the sap, on rising from the roots through the stem and branches, is propelled or attracted, and there both air and light exercise their beneficial influences. Leaves are thus indispensable to the growth of plants, and care should be taken not to injure them; for defoliation, either naturally or by art or accident, instantly arrests the growth, and the failure or diminished expansion of foliage is a certain sign of debility.

A leaf consists generally of two parts—the

petiole, or leaf-stalk; and the lamina, or blade. Sometimes, however, as in the rose tribe, stipules (*s*, *s*) are attached to the base of the petiole. The leaf-stalk (*a*) is that part which connects the leaf with the branch, and at the base will be found slightly hollowed, in which a bud rests. Sometimes the leaf-stalk is wanting, and thus the leaf is said to be sessile. In some Australian acacias and eucalypti, the petiole is flattened, and occupies the place of the leaves. Such petioles are called *Phyllodia*. The lamina, or broad part of the leaf (*b*), is frequently of a different colour on the under side. This is exemplified in the common silver-weed (*Potentilla anserina*), the leaves of which are hoary on the lower side, and green on the upper. Leaves are either *deciduous*—falling in autumn—or *evergreen*, lasting till the following season. Their forms are exceedingly varied—being *simple* or *compound;* and these, again, are distinguished as oval, lanceolate, cordate, hastate, sagittate, pinnate, &c.

An important character is afforded by the *venation* of leaves—that is, the arrangement of what are called their veins. In exogenous or dicotyledonous plants—as our timber trees, for example—the leaf is furnished with a strong midrib, from which secondary veins diverge, at regular distances; and these, again, branch off into still smaller tertiary veins, whose ramifications form a reticulation or network in the leaf. In endogenous or monocotyledonous plants—as grasses and lilies—there is usually no distinct midrib, but several primary veins, which originate in the base of the leaf, and proceed to its apex, being parallel throughout. In many tropical endogens, however, there is a distinct midrib, from which secondary parallel veins diverge on either half of the lamina. In acrogens or acotyledonous plants—as ferns—the veins are usually arranged in a forked manner.

The veins of leaves consist of woody tissue, accompanied by spiral vessels, the interspaces being filled up with the softer parenchyma, or cellular tissue. By maceration, the latter may be made to disappear, so as to leave merely the veins. In aquatic plants, there is a strong tendency to non-development of the parenchyma; thus, in many of the aquatic crow-foots, the submerged leaves consist almost wholly of veins, while the floating ones are entire; but the most remarkable instance of this occurs in the *Ouvirandra fenestralis*, a water-plant introduced to our hot-houses from Madagascar, whose leaves are so destitute of parenchyma, that they are, in fact, beautiful lattice-like skeleton-leaves. The leaves of the royal water-lily are perforated with minute holes at regular intervals, and large open spaces occur in the leaves of *Monstera* and *Dracontium*.

With regard to the manner in which leaves project from the branches, and their distribution over the woody cylinder to which they are attached, every possible variety may be observed. They may be opposite—that is, two leaves growing on either side of the branch, the one directly opposite to the other; alternate, when one leaf springs out on one side of the branch, and another on the opposite side, a little above it, and so on; whorled, or *verticillate*, when a number of leaves grow round the stem from a common knot or joint, as in the bed-straw. The distribution of alternate and opposite, however, is not regular; for in some instances it will be found that the leaves on the lower part of the stem are alternate, whilst those on the upper are opposite. There are many plants which have few or no leaves, but whose stems are much dilated, presenting a large superficies of parenchymatous exterior to the air and light—as, for example, in the cactuses.

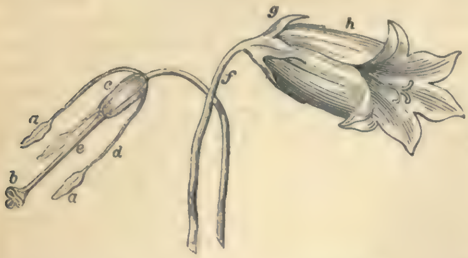
Green is the most general colour of leaves, but some are red, or purple, or yellow; some appear nearly white, in consequence of being clothed with short woolly or silky hair. Leaves are often variegated, in consequence of the non-development of chlorophyll in the cells of certain parts. They differ much in substance and structure: some are immensely thick and fleshy, as those of the genera *Aloe* and *Agave;* others remarkably thin, as those of the beech.

ORGANS OF REPRODUCTION.

The organs of reproduction are the flower, fruit, and seeds; and these, or some modification of them, exist in every perfect *Phanerogamous* or flowering-plant.

Flower.—A flower consists of several distinct parts—the calyx, corolla, stamens, and pistil. A flower is essentially constituted by the presence of the last two, which are the sexual organs. When there is only one of these present, the plant is termed unisexual; but more commonly these organs are both present in the same flower, which is in this case termed hermaphrodite. In some instances, although the same plant bears both

male and female organs, it is not hermaphrodite, as these organs occur in different flowers; in others, again, the male and female flowers exist only on different plants. Lastly, male, female, and hermaphrodite flowers are sometimes found together, either on the same or on different plants. Sometimes the male or female organs alone, protected by a small scale, constitute the flower; but in general they are surrounded and protected by the corolla and calyx, which are called the floral envelopes. All these are commonly borne on a stalk called the peduncle (from *pes, pedis*, a foot), which, expanding at its extremity, forms the receptacle, or torus, upon which the whole of the



a, a, anthers; *d*, filament; *b*, stigma, or summit of pistil; *e*, style; *c*, ovary, or seed-vessel; *f*, peduncle; *g*, calyx; *h*, corolla.

parts above mentioned are supported. What is called the berry in strawberries is nothing more than the fleshy receptacle bearing the carpels on its surface.

The *calyx* (from *kalyx*, the cup of a flower) is the external leafy envelope surrounding the corolla, and in which the latter rests as in a cup. Sometimes it is entire, but more frequently it is divided into segments, called *sepals*, which are more or less separated from each other. It is most commonly green, but in some flowers it is coloured.

The *corolla* (a little crown) is the conspicuous highly coloured part of the flower or blossom, and consists of several divisions or leafy parts called *petals*, which are articulated at the base, and consequently fall off at the earliest manifestations of maturity or decay. The variety of tints in the flowering part of plants is remarkable. The lower part of the single petal of a corolla is called the claw, and the broad part is called the limb. The corolla is frequently furnished with certain secreting organs, attached to the throat or the base of the petals, called nectaries. In some plants the corolla is absent.

Stamen (a distaff).—Within the beautiful corolla are observed several small filaments, arranged in a circle around the central parts, and bearing on their summit little oblong bodies; which are usually apparently covered with particles of a fine coloured matter like dust. These are the male parts of reproduction, the stamens, which are always next to the petals—that is, between their base and the base of the seed-organ, or *pistil*. The number of stamens in each flower varies from one to twenty, or more. In length they are equal or unequal. In the *Cruciferæ* there are four long and two short, and in the *foxglove tribe* there are generally two long and two short. In position, they may be opposed to the divisions of the petals, or they may alternate with them, which is their normal condition. Sometimes they protrude beyond the corolla, at other times they are wholly included within it. The filament which supports the anther is most commonly straight and filiform. On the summit is that essential part the *anther* (from *antheros*, belonging to a flower), which is generally formed of two small membranous sacs, or lobes, attached immediately to each other, or united by an intermediate connecting body. In form, anthers are subject to great variety, and, like the filaments, they sometimes cohere so as to form a sort of tube, as in the *Compositæ*.

The *pollen* (fine flour) contained in the anthers consists of numerous small bodies, which possess in different plants a very different figure, size, and colour. The number of these in an anther-lobe sometimes amounts to many thousands. In some flowers, the pollen-grains are transparent; in others, they are of a white, purple, blue, or brown, and more frequently of a yellow colour; and they often display exquisite markings on their surface, which enable the pollen of certain orders to be identified under the microscope. When a grain of pollen is dropped into water, it swells, and sometimes bursts, emitting a minute quantity of granular matter, called *fovilla*, which is the portion more essential to fecundation. In orchids and some other plants, the pollen occurs in masses, or *Pollinia*.

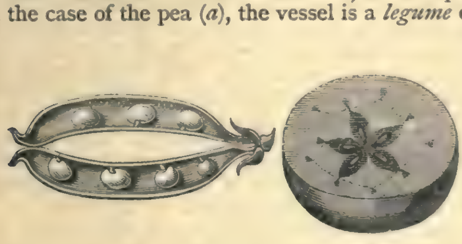
Pistil (from *pistillum*, a pestle).—The pistil is the more or less filamentary body which in most plants rises from the centre of the flower terminating the axis of growth, and is surrounded by the stamens. The pistil represents the female part of fructification. Its parts are—1. The *ovary*, containing ovules or rudimentary seeds; 2. The *style*, or filamentous part; and 3. The *stigma*, or enlarged club-shaped or cloven part forming the apex. The first and last of these are essential, and always present; but the intermediate one, the style, is sometimes not developed, as in the poppy and mangosteen. The pistil consists organically of one or more carpels (folded leaves), which may either be syncarpous (united into one) or apocarpous (separate); in the latter case, we have two or more pistils in the flower.

Having thus briefly described the visible reproductive organs, let us now turn to their functional phenomena. When the flower expands, and its essential organs have arrived at maturity, the anther-valves open and emit the pollen-grains; some of these fall upon the stigma, or terminal point of the pistil, where a peculiar tissue, formed of papillary or hair-like cells, is ready to retain them. A curious phenomenon is now observed. The pollen-grain—a single free cell—develops one or more tubes from its surface, these being formed by its inner membrane, which thus grows through the outer one. These tubes are destined to reach the ovules at the base of the pistil, and thus to carry down from the pollen-grain the matter or influence necessary for fertilisation. The tube, accordingly, penetrates the soft tissue of the stigma, and passes down the centre of the pistil, where a loose conducting tissue is specially formed to facilitate its progress. In this way the pollen-tube often acquires a length several thousand times greater than that of the pollen-cell whence it was produced, its nourishment being derived from the surrounding tissues which envelop it. Mohl regards the development of this filament or

tube as indicating a new analogy between the pollen-grain and the spore of cryptogamic plants; for it is, in fact, a process of germination. The length of time required for the growth of the pollen-tube down to the ovule, is very various in different plants, and by no means depends upon the length of the style; thus, in the night-flowering cactus, which has a style from eight to nine inches long, the pollen-tube reaches the ovules a few hours after the pollen has been applied to the stigma; while in the pine, where there is no proper style, a whole year elapses before the pollen-tubes reach their destination. The lower extremity of the pollen-tube ultimately comes into contact with the ovule, and enters the foramen or micropyle of the latter, so as to reach the embryo sac pre-existing there. The result of the access of the pollen-tube to the ovule, is the production of an embryo in the latter, and the ovule, with its contained embryo, ultimately ripens into a perfect seed. Fertilisation with pollen is essential for the production of fertile seeds, although the ovule exists previous to the act. Fruits may, in some instances, swell and ripen without any process of fertilisation; but in that case, they will not contain seeds capable of producing new plants.

It is not essential for success in this process that the pollen should fall immediately from the anthers upon the stigma, for we have several historical facts which indicate that pollen may retain its vitality unimpaired, in the manner of seeds. Thus, in the cultivation of the date-tree, it is necessary to bring the fruitful plants under the influence of the male flowers; but on one occasion, during a civil war in Persia, the male date-trees of a whole province were cut down by the invading troops, that the fructification of the fertile trees might be prevented, and the season's crop thus destroyed. But the inhabitants, apprehending such a result, had been careful previously to gather the pollen, which they preserved in closed vessels, and thus were enabled to impregnate their trees when the country was freed from the destroying enemy. The pollen-grains of the date and of the European palm (*Chamærops humilis*) are said to have retained vitality after the lapse of eighteen years.

Seed-vessels are various in form—as, for example, in the case of the pea (*a*), the vessel is a *legume* or



a *b*

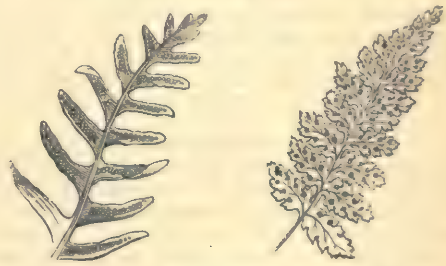
pod; in the apple (*b*), it is a *pome;* and in the filbert, a nut.

All our esculent fruits are in reality so many vessels or receptacles for the seeds; and the various forms in which they appear are individually suitable to the purposes of their growth. As we have already indicated, the seed contains the *embryo*, or germ, of the future plant, which is generally surrounded by a nutritious substance termed the albumen, destined for the support of the young plant before its organs are sufficiently matured to allow of its supporting itself. This albumen varies very much in quantity, sometimes being much smaller than the embryo; while in other cases, as in the coco-nut, it weighs as many or more ounces than the embryo does grains. Its texture is variable. It is generally fleshy, as in the pea and bean; but sometimes it is farinaceous or floury, as in the wheat; at other times it is oily, as in linseed; horny, as in the coffee; or even stony, as in the vegetable ivory palm. If the embryo consists of one seed-lobe or cotyledon, as the wheat, it is said to be *monocotyledonous;* if of two, as in the beech and oak, *dicotyledonous*—and these terms are generally used respectively for endogenous and exogenous; while cryptogamous, or flowerless plants, from being propagated by spores instead of seeds, are said to be *acotyledonous*—that is, without any cotyledon whatever.

FRUCTIFICATION OF FLOWERLESS PLANTS.

As already stated, the lowest forms in which plants make their appearance are those of the *cryptogamous*, or flowerless orders—such as the ferns, lichens, mosses, sea-weeds, and fungi. In these, the mode of fructification is very remarkable, and quite different from that of flowering-plants. They have neither flowers nor proper seeds, but are propagated by minute unicellular bodies called *spores*.

Ferns.—In the ferns (*Filices*), which are the largest and most highly organised of the flowerless orders, little brown patches, called *sori*, may be seen on the under sides of the leaves or fronds (see figs.). Each of these is composed of a number



Ferns, shewing the Sori on the back of the Fronds.

of minute membranous capsules (*thecæ*), which contain the reproductive spores, and which are often furnished with an elastic ring, for assisting in rupturing the spore-case, and thus facilitating the dispersion of the spores. These spores are not the result of a process of fecundation similar to what has been described in the case of flowering-plants. Impregnation takes place, not upon the mature frond, but upon the infant fern, while as yet scarcely visible to the naked eye. The spores, when scattered over the soil, give rise to minute cellular expansions of tissue resembling liverworts, upon which male and female bodies, called respectively *antheridia* and *archegonia*, are produced. The former emit *spermatozoids*, which move about freely, by means of attached cilia. The archegonia have a central canal, leading down to a large globular cell. A spermatozoid enters the archegonial canal, reaches the globular cell, and

fertilises it. This cell divides, and is soon developed into an embryo, with a bud above and a radicle below; and then the circinate fronds shewing the genuine fern-structure arise. As an order, ferns are very widely distributed, generally consisting of a number of leaf-like members called *fronds*, which are the only visible portion of the plant. In some species, however, the stem rises above ground to the height of thirty to sixty feet, forming the well-known *tree-ferns* of New Zealand and tropical islands.

Fern Allies.—In the horse-tails (*Equisetaceæ*) of our marshes and ditches, the spores are placed on bracteated spikes, terminating the stems. Each spore is furnished with two elastic filaments, which are coiled around it, and are very hygrometric. The horse-tails are herbaceous perennial plants, having hollow striated stems, these being either simple or branched. In point of size, they are now insignificant members of the vegetable kingdom; but geology has revealed the gigantic proportions they bore in ages long past, when, instead of slender stems of a foot or two high, they reared their gigantic pillar-like trunks to a height of twenty or thirty feet. The spores of the pillworts (*Marsileaceæ*) are inclosed in little ball-like receptacles at the bases of the leaves (see fig.); the club-mosses (*Lycopodiaceæ*) have little cone-like spikes at the tips of their branches, between the scales of which occur small spores, while large ones occupy the axils of the leaves lower down.

Pillwort.

In the true mosses (*Musci*), the spores are inclosed in urn-shaped capsules, which generally stand out from the leaves on slender hair-like stalks. In the liverworts and lichens there is a somewhat similar provision; and in the algæ (sea-weeds), the spores are often inclosed in the substance of the plant.

The *fungi*, or mushroom tribe, are extremely diversified in their size, shape, colour, and consistence. They are entirely composed of cellular tissue. The common field-mushroom is one of the best known, and may be cited as typical of the family; but the mould on cheese, stale bread, the mildew on vines, the rust and smut on corn, and many other minute and yet unobserved appearances of a similar nature, are all fungi. Their organs of reproduction consist of spores variously arranged in different tribes, presenting resemblances in some to the lichens, and in others to algæ.

There is still much to learn respecting the cryptogamic orders, which yearly receive increasing accessions of students, for it is in these plants that the whole vital phenomena of vegetation can best be studied. 'We are entirely ignorant,' says Professor Lindley, 'of the manner in which the stems of those that are arborescent are developed, and of the course taken by their ascending and descending sap—if indeed in them there really exist currents similar to those of flowering-plants; which may be doubted. We know not in what way the fertilising principle is communicated to the sporules or reproductive grains; the use of the different kinds of reproductive matter found in most tribes is entirely concealed from us. It is even suspected that some of the simplest forms—of algæ and fungi, at least—are the creatures of spontaneous growth: and, in fine, we seem to have discovered little that is positive about the vital functions of those plants, except that they are reproduced by their sporules, which differ from seeds, in germinating from any part of their surface, instead of from two invariable points.'

General Economy of Flowerless Plants.—Insignificant and lowly as the cryptogamia may appear to the eye of the common observer, they are nevertheless important auxiliaries in the operations of nature. It is true that man and his works may suffer from their ravages, that mildew, rust in corn, and other microscopic forms of vegetation, by their rapid increase and destructive effects on the substances from which they spring, may cause incalculable damage; but this very scourge provides an incentive to intelligent prevention and care, while in creation there are no more useful scavengers of decaying matter than the fungi. In a dry season, for example, and on a favourable soil, rust rarely makes its appearance: certain conditions are necessary for its development; and it is to obviating these that the farmer must look for exemption from this destructive malady in his crops.

It will now be understood that mould is a fungus, produced by a previous deposit of germs in the tissue or on the surface of the object on which it grows. The proximate cause of its development is generally damp, and without this condition, the embryo remains in a dormant state. Still it may be asked, how cheese happens to have green mould at its very centre?—the reply is, that the germs floating in the atmosphere had various opportunities of finding admission into this article of diet. They may have been deposited on the grass of a field; the grass was eaten by the cow, and the germs were so lodged in the milk; or, what is more probable, the germs fell upon the curd, and there lay concealed till a certain dampness in the cheese brought their vegetative powers into operation. It is well known that the exposure of curd for a day to the atmosphere will have the effect of producing cheese liable to mould. A fully more surprising instance of fungus vegetation in a secluded situation, is that which occurs in the fermenting of yeast and other substances. Fermentation is, in one respect, a chemical process, forming a first step towards dissolution; but the action is also vegetative. The whole mass of matter gradually assumes the condition of active vegetative growth. The fungus germs which had been incorporated in the material begin to live and expand, each being a plant which grows and gives rise to new plants of the same species, until the entire fermenting principle is exhausted.

One great object which nature has in view by the germination and dispersion of the algæ, mosses, and lichens, is clearly that of preparing the way for a higher order of vegetation. It cannot possibly escape our observation that the tendency to vegetate is a power restless and perpetual. We hew a stone from the quarry, and place it in a damp situation, on the ground or in a wall, and shortly a green hue begins to creep over it. This is the commencement of a vegetable growth, produced by germs floated in the atmosphere; which, being attached at random to the stone, have been

brought to life through the agency of the moisture. Other stones equally exposed, but in dry situations, have also received a clothing of these germs, but circumstances not being suitable, they have not been developed: give the moisture, and they will immediately appear. We hew another stone from the quarry, and build it into the pier of a bridge, just within the surface of the water: shortly, a kind of green alga will appear; but the wet being in greater abundance, and more continuous, the growth will become more luxuriant than that of the terrestrial wall. Instead of the simple green coating, we have the addition of long filaments resembling hairs (*Confervæ*), which float and accommodate themselves to the water around.

Nature is incessantly working out vast ends by humble and scarcely recognisable means. It seems to be a principle that nothing shall remain stationary or unchanged. The whole surface of our planet is every instant altering in its features: mountains are being washed down into the plains, rocks are mouldering into soil, the sea is filling up at one place and encroaching on the land at another, and water-courses are constantly shifting their outlines. The duty of filling up seas, ponds, lakes, and rivers, is consigned to diverse means within the animal and vegetable economy; and one of these is the growth of algæ and other aquatic plants. Take a pond of water, and shut off its means of supply from rivulets and springs, and then observe what an effort nature will make to fill it up. The sides and bottom become speedily covered with a luxuriant crop of confervæ; other plants, which grow only in water, begin to make their appearance, their seeds being wafted thither by winds; at length the superficial matting of herbage is able to support the weight of birds; there is alternate vegetation and decay; finally, the pond is filled up, and a forest of the highest order of trees may in time cover the site of the original humble confervæ. What, indeed, are the extensive peat-mosses but lakes and pools choked with vegetable matter, which remains in a half-reduced condition. Thus we see that the green alga which grows upon stones in the water, humble and apparently insignificant as it is, performs a distinct and important part in creation.

SPECIAL PHENOMENA OF VEGETATION.

In addition to the ordinary functions of the organs, which are common to all plants, there are certain anomalous phenomena which cannot be reduced to regular laws, and which merit notice in this place; the most remarkable of these are the occasional *irritability* and *movements* of plants.

Irritability.—The irritability of animals depends entirely on their nervous system; but as plants have no nervous system, their irritability is more difficult to be accounted for. The principal phenomena of vegetable irritability may be divided into three kinds—namely, those caused by atmospheric influence, those depending upon the touch of other bodies, and those which appear to be perfectly spontaneous. Atmospheric influence occasions the closing of the leaves over the extreme point of the young shoot at night, as may be observed in the chickweed and several other common plants. The folding of some flowers in the absence of the sun, and the opening of others as soon as that luminary has withdrawn its beams, are ascribable to a similar cause. The pimpernel closes its flowers on the approach of rain. Most blossoms expand during sunshine; but the evening primrose, on the contrary, will not open its large yellow flowers till the sun has sunk below the horizon; and the night-flowering cereus only expands its magnificent blossoms about midnight. Some flowers are so regular in their hours of opening and shutting, that Linnæus formed what he called *Flora's Time-piece*, in which each hour was represented by the flower which opened or closed at that particular time. Solar light is the principal agent in producing these phenomena; but in some cases flowers will open by artificial light. De Candolle found blossoms expand beneath a lamp nearly as well as beneath the sun itself; and the crocus and gentian, which close at night, will expand as wide as possible when gently exposed to the light and heat of a fire. One of the most remarkable circumstances respecting the effect of atmospheric influences is, that the same causes do not affect all plants, and yet no peculiarity of construction has been discovered in those that are so affected to distinguish them from those that are not.

The irritability produced by external touch is a familiar but little understood phenomenon. The movements of the sensitive plant are well known; and it is also known that if the ripe seed-vessels of the noli-me-tangere be touched in the slightest manner, they will open with elasticity, and scatter their contents. In the same manner the fruit of the squirting cucumber (*Elaterium*) throws out its seeds, and the pulp in which they are contained, with violence, and to a considerable distance. The stamens of the barberry, when touched with a pin, spring forward towards the stigma, after which they return to their original position; while the column of the stylidium, which includes the style and stamens, and which generally hangs on one side, when touched, springs with a jerk to the other side of the flower. The most remarkable instance of irritability by contact is that exhibited by Venus's fly-trap (*Dionæa muscipula*), a native of North America. The leaves are very curiously constructed. They have broad leaf-like petioles, at whose extremity are two rounded fleshy lobes, which form the real leaf, and which are armed with strong spiny hairs, three on the blade of each lobe, and a fringe of longer ones round the margin. When an insect touches the central hairs, the leaf collapses, and the insect is entrapped. The leaf generally remains closed till the insect is dead. In Sarracenia, or the side-saddle flower, the leaves have a pitcher-shaped petiole, which forms a trap for flies and other insects, as well as the leaves of the Nepenthes, or pitcher-plant, but these do not display irritable phenomena.

a, Leaf of Venus's Fly-trap.
b, Leaf of Sarracenia.

The *spontaneous movements* of plants are equally difficult to be accounted for with those occasioned by atmospheric phenomena or by external touch.

It is true that the leaves elongate, the flowers expand, the anthers burst, and the seed-vessels open spontaneously; but these are movements caused by the progressive development of the plant, and subjected to regular laws. The spontaneous movements to which reference is now made are quite different—as, for example, those of the leaves of *Hedysarum gyrans*. This plant has compound leaves, the terminal leaflet of which displays a slight oscillatory motion; but the side-leaflets have such eccentric movements, as to render it difficult, if not impossible to explain them, and which might appear, indeed, to a fanciful mind as though the whole plant were actuated by a feeling of caprice. Generally, all the leaflets twist and whirl themselves about in an extraordinary manner, though the air of the hot-house in which they grow is perfectly still; but frequently the leaflets on only one side will be affected, and sometimes only a single leaflet will move, or all will become motionless together; and when this is the case, it is quite in vain to attempt to set them again in motion by touching them; though sometimes in a moment, after the touching has ceased, the leaflets will begin to move again as rapidly as before. In like manner, the side-leaflets frequently continue their movements all night, while the terminal leaflet remains quietly folded up. Cold stops the motion of the leaves, which begins again so soon as the heat of the stove in which the plant grows is renewed.

Plants may be deprived of their irritability by the vapour of prussic acid, chloroform, or ether.

Colour.—The colours of plants present many points of interest for the consideration of the student, and are connected with many important phenomena in vegetation. It is to colour, perhaps, more than to form, that vegetation, as a whole, often owes its importance in the landscape. The gay colours of plants usually reside in the corolla, the leaves being usually some shade of green; but in the case of sea-weeds and other cryptogams, the whole plant is often of a bright red, or green, or olive, according to the species, a character which has afforded the basis of the classification of sea-weeds now in use.

The green colour of leaves and the gay colour of flowers depend upon different kinds of colouring-matter contained in the cells of the plant, for the cell-walls are without colour themselves. In the green parts of plants, this colouring-matter is in the form of microscopically minute green granules of chlorophyll, which are only produced under the action of light; hence plants grown in the dark are etiolated. The changes which it undergoes, according to its state of oxidation, explain the tints which green leaves acquire in autumn. The yellow leaves of autumn contain proportionately more wax than the green leaves of summer, and the yellow rind of ripe fruits more than the green rind of unripe fruits.

The colours of parts not green are due to a different kind of colouring-matter, termed chromule, whose chemical relations to chlorophyll have not been fully investigated. Chromule is usually diffused throughout the sap of the cells; as in the flower of the tulip, for example, a strip of the epidermal tissue of which will shew well, under a common compound microscope, the beautiful arrangement of cells of different colours, so as to give the general effect seen in this gaudily painted flower. In some cases, however, chromule is found in the form of distinct granules. The colours of flowers are arranged in two series—the cyanic or blue, and the xanthic or yellow. A species belonging to the blue series may exhibit all shades of white, purple, and violet, but will not become yellow; and one belonging to the yellow series may exhibit all shades of white and orange, but will not become pure blue. Both series unite in red. Although light is essential to the development of the green colour of leaves, its immediate action is not always required for the development of the chromule of flowers—a fact quite in accordance with the practice of florists, who keep their favourite dahlia and pansy blooms covered up in their later stages. In accordance with this, also, is the fact, that flowers grown in the shade are seldom different in colour from those fully exposed to the air and light. Flowers may be made to change their colours by the influence of the soil in a most remarkable manner. The petals of the common hydrangea, which are naturally pink, are said to be made blue by planting the shrub in soil impregnated with iron, or providing it with charcoal. The change produced in tulips, carnations, heart's-eases, &c. is still more extraordinary. The flower of a seedling tulip is generally uniform; and after remaining of this colour two or three seasons, it will suddenly *break,* as the florists term it, into the most brilliant and varied tints of rose, white, yellow, brown, or purple, without leaving any trace of the original colour. To produce this change, florists try a variety of means, all of which have relation to the soil; for example, they sometimes keep their tulips in poor soil, and then suddenly transplant them into one exceedingly rich; or they reverse the process: at other times they change them suddenly from a sandy to a clayey soil. Even the chlorophyll of plants is often developed under circumstances where the influence of light is very slight, and would appear to depend in some measure upon other agents. Ferns and mosses have been found green in mines where they have grown in almost total darkness; and green and red sea-weeds of the most brilliant tints grow at great depths in the ocean, where the light, being weakened by passing through such an immense body of water, can have but little colouring effect.

Although it has been stated by Ruskin that 'the natural colour of objects never follows form, but is arranged on a different system,' the investigations of Professor Dickie on the relations between colour and form in plants seem to indicate a different result. He finds—1. That in polypetalous and gamopetalous flowers, of regular form—such as the primrose, gentian, and pimpernel—the distribution of colour is uniform on the different petals, whether free or in cohesion, whatever be the number of colours present; 2. That flowers whose form is irregular—as, for example, papilionaceous flowers, where certain petals are larger than the others—present an equally irregular distribution of colour, whether one or more colours be present; 3. That different forms of corolla, in the same head of flowers, often present differences of colour; but all of the same form agree also in colour.

Fragrance.—The cause of fragrance in flowers has never yet been fully explained. All organised bodies consist partly of volatile matters,

and thus we can readily account for the odours given out by decaying animal and vegetable substances, as they evidently proceed from the volatile parts being liberated by decomposition. The fragrance of flowers, however, escapes while the plants are in a living state, and that most abundantly when they are in vigorous and healthy condition. Besides the flowers, other parts of living plants frequently exhale fragrant odours—such as the leaves of the myrtle and geranium, and the wood and bark of pines. All these odours proceed from oily or resinous matters contained in the receptacles of secretion; but the laws which regulate their liberation, and define their physiological uses, are as yet imperfectly known. The odours of plants are of three kinds: permanent, fugitive, and intermittent. Permanent odours are those given out slowly by the plant, not only whilst it is living, but also after the fragrant part has been separated from the living plant. Of this kind are the odours of fragrant wood, of the dried petals of roses, and some other flowers. Intermittent odours are the most difficult to be accounted for by the vegetable physiologist. It is well known that the night-smelling stock and several other plants, which are entirely devoid of scent during the day, are delightfully fragrant during the night. One of the orchideous plants produces its powerful aromatic scent only when exposed to the direct rays of the sun; and the flower of the night-blowing cereus is fragrant only at intervals during the time of its expansion.

Tastes.—The tastes produced by vegetable substances are generally recognised as sweet, acid, bitter, astringent, austere, or acrid. As a general law, it may be stated that the drier and warmer the situation, the more exposed to light, and the slower the growth of any vegetable, the more intense is its peculiar flavour.

Luminosity, Heat, Electricity.—The luminosity of plants—that is, the evolution of light either from living or dead vegetable structure—is a rare and curious phenomenon. Flowers of an orange colour, as the marigold and nasturtium, have been occasionally observed to present a luminous appearance on still warm evenings; this light being either in the form of slight electric-like sparks, or steadier, like the phosphorescence of the glow-worm. Certain fungi, which grow in warm and moist situations, produce a similar phosphorescence; and decaying vegetables, like dead animal matter, have been observed to emit the same kind of luminosity. This phenomenon seems connected with the absorption of oxygen; and the parts emitting it are said to be most luminous when immersed in pure oxygen, and cease to emit it when excluded from that element.

The evolution of heat by living plants is a more common phenomenon. We are aware that warm-blooded animals have the power of keeping up a certain temperature within them, which varies at certain stages of their growth, and perhaps periodically. This result is obtained by respiration—the oxygen of the atmosphere uniting with the carbon of their blood, and producing a kind of combustion. A similar, though less understood phenomenon, seems to take place in the respiration of plants. In germination, heat is sensibly evolved; a piece of ice placed on a growing leaf-bud will dissolve, when it would remain unchanged in the open air; and experiment has proved that the surface of plants is three or four degrees higher than the surrounding medium. Again, the internal temperature of a large trunk is always higher than the surrounding atmosphere, and though young shoots are sometimes frozen through, the general structure both of the wood and bark is such as to conduct heat so slowly, that the internal warmth is seldom reduced beyond what seems necessary to the maintenance of vitality. Generally speaking, it may be asserted that plants possess an internal vital temperature, and that in the so-called process of respiration—the giving off of carbonic acid or oxygen, as the case may be—a certain degree of heat is evolved; but precise experimental results are wanting. At the time that the essential organs of flowers are fully developed, a certain amount of heat is given out. This heat is rapidly carried off by the air, and is therefore not easily detected; but in certain cases, especially in plants belonging to the natural order *Araceæ*, the elevation of temperature is very marked; the temperature inside the flowering spathe varying from 10° to 50° F. above the surrounding atmosphere.

The connection of electricity with vegetable growth has recently excited the attention of physiologists; but little positive information has yet been ascertained. It has been long known that growth takes place with great rapidity during thundery weather; but this may result from the nitrogenised products of the showers which then fall, as well as from the effects of electricity. The progressive states of vegetable growth are the result of chemical changes; and as these changes are more or less accompanied by electricity, it is supposed that plants evolve electricity as well as heat. The general electric state of plants is said to be *negative;* and some have attempted to connect the luxuriant vegetation of the tropics with the thunder-storms of these regions, on the supposition that when the atmosphere is *positively* electrified, the two opposite states will give rise to such commotions.

SECRETIONS AND EXCRETIONS OF PLANTS.

Substances of varied properties are secreted by plants, and otherwise formed in their tissues according to their respective natures, and their healthy or diseased condition at the time of secretion. Some of these substances are produced by the ascending sap; but the greater number are deposited by the elaborated or proper juice, and consequently are seldom secreted during spring or early summer. The intensity of those derived from the latter source depends in a great measure upon the influence of solar light; hence they are much stronger, and more abundantly produced, in tropical than in temperate climates. From the manner in which many of these are deposited or ejected, they appear to be of little or no utility in the vegetable economy. Some of them may be regarded as *excretions* as well as *secretions;* but whether they are to be considered as essential components of the sap, or evacuations necessary to the healthy condition of the organs, has not yet been determined. Being exceedingly varied in their properties, they are of great utility to man as articles of food, medicine, ornament, and luxury.

The economical applications of vegetable secretions and excretions are so numerous, that it would be impossible, in our limited space, to enter upon

anything like details. It is even difficult to attempt any classification of them; for, though differing in their properties and external appearance, many of them are identical in chemical composition, and, subjected to peculiar treatment, readily pass into new and singular combinations. Some, for instance, are saccharine, as the juice of the sugar-cane. Many are oleaginous, balsamic, or resinous; some are narcotic, aromatic, or mucilaginous; while others are astringent, purgative, or poisonous. For examples of these divisions, we have such substances as palm and olive oil, myrrh, resin, opium, camphor, gum-arabic, tannin, gamboge, prussic acid, aloes, colocynth, and many others of everyday familiarity.

Besides the proper excretions and secretions, there are several adventitious substances found in plants, which are not the products of vital organisation. Lime, for instance, is found in the ashes of many plants in union with acids; sometimes it is excreted in the form of a thin crust on their leaves, and in other cases in peculiar cells. Silica also occurs in considerable quantities, especially in the stems of reeds and grasses; it forms the glossy pellicle of the cane, and is sometimes found in the joints of the bamboo, where it is deposited in a soft pasty mass, called *tabasheer*, which ultimately hardens into pure semi-transparent silica. *Equisetum hyemale*, called Dutch-rushes, contains a large quantity of silica, and is used for polishing mahogany. Besides these earths, there are various metallic oxides and salts, and the well-known alkalies—potash and soda. The physiological uses of such products are but imperfectly known. Many of them—such as starch, gum, sugar, and the fixed oils—directly administer to the support of the young plant and to the formation of new tissues. Others, again—such as silica and metallic oxides—give hardness and stability to the stems and branches; some give elasticity and pliancy to the young shoots, thereby preventing them from being broken by winds; and several—as tannin, for example—seem to administer to the durability of the woody tissue.

METAMORPHOSES OF PLANTS.

The metamorphoses of plants, in the general sense of the term, form one of the most interesting sections of Vegetable Physiology. Technically, it is termed *Morphology*—that is, a consideration of the changes and transformations which various parts of plants undergo, either from natural or artificial causes. We know, for instance, that many plants are made to change their appearance and qualities by cultivation; that by grafting, hybridising, and other means, the gardener can change the size, colour, and qualities of his fruits and flowers: and that analogous changes take place in a state of nature—such as the conversion of petals into leaves, and leaves and branches into thorns and spines. It is also well known that flowers become double by changing their stamens into petals; and it is from a knowledge of such facts that botanists have asserted that all the parts of the flower and fruit, as well as the appendages of the stem or ascending axis, are modifications of a single typical organ, and may be considered *as leaves adapted to special purposes.*

The law which it seeks to establish may be stated to be this: that all the appendages of a plant have a common origin with the leaf, and may therefore successively assume the form and appearance of that primary organ. The branches of the stem take their origin from leaf-buds, and are clothed with branches and leaves by the same process as in the main stem. Towards the point of fructification, the leaves assume the form of bracts; these, again, are succeeded by the leaf-like sepals of the calyx; and next by the petals of the corolla. Within the petals are the stamens—which sometimes assume a leafy form—next the pistil, and ultimately the seed-vessels. Even the seeds are but leaves in another form. Thus, the growth and reproduction of plants may be regarded as a circle of leaf-like changes, the leaf, or some modification of it, being in all cases the organ which administers to the functions of vitality. As there is an indubitable passage from leaves to every other organ, so may any one organ be found to revert to the primary form of the leaf. In the double-flowering cherry, so common in shrubberies, the stamens are changed into petals, and the ovary into a green leaf!

The *hybridism* of plants is closely allied to the subject of morphology, and is, in fact, a process of transformation of an artificial character. As among animals two distinct species of the same genus will produce an intermediate offspring—such as the *mule*, which is the offspring of the horse and ass—so among vegetables, two species belonging to the same genus can be made to produce a *hybrid;* that is, a new plant possessed of characters intermediate between its parents. This power of hybridising is more prevalent among vegetables than animals; for the different species of *many* genera of plants are capable of producing this effect, if the pollen of one species be put upon the stigma of another. And this crossing may even be applied to separate genera. Hybrids have not the power of perpetuating their kind like naturally distinct species; for, though occasionally fertile in the second and third generations, they have never been known to continue so permanently. But though incapable of propagating beyond a limited period, the pollen of the parent species may be made to fertilise them, or their pollen to fertilise the parent; but in either case the new offspring gradually merges into the original species. Thus nature has wisely set a limit to the intermingling of species, by which they are preserved from ultimately running into confusion and disorder. In an economical point of view, hybridism is of great value to man. By a knowledge of its principles, he has been enabled to modify the characters of natural species, so as to adapt them to his special purposes; and thus have arisen most of those beautiful varieties of what are termed florists' flowers, which now adorn the flower-garden. So also by crossing varieties of the same species, our grains, fruits, and kitchen vegetables have been brought to a high state of perfection.

SYSTEMATIC BOTANY.

BOTANY is the science whose purpose it is to investigate the Vegetable Kingdom. *Vegetable Physiology*—treated of in the preceding article—is that department of the subject which explains the organisation and vital functions of plants; *Systematic Botany*, that which recognises their arrangement into groups, according to their form and structure. The former relates to functions which are common to all vegetables; the latter takes notice only of such peculiarities as serve to distinguish one species from another, or one family from another family. The vegetable kingdom is supposed to contain upwards of 150,000 species; and therefore, without some system of arrangement into smaller groups and orders, it would be difficult to acquire a knowledge of the special characteristics of plants, or to convey that knowledge to others by any process of description. It is the aim of Systematic Botany to obviate this difficulty, by classifying plants according to certain types and resemblances which are common to a number of species; thus making one description equally applicable to a class as to a species.

The advantages of classification in lessening the labour of memory and description, become strikingly apparent when we reflect on the difficulty which would exist were each plant to be known by an entirely distinct name. For example, there are many species of roses, all of which are known by the generic term *Rosa*, each having a second or specific name to designate it separately, as *Rosa canina* (the dog-rose), &c. Now, if a botanist hear of a plant called *Rosa*, though its specific name be quite new to him, he has instantly a general idea of what sort of plant it is, from his previous knowledge of the common characteristics which belong to the genus *Rosa*. The principle of classification is to assemble those plants which bear most resemblance to each other; and this has been done in different ways by different botanists; each method being called the *system* of the individual who devised it—as Tournefort's system, Linnæus's system, Jussieu's system. Of the several systems which have been suggested, only two are in use at the present time—namely, that of Linnæus, the great Swedish naturalist (1707-1778); and the Natural System, in its numerous modifications, that of Jussieu, an eminent French botanist, who, during the long period between 1789 and 1836, was closely engaged in improving the nomenclature and arrangement of the vegetable kingdom, having afforded the basis of those mostly in use.

The system of Linnæus is founded on the *sexes* in plants—the number, situation, proportion, and connection of stamens and pistils, which are regarded as respectively the male and female organs, being chosen to supply characters for the classes and orders. This system appears at first sight extremely simple, as it depends entirely on the counting of so many visible parts; but it is very uncertain, as the number of stamens often differs, from accidental circumstances, in plants of the same genus; and it tells nothing of the plant but its class and order, which lead only to the discovery of its technical name, as plants of the most opposite qualities frequently agree in the number and disposal of their sexual organs. This mode of classification is known among botanists as the Sexual System, or the *Artificial System*, because it is founded on mere artificial enumeration, on a single series of characters, and not upon natural qualities or resemblances of the plants so arranged. That of Jussieu, on the contrary, is founded on the natural affinities; and the botanist who is acquainted with its principles can at first sight assign any plant to its proper class and order, as there is always a general resemblance among the plants belonging to the same natural order. Again, knowing the order, which is usually typified by some common plant, he can predict as to its properties—a species of information which the artificial system does not attempt to convey. Jussieu's method has been greatly improved since the time it was suggested, particularly by the late Professor De Candolle of Geneva; and it is his modification of the original plan, with further improvements, which constitutes the most generally adopted *Natural System* of the present day.

According to both systems, plants are divided into classes, orders, genera, species, and varieties. A *class* consists of plants resembling each other in some grand leading feature, and as strongly differing from another class as mammalia do from birds, for example. Thus, flowering-plants with one cotyledon (or seed-lobe), whose trunks increase in thickness from within—as the palm—form a distinct class; while flowering-plants with two cotyledons, and whose trunks increase by external layers, constitute another class. An *order* consists of plants still more closely allied, so that many orders may be found in the same class. Thus, as ruminant or cud-chewing animals form an order of mammalia, so do the leguminous or pod-bearing plants constitute an order of dicotyledonous vegetation. A *genus* consists of plants so very closely allied, that they may be compared to members of the same family. The pea, for example, constitutes a genus of leguminous plants, just as sheep form a family of the ruminants. A *species* may be compared to one of the members which compose the family; thus the garden-pea and sweet-pea are different species of the same genus. A *variety* is merely a departure from the common appearance of the species in trivial characters, or differences which arise from climate, situation, greater or less humidity of soil, and other accidental causes. The boundaries between species and varieties are often very vague, some botanists regarding those plants as species which others consider mere varieties; but much doubt might be removed by attending to the fact, that a species reproduces itself from seed, and is always persistent under the same circumstances, whereas a variety has often a tendency to revert to its parent species, unless propagated by cuttings, and fostered by artificial means. A *hybrid* is a plant raised by fecundating the stigma of one species with the pollen of another—a process which

occasionally occurs among plants in a wild state, but is more common in cultivation. Unless perpetuated by artificial processes, they are liable to die out, or revert to their original stock.

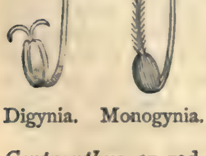
In botanical nomenclature, the name of every plant consists of two words; the first is the name of the genus, and the second that of the species—as, for example, *Quercus alba*, the white oak. When three names are given, the third signifies that the plant is a variety; and this is sometimes more strongly marked by using the contraction *var.* before the third name—as, *Quercus Ilex* var. *crispa*, the curled-leaved variety of the evergreen oak. The third name is for the most part omitted in botanical catalogues, and the varieties indicated by letters of the Greek alphabet—observing that the varieties begin with the letter β—as, *Quercus Ilex β crispa*.

The primary arrangement of plants, according to both the artificial and natural systems, is into those with flowers and those without flowers. The first division, or that which includes the flowering-plants, is distinguished by the name PHANEROGAMIA, and in them the organs of reproduction are apparent. It comprehends all the trees and shrubs used in the economical arts, as well as the common ornamental plants of our gardens, and, in short, all those that have distinct organs—as leaves, branches, flowers, and proper seeds. The second division, known by the term CRYPTOGAMIA, embraces, as the name implies, those plants in which the organs of reproduction are not apparent—as the ferns, lichens, mosses, and sea-weeds. They have no flowers or seeds, in the common acceptation of these words, and their *fronds* or leaves are very different from those of flowering-plants; instead of flowers, fruit, and seed, they are furnished with little cases or *thecæ*, and in these are lodged the reproductive spores, minute as the particles of the finest dust. Here the resemblance between the two systems ceases—their classes and orders being arranged on totally different principles. We shall present, in the first place, an outline of the Linnæan system, both on account of its priority and simplicity, and as an initiatory step to gaining a knowledge of the different forms of flowers. It is true that it is now disused by most men of science; but for the reasons already stated, as well as from the fact that many excellent works have been arranged on its plan, it is necessary that the general reader, as well as the botanist, should have an acquaintance with its leading features.

THE LINNÆAN SYSTEM.

The sexuality of plants had been discovered before the time of Linnæus; but as far as is now known, he was the first who suggested the adoption of this characteristic as a basis of classification. According to his system, the vegetable kingdom is divided into twenty-four *Classes*, founded upon the number, the proportionate lengths, the connection, or the situation of the stamens. These classes are again subdivided each into one or more *Orders*, depending upon the number of the pistils, the presence or apparent absence of a seed-vessel, its shape, or the number and connection of the stamens, or on the arrangement of the florets. Terms compounded of the Greek numerals and the word *andria*, or male, are for the most part used to designate the classes; and similar compounds of these numerals, and the word *gynia*, or female, are employed to designate most of the orders. The following synopsis presents an outline of the system.

CLASSES.			ORDERS.
1. Monandria	1 stamen		has 2—Monogynia and Digynia, or 1 and 2 pistils.
2. Diandria	2 stamens		" 3—Monogynia, Digynia, and Trigynia.
3. Triandria	3 "		" 3—Monogynia, Digynia, and Trigynia.
4. Tetrandria	4 "		" 3—Monogynia, Digynia, and Tetragynia.
5. Pentandria	5 "		" 6—Mono., Di., Tri., Tetra., Pentagynia, and Polygynia.
6. Hexandria	6 "		" 4—Monogynia, Digynia, Trigynia, and Polygynia.
7. Heptandria	7 "		" 4—Monogynia, Digynia, Tetragynia, and Heptagynia.
8. Octandria	8 "		" 4—Monogynia, Digynia, Trigynia, and Tetragynia.
9. Enneandria	9 "		" 3—Monogynia, Trigynia, and Hexagynia.
10. Decandria	10 "		" 5—Monogynia, Digynia, Trigynia, Pentag., and Decagynia.
11. Dodecandria, from 12 to 19	"		" 7—Mono., Di., Tri., Tetra., Penta., Hexa., and Dodecagynia.
12. Icosandria	20 or more "	on the corolla or calyx	" 3—Monogynia, Di.-Pentagynia, and Polygynia.
13. Polyandria	20 or more "	on the receptacle	" 6—Mono., Di., Tri., Tetra., Pentagynia, and Polygynia.
14. Didynamia	4 "	2 long and 2 short	" 2—Gymnospermæ and Angiospermæ.
15. Tetradynamia	6 "	4 long and 2 short	" 2—Siliculosa and Siliquosa.
16. Monadelphia, all the filaments united			" 8—Tri., Pent., Hex., Hept., Oct., Dec., Dodec., and Polyand.
17. Diadelphia, filaments united into two bundles			" 4—Pentandria, Hexandria, Octandria, and Decandria.
18. Polyadelphia, filaments in three or more bundles			" 2—Decandria and Polyandria.
19. Syngenesia, five stamens united by their anthers			" 5—Polyg.-Æqualis, Superfl., Necess., Frustranea, Segregata.
20. Gynandria, the stamens growing on the pistil			" 3—Monandria, Diandria, and Hexandria.
21. Monœcia, flowers with stam., others with pist. on same plant			" 10—Mona., Di., Tri., Tet., Pen., Hex., Oct., Icos., Polyan., Monadelphia.
22. Diœcia, stamens on one plant, and pistils on another			" 13—Mo., Di., Tr., Tet., Pen., Hex., Oc., En., Dec., Do., Ic., Polyand., and Monadelphia.
23. Polygamia, unisex. or bisex. flowers on same or diff. plants			" 2—Monœcia, Diœcia.
24. Cryptogamia—inconspicuous flowers			" 5—Filices, Musci, Lichenes, Fungi, Algæ.

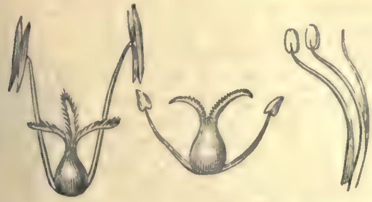


Digynia. Monogynia.

I. MONANDRIA.—The first order of this class contains many highly ornamental exotics, chiefly herbaceous plants, with large leaves and showy flowers. Examples—turmeric, arrow-root, and ginger of commerce. Several of the genera are British—as *Hippuris*, or mare's-tail, and *Centranthus*, or red valerian. The second order, DIGYNIA, contains *Callitriche*, the water-starwort, and *Blitum capitatum*, the strawberry blite.

II. DIANDRIA.—Flowers with two stamens, and with one, two, or three pistils; thus constituting three orders, of which there are upwards of sixty genera. The first, MONOGYNIA, contains by far the greater number of the genera. Examples—the speedwells, olive, fragrant jasmine, lilac, and many evergreen shrubs. The rosemary, and the numerous species of sage and salvia, are ranked

in this order, though some botanists have suggested the removal of the latter plant to the class DIDYNAMIA, because, in addition to the two perfect



Trigynia. Digynia. Monogynia.

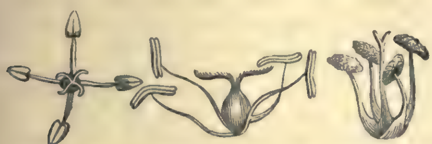
stamens, there are the rudiments of two others in the flower.

III. TRIANDRIA.—Almost all the grasses, including the grain-bearing *cereals*, are found

Trigynia. Digynia. Monogynia.

in this class. The crocus, corn-flag, and iris, and many allied foreign genera, also belong to it.

IV. TETRANDRIA.—Flowers with four stamens *of equal length*. The equal length of the stamen should be specially kept in mind, because the fourteenth class (DIDYNAMIA) has also four stamens, but of these two are longer than the others. Many of the genera of this class are beautiful shrubs and



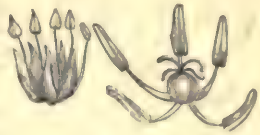
Tetragynia. Digynia. Monogynia.

trees, chiefly natives of the Cape of Good Hope and Australia—as the *Proteas*, *Hakias*, *Banksias*, and the splendid waratah or *Telopia speciosissima*. The common pond-weeds (*Potamogeton*), the bed-straws (*Galium*), and the Lady's-mantle (*Alchemilla*), also belong to this class.

V. PENTANDRIA.—The curious *Stapelia*, bearing flowers of uncommon character both in shape

Digynia. Monogynia.

and colour, and moreover diffusing a scent so loathsome, that blow-flies lay their eggs on the petals! The dodder (*Cuscuta Europæa*), the elm-tree, the ornamental laurustine, the elder, the sumach family, the Grass of Parnassus, pansy, primrose, forget-me-not, hemlock, flax, potato, and other plants, belong to this class.



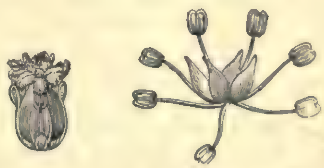
Pentagynia. Tetragynia.

VI. HEXANDRIA.—Flowers with six stamens of *equal length*. By far the greater number of our bulbous flowering and culinary plants—as the narcissus, the tulip, the lilies, the long-lived American aloe, the magnificent *Crinum* and *Pancratium*, the pine-apple, the onion, asparagus, &c.—belong to this class.

Digynia.

VII. HEPTANDRIA.—This class is illustrated by the *Æsculus* and *Pavia*, better known by the name horse-chestnuts. It is remarkable that among above 3000 genera, so few should occur with seven stamens. The chickweed winter-green (*Trientalis Europæa*)

Digynia. Monogynia.



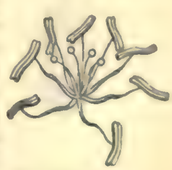
Heptagynia. Tetragynia.

is the only British plant belonging to this class.

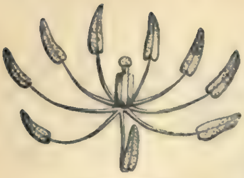
VIII. OCTANDRIA.—The heaths are the most conspicuous and numerous examples of the class. Of this family alone there are about 550 species

Trigynia. Digynia. Monogynia.

already described, chiefly natives of the southern parts of Africa. Six are found in Britain, and several in other parts of Europe. The curious *Rhexia*, the day and night flowering *Œnothera*, the *Fuchsia*, the *Mezereon*, the sea-side grape and soap-berry of the West Indies, the curiously organised *Bryophyllum*, and other genera, belong to the class.

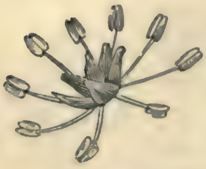


Tetragynia.



Monogynia.

IX. ENNEANDRIA.—This class includes the cinnamon, the laurel, the medical and culinary rhubarb, the flowering rush of Britain (*Butomus umbellatus*), found in ponds and ditches in a few localities in this country.



Hexagynia.

Trigynia.

X. DECANDRIA.—Many of the species of this

Decagynia.

Pentagynia.

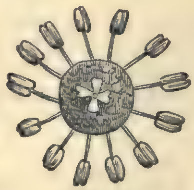
Trigynia.

class are brilliantly flowering plants, such as those of the *Kalmia*, *Ledum*, *Rhododendron*, *Andromeda*, *Arbutus*, *Hydrangea*, *Saxifraga*, *Dianthus* (which includes the carnation, pink, and sweet-william), *Lychnis*, *Stellaria*, *Oxalis*, and *Sedum*.

Digynia.

XI. DODECANDRIA.—There is no plant yet discovered with eleven stamens, and all those of this class have the number varying from twelve to nineteen. The class includes the mangosteen, the garlic-pear, the showy British *Lythrum Sali-*

Pentagynia.



Tetragynia.

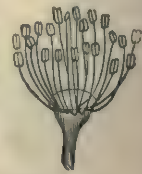
caria, agrimony, *Reseda*, one species of which (weld) is used by the dyer for producing a yellow colour; while another, *R. odorata*, is the mignon-

Monogynia.

Dodecagynia.

ette, *Sempervivum*, or house-leek, *Asarum* or Asarabacca, *Cephalotus*, whose leaves are formed into pitchers, like those of the *Nepenthes*, or pitcher-plant.

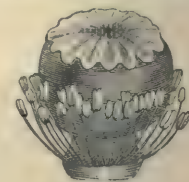
XII. ICOSANDRIA.—Flowers having twenty or more stamens seated upon the corolla or calyx. The situation, and not the number of the stamens, furnishes the characters of the class. It includes the roses, the Cactal genera, *Cereus*, *Epiphyllum*, and *Opuntia;* the myrtle, and its allied genera, *Eugenia* and *Eucalyptus*, the guava, pomegranate, pear, apple, quince, cherry, strawberry, raspberry, &c.



Monogynia.

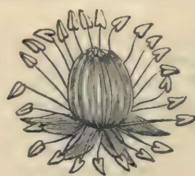
XIII. POLYANDRIA.—Flowers having an unlimited number of stamens, distinct from each other, and seated on the receptacle. This class comprises, among many others, the

Trigynia.



Monogynia.

caper-tree, the poppy, the curious sarracenia, the magnificent water-lilies, the *Bixa orellana* (arnotto),



Polygynia.

Pentagynia.

the magnolia, the pæony, the larkspur, the aconite, the columbine, the anemone, the buttercups, the globe flower, the marsh-marigold, &c.

XIV. DIDYNAMIA.—The flowers of this class are generally ringent; they have four stamens, *two of which are longer than the others.* The flowers of the fourth class have also four stamens, but these are of equal lengths; while in this, two are long and two short. The calyx also is tubular, divided into five or two lipped segments, which are unequal and persistent. The corolla is of one petal; the upper lip concave, and sometimes bifid; the lower lip trifid. In the first order, the so-called GYMNOSPERMÆ, the germander, lavender, mint, dead-nettle, and many others of similar

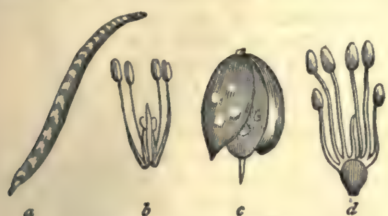
Angiospermæ.

Gymnospermæ.

character occur. The order ANGIOSPERMÆ, so called because, though the stamens are the same

in number and position, the seeds are differently disposed, being contained in a more evident capsule than the preceding. To this order the bignonia, antirrhinum, mimulus, gloxinia, common foxglove (*Digitalis purpurea*), &c. belong.

XV. TETRADYNAMIA.—Flowers with six stamens, four of which are longer than the other two. Linnæus divided this class into two orders—SILICULOSÆ and SILIQUOSÆ—the former being a short roundish pod (*c*), and the latter a long one (*a*). The cabbage, turnip, radish, wallflower, stock, rocket, &c. belong to this class. This is a truly natural class of plants, forming the order *Cruciferæ* of Jussieu; great similarity of the flowers, seeds, &c. being observable throughout the whole of the genera. The calyx is four-leaved,



Stamens and Seed-vessels.

sepals concave, equal, and deciduous; corolla of four petals, claws inserted into the receptacle, limbs widening outwards in a cruciform manner.

XVI. MONADELPHIA.—The stamens are united into one set or brotherhood in this class, which is divided into eight orders, founded on the number

Octandria. Heptandria. Pentandria. Triandria.

of the stamens, not on that of the pistils, as in other classes. In the first order, TRIANDRIA, we find several beautiful Cape bulbs—as the *Tigridia*, *Herbertia*, &c. Of the second order, PENTANDRIA, the passion-flower is the most remarkable. There is also the *Erodium* or stork's-bill, a genus allied to the geraniums. The third order, HEXANDRIA, contains but one genus, a bulbous-rooted plant, called *Gilliesia graminea*, having grass-like leaves and curious flowers. The fourth order, HEPTANDRIA, contains the pelargoniums, commonly called geraniums. The fifth order, OCTANDRIA, having eight stamens, united in one set, contains the genus *Aitonia*, named by Linnæus in honour of the late William Aiton, royal gardener at Kew. In the sixth order, DECANDRIA, we find the true geraniums or crane's-bills. The seventh order, DODECANDRIA, are all tropical plants. In the

Polyandria. Dodecandria. Decandria.

eighth order, POLYANDRIA, are *Althea*, *Lavatera*, *Hibiscus*, *Sida*, silk-cotton tree, the tea-tree, and its magnificent congener, the camellia.

XVII. DIADELPHIA.—Flowers having two sets or brotherhoods of stamens. In general, nine are

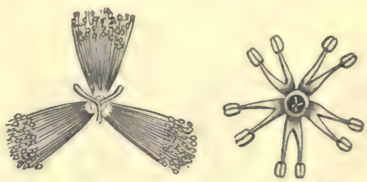
Hexandria. Pentandria.

united together, with a single one by itself, which is accounted the second brotherhood. Examples: *Monnina trifolia*; *Fumaria*, fumitory; and *Poly-*

Decandria. Octandria.

gala, the milkwort, and many leguminous plants—such as the common pea, furze, broom, genista, laburnum, rest-harrow, and lupine.

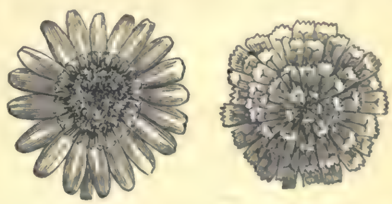
XVIII. POLYADELPHIA.—This class contains all plants whose flowers have their stamens arranged in many brotherhoods. Among the plants of this class is the *Theobroma*, which yields



Polyandria. Decandria.

chocolate. This disposition of the parts on which the order is founded, is exemplified in the species of *Hypericum* or St John's wort.

XIX. SYNGENESIA.—This large class contains all the compound or composite flowers which form the natural order *Compositæ*. The first order is ÆQUALIS, in which all the florets are hermaphrodite. It contains the sow-thistle, lettuce, hawkweed, burdock, artichoke, &c. The second order

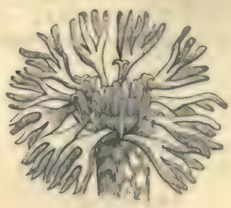


Superflua. Æqualis.

is SUPERFLUA, the flowers of which have the florets of the disc bisexual, and those forming the rays female. This is also a very large order, of which tansy, chamomile, helichrysiums, xeranthemums, dahlias, &c. are examples. The third order is FRUSTRANEA, so called because the florets of the disc are bisexual, and those in the ray or margin neuter. To this belongs the sunflower, the *Rudbeckia*, *Coreopsis*, &c. The fourth

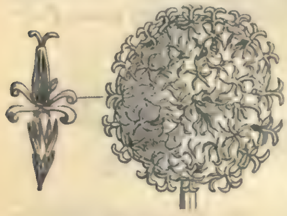
order is NECESSARIA, because the florets of the

Necessaria.



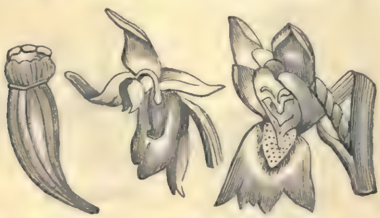
Frustranea.

disc, or centre of the flower, being all male, it is necessary that those of the ray or margin should be female, in order that there may be perfect seed produced. Example: *Calendula*. The fifth order is called SEGREGATA, because the florets have each its proper involucre. All the plants in this order are exotic herbs and under-shrubs, the globe-thistle being the most common in British gardens.



Segregata.

XX. GYNANDRIA.—This class contains plants which have their stamens seated upon the pistil. The class is divided into three orders; the first,



Hexandria. Diandria. Monandria.

MONANDRIA, having one anther seated on the pistil, and comprises *Orchis*, *Ophrys*, *Epipactis*, &c. In the second order, DIANDRIA, the flowers have two anthers on the pistil; to this belongs the ladies'-slipper. The third order, HEXANDRIA, containing plants which have six stamens seated in the pistil, has only one genus—namely, the *Aristolochia*, or birthwort.

XXI. MONŒCIA.—This class (meaning one

Diandria. Monandria.

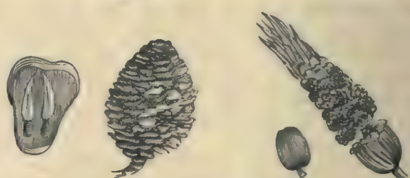
household) consists of plants which have male and female flowers separate, but on the same root—such as the bread-fruit tree, the *Zannichellia palustris*, the maize or Indian corn (*Zea*), the box, the mulberry, the common nettle, the *Aucuba japonica*, the *Amaranthus*, the coco-nut and other palms, *Begonia*, the chestnut, beech, hazel, walnut, oak, pines and firs, larch, cedar, cypress, gourd, melon, and cucumber, the poisonous manihot, the castor-oil, and the cuckoo-pint or wake-robin (*Arum maculatum*). There are ten orders, distinguished by the number and arrangement of the stamens, &c. some of which are illustrated in the wood-cuts. To this class belong the *Carices* or sedges, and also the *Eriocaulon septangulare*.

Triandria. Monandria.

Triandria.

Pentandria. Tetrandria.

Polyandria. Hexandria.



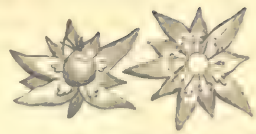
Monadelphia.

XXII. DIŒCIA.—This class is composed of plants which have unisexual flowers, not on the same, but on different individuals, such as the screw-pine, the willow, poplar, crow-berry, date-palm, candle-berry myrtle, sweet gale, spinach, mistleto, hop, hemp, &c. The orders are distinguished by the number, &c. of the stamens, as indicated in the following wood-cuts:

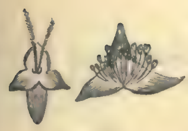
Hexandria. Pentandria.

Enneandria.

Octandria.

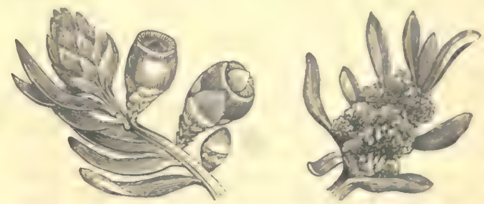


Decandria.



Polyandria.

Icosandria.



Monadelphia.

XXIII. POLYGAMIA.—The class POLYGAMIA (a word signifying many marriages) contains plants having both unisexual and bisexual flowers on the same or on different individuals. There is considerable uncertainty about the arrangement of this division, because some of the genera are not always constant in their modes of flowering; and even single plants will occasionally exhibit all the characters by which the different orders are distinguished. Here are the mimosas, the acacias,

Diœcia.

the maples, the Ailantus, the mango, some palms, the anacardium, and the figs.

XXIV. CRYPTOGAMIA. — The class CRYPTOGAMIA (a term signifying hidden marriages) consists of the flowerless plants corresponding with the class of the same name in the natural system. It is illustrated by ferns, mosses, lichens, fungi, and sea-weeds.

THE NATURAL SYSTEM.

'The Natural System of Botany,' says Dr Lindley, 'being founded on these principles—that all points of resemblance between the various parts, properties, and qualities of plants shall be taken into consideration; that thence an arrangement shall be deduced in which plants must be placed next each other which have the greatest degree of similarity in these respects; and that consequently the quality of an imperfectly known plant may be judged of by that of another which is well known —it must be obvious that such a method possesses great superiority over artificial systems, like that of Linnæus, in which there is no combination of ideas, but which are mere collections of isolated facts, having no distinct relation to each other. The advantages of the Natural System, in applying botany to useful purposes, are immense, especially to medical men, who depend so much upon the vegetable kingdom for their remedial agents. A knowledge of the properties of one plant enables the practitioner to judge scientifically of the qualities of other plants naturally allied to it; and therefore the physician acquainted with the natural system of botany may direct his inquiries, when on foreign stations, not empirically, but upon fixed principles, into the qualities of the medicinal plants which have been provided in every region for the alleviation of the maladies peculiar to it. He is thus enabled to read the hidden characters with which Nature has labelled all the hosts of species which spring from her teeming bosom. Every one of these bears inscribed upon it the uses to which it may be applied, the dangers to be apprehended from it, or the virtues with which it has been endowed. The language in which they are written is not indeed human: it is in the living hieroglyphics of the Almighty, which the skill of man is permitted to interpret. The key to their meaning lies enveloped in the folds of the natural system, and is to be found in no other place.' Such a system as is here eloquently delineated, we aim at rather than possess. All the modifications—and they are neither few nor unimportant—of Jussieu's original plan which have been promulgated, are merely contributions to one great end; and years of patient research, crowned by the most extensive powers of generalisation, must elapse before botany can boast of a perfect system.

According to the original system of Jussieu, all the known plants were arranged into a hundred Orders, beginning with the *Fungi*, and mounting upwards to the *Coniferæ;* and these Orders were divided into three great Classes — namely, the ACOTYLEDONES, or plants without any cotyledon or seed-lobe; the MONOCOTYLEDONES, plants with one cotyledon; and the DICOTYLEDONES, those with two or more cotyledons. The Acotyledonous plants were not subdivided; but the Monocotyledones were arranged into sub-classes, according as the stamens were *hypogynous*, or arising from under the pistil; *perigynous*, or growing from the calyx; and *epigynous*, or arising apparently from above the ovary by adhesion to it. The Dicotyledones were divided into the *apetalous*, or those without petals; the *monopetalous*, those with one petal; and the *polypetalous*, those with several separate

petals; and these again were subdivided, according to the position of the stamens with regard to the pistil, in the same manner as the Monocotyledonous plants. To these were added what Jussieu called *Diclines*, or those plants with separated unisexual flowers. The fault of this system, like that of Linnæus, was that it associated species dissimilar in their nature; the classification depending on one peculiar feature more than on the general appearance, qualities, and habits of the plant.

The system of Jussieu was improved by De Candolle, who at first made 161 orders; but these were afterwards greatly increased, and Lindley enumerates upwards of 300.

The first grand division of De Candolle, like that of Linnæus, is into the Flowering and Flowerless plants, which he designates respectively the *Vasculares* and the *Cellulares*. This division, however, is not absolutely correct; for although all the flowering-plants contain vascular tissue, and the flowerless consist principally of cellular tissue, yet scalariform or ladder-like vessels are common in the ferns and club-mosses. The *Vasculares* and *Cellulares* of De Candolle may be considered as equivalent to the *Phænogamia* and *Cryptogamia* of the older botanists.

His second division depends upon the cotyledons of the embryo; and, like Jussieu, he divides the flowering-plants into DICOTYLEDONES, or those

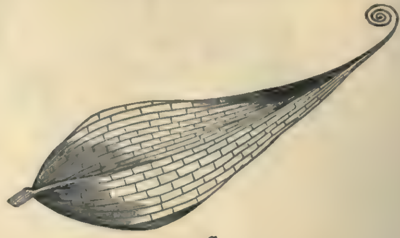
a b b

with two or more cotyledons or seed-leaves, as *a*; MONOCOTYLEDONES, those which have only one seed-leaf (*b*, *b*); and ACOTYLEDONES, those having no seed-leaf, and, in fact, no proper seeds—such as the Cryptogamia. The differences between these three divisions are decided, and are exhibited in different parts of the plant; but they are particularly conspicuous in the leaves—the venation of

a

Dicotyledonous leaves being reticulated, as in the apple (*a*); and that of Monocotyledonous being chiefly in parallel lines, as shewn in the leaf of the Gloriosa (*g*). Dicotyledonous trees are said to be *Exogenous*, from the fact of their trunks increasing by external layers; Monocotyledonous ones, *Endogenous*, on account of the enlargement taking place from within; and Acotyledonous trees, *Acrogenous*, because the increase takes place only at the top or growing-point.

Dicotyledonous plants are divided into the *Dichlamydeæ*, or those with two floral envelopes—that is, having a separate calyx (*a*) and corolla (*b*); and the *Monochlamydeæ*, or those having only one

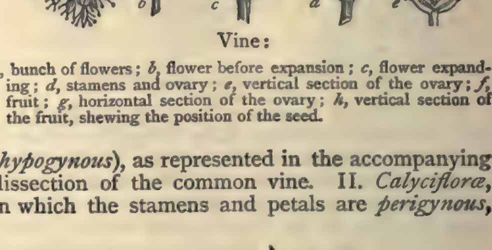


g

floral envelope, which is always called the calyx, as in the detached floret in the wood-cut (*c*).

These distinctions, however, are not always invariable, as many plants in the first division have no corolla, but simply a coloured calyx.

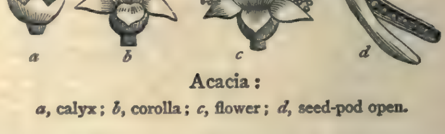
The *Dichlamydeæ* are further divided into three sub-classes: I. *Thalamifloræ*, in which the stamens and petals are all inserted in the receptacle



Vine:

a, bunch of flowers; *b*, flower before expansion; *c*, flower expanding; *d*, stamens and ovary; *e*, vertical section of the ovary; *f*, fruit; *g*, horizontal section of the ovary; *h*, vertical section of the fruit, shewing the position of the seed.

(*hypogynous*), as represented in the accompanying dissection of the common vine. II. *Calycifloræ*, in which the stamens and petals are *perigynous*,



a b c d

Acacia:

a, calyx; *b*, corolla; *c*, flower; *d*, seed-pod open.

inserted in the calyx, as shewn in the preceding dissection of an *Acacia*; or *epigynous*, arising from the upper part of the ovary. III. *Corollifloræ*, in

which the stamens are inserted on the petals, as in the annexed dissection of the acanthus, or in a

Acanthus:

a, corolla opened, shewing the stamens and pistil; *b*, one stamen; *c*, pistil; *d*, ripe seed-vessel, covered with its calyx and bracts; *e*, seed-vessel burst previously to shedding its seeds; *f*, seed opened, shewing the radicle and plume.

few cases on the receptacle, the parts of the corolla being united together. The *Monochlamydeæ* are those having only one, or sometimes no floral envelope.

Monocotyledonous plants are divided into those with petals, called *Petaloideæ*, and those with glumes, as grasses, *Glumiferæ*.

Flowerless or *Cryptogamous* plants are divided into two classes—those formed of a cellular expansion without distinct stem or leaves, which are called *Thallogens* (*a*); and those with leaves (fronds) borne upon a distinct stem or rhizome, *Acrogens* (*b*).

Cryptogamous Plants.

The distinctions between the orders are drawn from the number and arrangement of petals, sepals, and stamens; the construction of the anthers, and the manner in which they burst; the structure of the seed-vessel and of the seeds, with the position of the embryo; the position of the leaves, whether alternate or opposite, or with or without stipules; and the general habits and properties of the plants.

Having thus explained the basis of arrangement, we shall now proceed to consider the ORDERS—premising that while the whole are tabulated, our space will only permit us to detail the more interesting and important ones. This, however, we shall endeavour to do in such a manner as may at once present an outline of the System, and render the reader familiar with the phraseology and plan of procedure.

In this and the subsequent lists of natural orders, those orders marked with an asterisk contain species indigenous in Britain.

EXOGENOUS OR DICOTYLEDONOUS PLANTS.

§ THALAMIFLORÆ.

*Ranunculaceæ—Crowfoots.
Dilleniaceæ—Dilleniads.
Magnoliaceæ—Magnoliads.
Anonaceæ—Anonads.
Schizandraceæ—Schizandra order.
Menispermaceæ—Moonseeds.
Lardizabalaceæ—Lardizabala order.
*Berberidaceæ—Barberry order.
Cabombaceæ—Watershields.
*Nymphæaceæ—Water-lilies.
Nelumbiaceæ—Water-beans.
Sarraceniaceæ—Water-pitchers.
*Papaveraceæ—Poppy order.
*Fumariaceæ—Fumeworts.
*Cruciferæ—Crucifers.
Capparidaceæ—Capparids.
*Resedaceæ—Weldworts.
Flacourtiaceæ—Arnotto order.
*Cistaceæ—Rock-roses.
*Violaceæ—Violets.
*Droseraceæ—Sun-dews.
*Polygalaceæ—Milkworts.
Krameriaceæ—Rhatany order.
Tremandraceæ—Poreworts.
*Tamaricaceæ—Tamarisks.
*Frankeniaceæ—Frankeniads.
*Elatinaceæ—Water-peppers.
*Caryophyllaceæ—Cloveworts.
Vivianiaceæ—Viviania order.
*Malvaceæ—Mallowworts.
Sterculiaceæ—Silk-cottons.
Byttneriaceæ—Chocolate order.
*Tiliaceæ—Lindenblooms.
Dipteraceæ—Dipterads.
Chlænaceæ—Chlænads.
Ternströmiaceæ—Tea order.
Olacaceæ—Olax order.
Icacinaceæ—Icacina order.
Cyrillaceæ—Cyrilla order.
Aurantiaceæ—Orange order.
*Hypericaceæ—St John's worts.
Guttiferæ—Guttifers.
Marcgraviaceæ—Margraviads.
Hippocrateaceæ—Hippocrateads.
Malpighiaceæ—Malpighiads.
Erythroxyleæ—Redwoods.
*Aceraceæ—Maples.
Sapindaceæ—Soapworts.
Rhizobolaceæ—Suwarrow-nuts.
Meliaceæ—Meliads.
Humiriaceæ—Humirium order.
Cedrelaceæ—Mahogany order.
Vitaceæ—Vineworts.
*Geraniaceæ—Cranes'-bills.
*Linaceæ—Flaxworts.
*Oxalidaceæ—Wood-sorrels.
*Balsaminaceæ—Balsams.
Tropæolaceæ—Indian Cresses.
Limnanthaceæ—Limnanthids.
Pittosporaceæ—Pittosporum order.
Brexiaceæ—Brexia order.
Zygophyllaceæ—Bean-capers.
Rutaceæ—Rueworts.
Xanthoxylaceæ—Prickly-ash order.
Ochnaceæ—Ochnads.
Simarubaceæ—Quassia order.

RANUNCULACEÆ.—The plants constituting this order are herbs, or rarely shrubs, with generally deeply cut, rarely stipulate leaves, and stem-clasping petioles. The majority of the species are hardy, and abound in an acrid poisonous juice, as is well exemplified in the common buttercups of the meadows, belonging to the genus *Ranunculus*, from which the order takes its name. The plants of the order are very variable in their flowers; many of them having merely one floral envelope, and others having a coloured calyx, with only very small and inconspicuous petals. When the flowers are regular—that is, when the parts are all of one size—the corolla consists generally of five petals, and the calyx of five sepals, though the number of the petals sometimes varies from three to fifteen. There are numerous stamens which grow from beneath the pistil, and are always separate, having their anthers bursting outwardly. The seeds are for the most part contained in carpels which are separate. The embryo is very small, and placed at the base of the albumen, which is either fleshy or bony. In consequence of the variable character of their flowers, the *Ranunculaceæ* are somewhat perplexing to the learner, though they may be generally known by their numerous distinct stamens springing from below the pistil, and by their distinct carpels, which frequently grow in several whorls round an elevated receptacle, as in the crowfoot and pheasant's-eye. The calyx generally falls off with the petals, but in the pæony it remains till the seed is ripe. The carpels are in many cases only one-seeded, and are sometimes winged, as in the anemone and clematis, in order to scatter the seeds, as the carpels in this case do not open naturally, but fall with the seed.

Sometimes, however, the carpels are many-seeded, and open naturally when ripe, as in the pæony, the larkspur, the columbine, &c. The principal genera —which lie within the examination of every one— are the Ranunculus and Pæony, having regular flowers and two floral envelopes; the Anemone, the Hepatica, the Christmas Rose, and the winter Aconite, which have regular flowers, but generally only one floral envelope; and the Larkspur, Monkshood, and Columbine, which have irregular flowers. The Clematis is one of the few shrubby plants belonging to the order; it has regular flowers, and generally only one floral envelope. The *Ranunculaceæ* are of little economical importance. The juice of the whole order is acrid, the roots of many intensely bitter, and the bark of a few tonic and bitter. The seeds of the Nigella are aromatic, and were formerly used as pepper; but those of all the other genera are poisonous, unless husked. The flowers of some are objects of great beauty—as the larkspurs, ranunculuses, anemones, pæony, and columbine. The 'lesser celandine' of Wordsworth (*Ranunculus Ficaria*) has been used as an article of food in Austria, its small farinaceous tubers resembling peas. But most of the plants belonging to the order are acrid and poisonous, some of them eminently so. *Ranunculus arvensis* is one of the most dangerous farm-weeds which the agriculturist has to fear; but the monkshood (*Aconitum Napellus*) exceeds them all in virulence, and has been the cause of distressing accidents, from its root being mistaken for horse-radish. We read in classic story how the Roman stepmothers of old employed this root to poison their adopted children; and a nearly allied species has derived notoriety from having been employed by the Nepaulese to poison their wells against the approach of an enemy.

DILLENIACEÆ.—This order consists of woody plants having astringent qualities. Some of them yield excellent timber. They are chiefly confined to Australasia, India, and equinoctial America.

MAGNOLIACEÆ.—This order consists of woody plants remarkable for the beauty of their foliage and the fragrance of their flowers, of which the common Magnolia of gardens is a familiar example: they have bitter, tonic, and aromatic qualities. Winter's Bark (*Drimys Winteri*), and the tulip-tree of America (*Liriodendron tulipifera*), belong to the order.

BERBERIDACEÆ.—Plants of temperate and warm countries in both hemispheres, represented in Britain by the common barberry of our hedgerows, the stamens of which display irritability when touched near the base. According to the late Sir J. Y. Simpson, the roots of several species furnish the astringent matter called Lycium by Dioscorides. *Berberis dulcis* yields a table-fruit.

NYMPHÆACEÆ.—Gigantic aquatic herbs, with a thick rhizome in the mud, giving off large floating leaves on long petioles. The rhizomes exhibit a structure resembling that of endogenous plants; but the embryo is truly dicotyledonous. Water-lilies appear to occur in most parts of the world, except cold regions. The white water-lily (*Nymphæa alba*) is one of the greatest ornaments of the English and Scotch lakes; while the yellow one (*Nuphar lutea*) more commonly occurs in slow streams and pools. *N. pumila* is rare. The most magnificent of all is the *Victoria regia*, the royal water-lily of South America, whose size, in keeping with the gigantic proportions of the Amazons and Essequibos, on whose waters it displays its beauty, is unrivalled in the vegetable kingdom. Its floating leaves are two yards across, continuously covering miles of surface with their verdure, each having a turned-up margin like a tea-tray. The flowers are a foot across, formed of hundreds of petals of the most delicate rose-colour, and exhale a delicious perfume in the evening as they expand.

PAPAVERACEÆ.—This order consists of very handsome herbaceous plants, annual and perennial, most of which are natives of the temperate parts of Europe and Asia. The leaves are alternate, sometimes deeply cut, and without stipules. The flowers are solitary, elevated on long peduncles, showy, and usually white, yellow, or red; and the bud in all, except the large scarlet Eastern poppies, is shrouded in only two sepals, which fall off as soon as the flower expands. The Oriental species have three sepals, and one of them (*Papaver bracteatum*) has two large bracts which remain after the flower has expanded, and form a kind of calyx, though the real calyx has dropped off. There are generally four petals, or a multiple of four, which are crumpled in the bud, and soon fall off. The stamens are very numerous, inserted in four or more whorls beneath the pistil (*a*). The ovary is solitary, forming a capsule, which consists of several carpels grown together; stigmas generally stellate on the flat apex of the ovary. Notwithstanding the fleshy ovary, the fruit is a dry capsule, with only one cell, the divisions between the carpels having disappeared. The seeds are numerous, have a minute straight embryo, imbedded in albumen, and become loose in the capsule when they are ripe. Before the seeds are ripe, the walls of the capsules become as hard as a shell; and the stigmas, which are grown together, and become equally hard, form a star-shaped lid for the capsule (*b*). Under this there is a set of valves that open for the discharge of the seed.

Papaver somniferum.

The British genera are—*Papaver*, the poppy, of which there are five native species; *Meconopsis*, Welsh poppy; *Glaucium*, horned poppy; *Chelidonium*, greater celandine or swallow-wort. There are many more, however, grown in our gardens as ornamental plants, such as *Sanguinaria*, or bloodroot; *Argemone*, the prickly poppy; *Eschscholtzia; Rœmeria; Hypecoum; Platystemon;* and *Platystigma*. In the horned poppy, the seed-vessel is formed of two carpels grown together, which look like a pod; and when ripe, from their length and stiffness, bear a considerable resemblance to a horn; hence the name. The *Sanguinaria* has a red juice; the greater celandine, as well as the prickly poppy, has a yellow juice—the juice of the others is white. In the Eschscholtzias

the sepals do not separate; but becoming detached at the base, they retain the shape of a hood or extinguisher, till pushed off by the expansion of the corolla. The capsules of the Eschscholtzias are elongated, and are easily known by the large fleshy projection at their base. The plants of the order are easily detected by their general resemblance to each other, especially in their flowers.

All the Poppyworts abound in a thick glutinous juice, which poisons by stupefying. All parts of the plant furnish more or less this milky sap, but the main supply is derived from the unripe seed-vessels. When in a green state, those of the large white poppy (*P. somniferum*) are slightly wounded with a knife, which causes the juice to exude freely; and on exposure to the air, it concretes or becomes inspissated. In this state, it forms crude or lump opium, which, dissolved in spirit of wine, and filtered, produces the laudanum of the shops. Chemically, opium consists of an insoluble gum, a small quantity of resin, and caoutchouc. Its effects on the animal system depend upon two alkaline principles which it contains—namely, morphia and narcotine; the former producing a sedative, and the latter a stimulating effect. It is curious that the seeds possess none of the stupefying properties of the plant, but are mucilaginous and oily, and may be eaten with impunity. The seeds of one species, however (*Argemoné Mexicana*), are said to be narcotic, especially when smoked; but it is probable that in this case the opiate resides in the coating of the seed rather than in the albumen.

CRUCIFERÆ.—This is one of the most extensive and important of the natural orders. Most of the genera are herbaceous annuals and perennials. The leaves are alternate, and the flowers are produced in corymbs or racemes, being usually regular, with a calyx of four sepals, and a corolla of four petals, disposed in the form of a Maltese cross: hence the name *Cruciferæ*, or cross-bearing. There are six stamens, two much shorter than the others, as shewn under the Linnæan class *Tetradynamia*. The pods open naturally when ripe, the valves curling outwards, as in the common cabbage or wallflower, for example. The seeds have no albumen, and the cotyledons are curiously folded down on the radicle. There can be no difficulty in recognising a cruciferous plant when it is in flower, by the cross form of its corolla, as in the preceding figure, and its six stamens, two of which are shorter than the others.

Crucifer.

Among the more common genera may be mentioned *Brassica*, including the cabbage and turnip; *Cheiranthus*, the wallflower; *Mathiola*, the stocks; *Iberis*, the candy-tuft; *Isatis tinctoria*, the woad; *Armoracia*, the horse-radish; *Sinapis*, the mustard; *Raphanus*, the radish; and many other well-known plants. The plants are generally distributed, but abound in cold and temperate regions. There are about 1700 known species.

The properties of the Crucifers are antiscorbutic and pungent, combined with an acrid flavour; and the seeds of many abound in a fixed oil: properties of which the common cress, mustard, and rape may be taken as examples. Most of them form articles of human food, and are valuable not only for their antiscorbutic properties, but from the fact that they contain a large amount of nitrogen. All the cultivated varieties of turnip appear to have been derived from *Brassica Rapa*, which occurs in a wild state in Britain.

MALVACEÆ.—All the plants belonging to this natural order bear a striking resemblance to each other, and have large showy flowers. The petals and sepals are each five in number, but the calyx has three bracts on the outside, having the appearance of a second calyx below the true one. Æstivation twisted. The most remarkable part of the flower is the central column, and this is so decided, that a botanist is always able to recognise one of the Malvaceæ at first sight. This column is formed by the filaments of the stamens growing together, so as to leave only a small portion just below the anthers free, as is seen in the flower of the marsh-mallow—the lower portion forming a tube round the pistil. The anthers are one-celled, kidney-shaped, and burst transversely, opening inwardly. This peculiar construction of the stamens may be observed distinctly in the mallows, the hollyhocks, and, in short, in all the genera belonging to the order. The styles also grow together, as may be seen when the stamens are removed; and the carpels, which are of the same number with the styles, form what children call 'mallow cheeses.' The carpels are one or many seeded, sometimes closely united, sometimes separated or separable; fruit capsular or baccate. Most of the species are herbaceous plants; several, trees or shrubs. Leaves alternate, more or less divided and stipulate, often covered with stellate hairs. The plants abound in tropical regions and in the hotter parts of the temperate zone.

Marsh-mallow.

The economical uses of the order are highly important. Cotton, on which so much of British commerce depends, is obtained from several species of *Gossypium*, and is the downy hairs which are attached to and envelop the seeds. These hairs, originally of a cylindrical form, at maturity become collapsed into flat bands, and are much twisted. Much confusion exists in botanical works relative to the species of Gossypium, the varying character of the plants having, it is feared, given rise to unnecessary names. The researches of Royle seem to indicate that all the forms known in commerce should be reduced to four species of plants—namely, 1. *Gossypium herbaceum*, which is the common cotton-plant in India, and a variety of which, with buff-coloured hairs, supplies the Nankin cotton. 2. *G. arboreum*, the tree-cotton of India, with red flowers and a fine silky cotton. 3. *G. Barbadense*, Barbadoes cotton, called in India Bourbon cotton, which supplies the highly esteemed Sea Island cotton, as well as the Georgia and New Orleans cottons. 4. *G. Peruvianum*, Cavanilles (or *G. acuminatum*), which supplies the Pernambuco or Brazil cotton. The great difference in the value of different kinds of cotton depends chiefly upon the length of staple, precise measurements of which have recently been published by the United States government.

The inner bark of *Hibiscus cannabinus* furnishes a kind of sun-hemp in India. *H. mutabilis* has

showy flowers which change colour, passing in the course of the day from a cream-coloured rose to a delicate pink or rich rose. *H. tiliaceus* yields Cuba-bast. The tree-mallow (*Lavatera arborea*) grows on rocks exposed to the influence of the sea, as on the Bass Rock and Ailsa Craig. Various species of *Sida* furnish fibre. *S. Phyllanthos* and *S. Pichinchensis* ascend, on the mountain of Antisana and the volcano Rucu-Pinchincha, to the elevation of 13,000 or 15,000 feet.

Many of the Malvaceæ are also medicinal and dietetic. The *pâte de Guimauve*, which is made from a species of marsh-mallow, is used on the continent in disorders of the lungs; from the *Althæa officinalis* is prepared, in France, the vegetable tracing-paper known by the name of *papier végétal;* and a blue matter, not inferior to indigo, is obtained from the leaves of the hollyhock (*A. rosea*). The Chinese blacken their eyebrows with the flowers of *Hibiscus Rosa-sinensis*, and Europeans apply it to the less honourable purpose of blacking their shoes.

TERNSTRÖMIACEÆ.—This is one of the most interesting natural orders, as, besides other fine plants, it contains the camellias and tea-trees. All the members are trees or shrubs, with very handsome flowers. The leaves are alternate, and without stipules; they are frequently leathery, and are sometimes marked with pellucid dots. The flowers have generally five sepals and five petals; sometimes there are two additional sepals a little below the others. The stamens are numerous, and either grow together into a central column, or are in five distinct bundles. There are but few seeds, which are large, and entirely filled with an embryo having thick cotyledons like the bean, and no albumen.

Only a very few genera belonging to this order have been introduced into this country; but there are a number of equally beautiful species found in the East Indies and South America. Those best known in Britain are the genera *Gordonia*, *Stuartia*, *Camellia*, and *Thea*. The common camellia—*C. Japonica*—is too well known to need any description, and its beautiful flowers and thick glossy leaves must be familiar to every one. The double varieties are numerous, but the 'old double white,' as it is called, is still the favourite kind for ballroom decoration. The tea-tree is very nearly allied to the camellia, but its flowers and leaves are smaller. The teas of commerce are obtained from two different plants, named respectively *Thea Bohea* and *Thea viridis*, on the supposition that the former produced our ordinary black teas, while the latter afforded *green* tea. However, both kinds of tea are manufactured from either plant, the difference mainly depending on the time of gathering and the mode of preparation. The young leaves, quickly dried and subjected to a particular kind of manipulation, form green tea; while the older ones, dried more slowly, and undergoing fermentation, constitute black tea; but in some cases the green colour is imparted by means of a mixture of turmeric, Prussian-blue, and gypsum.

Long confined to China, this branch of Oriental agriculture has at length been successfully introduced into India. The Assam Tea is furnished by a larger plant than either of the preceding, which is now regarded as a distinct species, *T. Assamica.*

AURANTIACEÆ.—The golden fruit of the orange and lemon, so characteristic of this order, is so beautiful, that it is supposed to have been typified by the celebrated apples of the Hesperides. The order consists of elegant and fragrant trees or shrubs. The leaves, though apparently simple, are compound, because they are articulated with the petiole, which in the orange and some other

Lemon.

species is winged. The calyx is tubular, with five short teeth. The petals of the corolla are five in number, thick and fleshy, and when held up to the light, they appear full of pellucid dots, which are receptacles of secretion filled with fragrant oil. There are generally twenty stamens, which are divided into five bundles, the filaments in each bundle adhering together. The fruit—hesperidium, as it is called by botanists—is divided into numerous cells by dissepiments, and there is a central placenta, to which the ovules are attached in the ovary; but as the fruit swells, the seeds become detached, and the cells fill gradually with cellular tissue, till at last they become replete with an acid and bitter pulp, in which the seeds are immersed. The seeds are exalbuminous, and sometimes contain more than one embryo.

The most familiar genus is *Citrus*, the species of which are chiefly natives of the tropics—most of them being found in a wild state exclusively in the East Indies. The orange, however, appears to have an extraordinary facility of adapting itself to any country the climate of which is dry and sunny; and thus have arisen the orange groves of St Michael and of Florida, besides those of Malta, and various parts of Europe and North Africa. All the kinds of orange, lemon, shaddock, citron, &c. belong to the genus *Citrus. C. Aurantium* is the sweet orange, so generally cultivated. The principal kinds are the common orange, the Chinese or Mandarin, the Maltese, and the St Michael. *C. medica* is the citron; *C. Limonum*, the lemon; *C. Limetta*, the sweet lime; and *var. Bergamia*, the bergamot; *C. Paradisi*, the forbidden fruit; and *C. decumana*, the shaddock. The Wampee, the fruit of *Cookia punctata*, is much admired in China and the Indian Archipelago. *Ægle Marmelos*, the Indian Bael or Bela, yields a delicious fruit.

All the Aurantiaceæ abound in a fragrant oily matter, which is contained in the receptacles of secretion in the rind of the fruit, and in the leaves

of the tree. The pulp of the fruit is more or less acid. About 35,000 tons of oranges are said to be annually imported into Great Britain. The productiveness of the common orange is enormous: a single tree at St Michael has been known to produce 20,000 oranges fit for packing, exclusive of the damaged fruit and the waste, which may be calculated at one-fifth more.

SAPINDACEÆ.—The Soapworts are woody, rarely herbaceous plants, with usually compound leaves and unsymmetrical flowers, most of them being found in the hot parts of India and America, and little known in Europe, except from the writings of travellers. This remark will not apply, however, to the *Hippocastaneæ*, or horse-chestnuts (distinguished by their opposite leaves, and by the ovary having two ovules—one erect, the other suspended—in each cell), which are natives of Northern India, Persia, and the American States. This section consists of only two genera—namely, *Æsculus*, the horse-chestnut; and *Pavia*, the scarlet-flowering chestnut. The leaves are palmate

Æsculus Hippocastanum.

—that is, divided into five or seven parts; and are without stipules. The flowers are produced in large panicles or racemose cymes. There are five petals, two of which are smaller than the others, and all have small claws. In the *Pavia* there are only four petals, two of which are so much smaller than the others as to look like leafy stamens. There are seven stamens, three of which are much shorter than the others. The fruit of the horse-chestnut consists of a leathery capsule, which opens when it is ripe into three valves. The capsule of Pavia is smooth. The scar of the hilum is very strongly marked on the testa of the nuts of both genera; and in Pavia it is so conspicuous as to give rise to the American name of the genus, which is called *Buck's-eye*, from the resemblance of the hilum to the pupil of an eye. The horse-chestnuts have been so long cultivated in Europe as now to spring up like natives of the soil. Both of the genera are amongst the finest of our flowering-trees, and on this account are common in park-scenery. The seeds of the order abound in starchy and in saponaceous matter. The bark of the common *Æsculus Hippocastanum* is bitter, astringent, and has been recommended as a valuable febrifuge in intermittent and other fevers. The Akee fruit (*Blighia sapida*); the Li-chi (*Nephelium Litchi*) and Longan (*N. Longan*), fruits of China; the Guaraná plant (*Paullinia sorbilis*) of India, and the soap-berry (*Sapindus saponaria*), all belong to the order.

VITACEÆ.—This order comprises about 260 species, natives of temperate climates. Their prevailing habit is a long dangling growth of stem, with tendrils opposite the leaves, thyrsus of colourless flowers, and bunches of berried fruit. The stem and branches are furnished with tumid articulated nodes; the leaves are lobed or compound, generally alternate with stipules. The flowers are small, often the male and female distinct; calyx, very small; sepals and petals, four or five, the latter sometimes cohering at the tips, and falling off before the bursting of the anthers; stamens, equal in number to the petals, and opposite to them; ovary, two-celled; fruit, a berry, with the seeds immersed in pulp; seeds with a bony testa; albumen, hard; embryo, small. The curious formation of the flower and berry is well illustrated by the dissection of the common vine, as shewn in page 88.

The genera are—*Ampelopsis*, the vine-leafed ivy; *Vitis*, the grape-vine; *Leea*, *Cissus*, *Pterisanthes*, and *Rhaganus*. With the exception of the vine, the other genera are of little interest, being employed only as ornamental creepers. The grape-vine is said to be a native of the shores of the Caspian, whence it has been widely distributed, and greatly improved by cultivation.

The properties of the fruit, either in its fresh state or dried to form raisins, or expressed and fermented to form wine, &c. are too well known to require description. The average import of raisins to Britain amounts to more than 12,000 tons, the finest being the Muscatel. The dried currants of commerce—a corruption of Corinths—are the produce of the small seedless Corinthian grape, which is cultivated in many islands of the Mediterranean. Currants are annually imported to the extent of 21,000 tons. *Vitis vulpina* is a kind of wild vine which produces what are called fox-grapes in North America; it forms an ornamental creeper, being hardy in Britain; and has recently attracted notice as likely to form a good stock on which to graft our grape-vines. The Kangaroo Vine of Australia, which is well suited as an indoor window-creeper, is a species of *Cissus*. The berries of the Virginian creeper (*A. hederacea*) are small and unpalatable, but might be eaten with perfect safety. According to Von Martius, the leaves and fruit of *C. tinctoria* abound in green colouring-matter, which soon becomes blue, and is highly esteemed by the natives of Brazil as a dye for cotton fabrics. Acid leaves, and a fruit like that of the common grape, are the usual characters of the order.

GERANIACEÆ.—The *Geraniaceæ* comprise about 500 species. They are herbs or shrubs, with stems which are tumid and articulated at the joints. The leaves are generally lobed, and furnished with small stipules. Calyx persistent in five-ribbed sepals, sometimes spurred. Corolla generally of five petals, with strongly marked veins. Stamens twice as many as the petals; filaments slightly united at the base. Fruit consists of five elastic one-seeded carpels, adhering to an elongated central axis, from which they curve upwards, by means of the elastic styles, when ripe. Seed without albumen; cotyledons rolled up or folded.

The chief genera are *Geranium*, *Pelargonium*, and *Erodium*, respectively crane's-bill, stork's-bill, and heron's-bill, from the fancied resemblance of the ripe seed-vessel to these objects. Many of the species, which are very widely distributed, are natives of Europe; but the majority of our green-house favourites are from the Cape of Good Hope. The herb Robert (*G. Robertianum*) and the meadow crane's-bill (*G. pratense*) are British plants, as are also *Erodium cicutarium* and *moschatum*. All the pelargoniums have their flowers in heads or umbels, and the calyx remains till the seeds are ripe. Their leaves vary very much, some being round—as the horseshoe geranium—and marked with a dark line; and others are deeply lobed, as some of the scented varieties.

The Geraniaceæ are all innocuous plants, being generally slightly acid, and sometimes astringent. They are all more or less fragrant, secreting oils and resins; and in some these secretions are so abundant (*Monsonia spinosa*) that the stems burn like torches, and emit an agreeable odour during combustion. In America, the roots of *G. maculatum* are used as a remedy for diarrhœa; the British Erodiums are sometimes employed as aromatic bitters; from *P. odoratissimum* a fragrant oil has been distilled, resembling the attar of roses; the underground tubercles of *P. hirsutum* are esculent, and prized by the Arabs as food; the tubers of *G. parviflorum* are eaten by the natives of Tasmania, where it is called the Native Carrot. The pelargoniums, generally called geraniums, which are seen at horticultural exhibitions are chiefly hybrids and improved varieties of the Cape species of *Pelargonium*.

LINACEÆ.—A small order. The flowers are in five parts, like those of the cloveworts; but the sepals of the calyx are always distinct, and, instead of being arranged in a regular whorl, two are placed a little lower than the others, as in the *Cistaceæ*. There are five styles and stigmas; but the seed-vessel splits into ten valves, each carpel containing two seeds, separated by an obscure partition, which gives the carpels the appearance of being only one-seeded. The seeds are flat and shining, with a large embryo.

The only genera are *Linum*, *Cliococca*, and *Radiola;* the former comprehending many species. *L. catharticum* is the purging-flax of rural practice. But of all plants of the order, the common flax (*L. usitatissimum*) is the most important and best known. Flax will grow in almost any part of the world; and though an annual, its stem contains so much woody fibre that it is exceedingly tough and durable, yielding by maceration the flax of commerce. The seeds contain a great quantity of oil (*linseed-oil*), which is obtained from them by pressure, and the refuse forms *oil-cake*, employed by farmers in feeding cattle. The seeds also abound in mucilaginous matter, and are thus made use of medicinally, for coughs, &c.; or, when ground into meal, for poultices. Though lint was at one time pretty extensively grown in Britain, our manufacturers now derive the greater part of their supplies from the countries adjoining the Baltic, from which, in one year, not less than 70,000 tons of flax, and about 2,000,000 bushels of linseed, have been imported. The Valley of the Nile, anciently celebrated for its fine linen, now yields but an inconsiderable quantity, in consequence of the present barbarous condition of the inhabitants. It is there cultivated during the cold season. Of late years, the fibres of flax, by being steeped in a solution of carbonate of soda, and afterwards dipped in a weak acid solution, are so broken up as to form a substance like cotton, which is manufactured in the same way as that fabric.

§ CALYCIFLORÆ.

The plants comprised in this sub-class are dichlamydeous—that is, having both calyx and corolla—as in the preceding; the petals are usually separate, but sometimes united; the stamens perigynous, arising from the calyx, and thus surrounding the ovary; or epigynous, arising, apparently, from the upper part of the ovary, which is in this case inferior as regards the parts of the flower. It has been separated into two divisions: the one named *Polypetalæ*, from the petals being several and separated; the other *Monopetalæ*, from their being so united as to appear single; for example, a wild rose has five distinct petals, separate to the base, whereas a bell-flower (Campanula) has all its petals united into one piece. In no case do the stamens arise directly from the thalamus, which is the characteristic of the preceding sub-class. Here the parts of the flower are more or less united to each other. The following are the orders belonging to Calycifloræ:

POLYPETALÆ.

Stackhousiaceæ—Stackhousiads.
*Celastraceæ—Spindle-trees.
*Staphyleaceæ—Bladder-nuts.
*Rhamnaceæ—Buckthorns.
Anacardiaceæ—Cashews.
Amyridaceæ—Myrrh order.
Connaraceæ—Connarads.
*Leguminosæ or Fabaceæ—Leguminous Plants.
Moringaceæ—Moringas.
*Rosaceæ—Rose order.
Calycanthaceæ—Calycanths.
*Lythraceæ—Loosestrifes.
Rhizophoraceæ—Mangroves.
Vochysiaceæ—Vochysia order.
Combretaceæ—Myrobalans.
Melastomaceæ—Melastomads.
Alangiaceæ—Alangiads.
Philadelphaceæ—Syringas.
Myrtaceæ—Myrtles.
Chamælauciaceæ—Fringe-myrtles.
Lecythidaceæ—Monkey-pots.
Barringtoniaceæ — Barringtonias.
*Onagraceæ — Evening Primroses.
*Halorageaceæ—Mare's-tails.
Loasaceæ—Chili-nettles.
*Cucurbitaceæ — Cucumber order.
Papayaceæ—Papaw-worts.
Belvisiaceæ—Belvisiads.
Passifloraceæ—Passion-flowers.
Turneraceæ—Turnera order.
*Portulacaceæ—Purslanes.
Illecebraceæ—Knotworts.
*Crassulaceæ—Stonecrops.
Mesembryanthemaceæ — Fig-marigolds.
Tetragoniaceæ—Tetragonias.
Cactaceæ—Cactuses.
*Grossulariaceæ—Gooseberry order.
Escalloniaceæ—Escalloniads.
*Saxifragaceæ—Saxifrages.
Hydrangeaceæ—Hydrangeads.
Cunoniaceæ—Cunoniads.
Bruniaceæ—Bruniads.
Hamamelidaceæ—Witch-hazels.
*Umbelliferæ or Apiaceæ—Umbel-bearers.
*Araliaceæ—Ivyworts.
*Cornaceæ—Cornels.

MONOPETALÆ.

*Loranthaceæ—Mistleto order.
*Caprifoliaceæ—Honeysuckles.
*Rubiaceæ—Cinchona and Bedstraw order.
*Valerianaceæ—Valerians.
*Dipsaceæ—Teazelworts.
Calyceraceæ—Calycera order.
*Compositæ or Asteraceæ—Composites.
Brunoniaceæ—Brunoniads.
Goodeniaceæ—Goodeniads.
Stylidiaceæ—Styleworts.
*Campanulaceæ—Bell-flowers.
*Lobeliaceæ—Lobeliads.
Styracaceæ—Storax order.
Columelliaceæ — Columellia order.
*Vacciniaceæ—Cranberries.

LEGUMINOSÆ.—This is one of the most extensive and best defined orders in the vegetable kingdom. Many of its plants bear butterfly-shaped (papilionaceous) flowers, and all have pod-like seed-vessels; among which may be mentioned, as familiar examples, the pea, bean, lupine, broom, furze, and laburnum. The following may be stated

as the general characteristics of the *Leguminosæ:* Herbs, shrubs, or trees; leaves, alternate, generally compound, their petioles tumid at the base, where there are usually two stipules, and also two to each leaflet in the pinnate leaves; the pedicles are generally articulated, and the flowers are furnished with small bracts; calyx, five-parted, the segments being sometimes unequal and variously combined; petals, never more than five, but often less, and sometimes wanting, inserted into the base of the calyx, and variously arranged, papilionaceous in all European genera, the odd petal being always superior; stamens, definite or indefinite, inserted with the petals, in exceptional cases apparently hypogynous, thus shewing a transition from the preceding sub-class, distinct, or in one, two, or three bundles; ovary, superior, for the most part one-celled; ovules, one or many; style and stigma, simple; fruit, a true legume, a modified form of legume or loment, or sometimes, when containing only one seed, drupe-like; embryo, straight, with or without albumen; the radicle, in some instances, bent along the edge of the cotyledons.

Papilionaceous Flower.

The plants belonging to the order are found in all parts of the world, but they are most abundant in warm regions, and diminish on approaching the poles. There are above 6500 known species.

This family is amongst the most important to man, whether as affording objects of beauty, of utility, or of nutriment. The bean, the pea, the vetch, and the clover tribe belong to it; as do the logwood, the laburnum, indigo, the tamarind, liquorice, senna, and the acacias. Its general properties are considered by some to be wholesome, but there are several exceptions. Thus, the seeds of laburnum, and the juice of *Coronilla varia*, are poisonous. Senna, obtained from various species of cassia, is purgative, and several others of the order possess a similar property. The pericarp of some contains much tannin; dyes are obtained from others; and many yield gums and balsams. It would occupy pages to enumerate all the uses to which this, one of the most extensive orders in the vegetable kingdom, has been applied. We shall, therefore, briefly indicate the principal sections of the order, and the more important plants contained in each.—§ I. *Papilionaceæ*, petals papilionaceous, imbricate, upper one exterior. This, which may be called the Pulse section, is the only one containing British species, but these are numerous, and contribute much to the beauty of our Flora. The vetches and lathyrus, the rest-harrow, the trefoils and clovers, the lotus and the meliloti, are all gay flowers which we gather in our rural walks. Turning to plants of utility, we find here the bean and the pea, the clovers, vetches, sainfoin, and lucerne. The lentil (*Ervum lens*), although a crop of the most ancient cultivation, has only recently been introduced to the notice of British farmers; and may possibly be of some service on light soils. Kidney-beans and scarlet-runners also belong to the garden Papilionaceæ, the latter affording a characteristic illustration of the miscellaneous properties of this order, its roots being poisonous, while its seeds form an article of food. Other plants of the section are decidedly poisonous, such as *Coronilla varia*, and the seeds and bark of laburnum, which, being a common ornamental tree, and one which seeds freely, is apt to give rise to accidents, especially in the case of children. But perhaps the most remarkable of all poisonous species is the ordeal bean of Calabar, *Physostigma venenosum*. It is commonly used in Calabar in trials by ordeal, the suspected party being set free if (by vomiting) the bean does not prove fatal. In like manner, the bark of another species is used by the Caffres as a test in judicial trials. Of miscellaneous plants used in the arts, we find *Astragalus gummifer* and other species, from which gum-tragacanth is obtained; *Baptisia tinctoria*, a dye-plant and the wild indigo of America; *Crotalaria juncea*, whose fibrous bark yields Bengal hemp; *Dalbergia Sissoo*, which in India yields the valuable timber well known by its native name of Sissoo; *Dipterix odorata*, whose fragrant seeds are the Tonka-beans of commerce; *Glycyrrhiza glabra*, whose root forms liquorice; various species of *Indigofera*, from which the true indigo is obtained; *Pterocarpus santalinus*, the source of red sandal-wood; *P. draco*, which yields gum-dragon; and *Triptolomea*, from species of which the rose-wood of commerce appears to be derived. Kino is supplied by various species of *Pterocarpus*, and by *Butea frondosa*, one of the most gorgeous plants of India, with masses of bright orange-red flowers, resembling sheets of flame.—§ II. *Cæsalpinieæ*, petals imbricated, upper one interior. The plants of this section are chiefly important from yielding valuable timbers and dyes, while some are much used as purgative medicines. Of the latter, the various kinds of senna, consisting of the leaves of species of *Cassia*, are most important. The fruit of the tamarind likewise contains a laxative pulp, as also *Cassia Fistula*. Of dyes we have the sappan of India (*Cæsalpinia sappan*), the barwood or camwood (*Baphia nitida*), and the well-known logwood (*Hæmatoxylon campechianum*). Of timber-trees, the Brazil-wood of commerce (*Cæsalpinia Brasiliensis*) is not the least important. The West Indian locust-tree (*Hymenæa Courbaril*) affords a close-grained tough wood, which is found well adapted for the beams of steam-engines, while the Guiana purple-heart even excels it in toughness; and being found to resist well the shock of artillery discharges, it is sought after for mortar-beds.—§ III. *Mimoseæ*, petals valvate in estivation. The principal genera are *Acacia* and *Mimosa;* the latter genus chiefly remarkable on account of the irritability displayed by the leaves of *M. pudica* and *sensitiva*. Many species of *Acacia* yield gum-arabic and gum-senegal. The Australian species, called 'Wattles,' have astringent bark which is used in tanning; in these the leaf-stalk is often flattened into a phyllodium, or false-leaf; in the young plant there may be no compound leaves developed, but these ultimately appear at the tips of the phyllodia.

ROSACEÆ.—Like the preceding, this is one of the most extensive natural orders, comprehending nearly 1000 described species, which are herbs, shrubs, and trees, often of very dissimilar habits and appearance, but all bearing a striking resemblance in their fructification to the single or wild rose of our woods and hedges, which may be taken as the type of the order. Among the trees may be mentioned, as familiar examples, the almond

(*Amygdalus*), the pear and apple (*Pyrus*), the sloe and plum (*Prunus*), the peach and nectarine (*Persica*), the cherries and laurels (*Cerasus*); among the shrubs, the rose (*Rosa*), the hawthorn (*Cratægus*), the bramble and raspberry (*Rubus*), and the quince (*Cydonia*); among the herbs, the common yellow *Potentilla* of the roadsides, the *Geum*, the *Tormentilla* of our woods and commons, and the delicious strawberry (*Fragaria*). From the varied nature of its genera, the order is divided by some authors into seven sub-orders for the purposes of detailed description. All the different sections exhibit the following general characteristics: Leaves, alternate, generally compound, and always furnished with stipules; calyx, five-lobed, united below, but separate and expanding above; corolla, of five, or sometimes four petals. The ovary is one-celled, and there is seldom more than one seed, scarcely ever more than two in each cell. Carpels numerous, and generally inclosed in the fleshy tube of the calyx.

Rosaceous Flower.

The following are the sub-orders: 1. CHRYSOBALANEÆ, or cocoa-plum family, represented by *C. icaco*, a shrub found in the West Indies, where its fruit, which is about the size of a plum, of a whitish-yellow, and possessing a sweetish taste, is brought to the markets. There are about nine genera belonging to this tribe, all of which are trees or shrubs, with simple alternate stipulate leaves, and flowers in racemes or panicles. They are natives of the tropical countries, and differ from the almond tribe in having irregular petals and stamens, and in the style arising from the base of the ovary; the stipules are not united to the petiole.—2. AMYGDALEÆ, or almond family, represented by the common almond (*Amygdalus communis*), and embracing the peach, apricot, nectarine, plum, cherry, &c. well known for their delicious fruits, and a few bushes remarkable for their gay appearance during the flowering season. The fruits of this tribe are for the most part edible; and though the leaves and bark possess medicinal properties, yet one of the most subtile poisons—prussic acid—can be extracted both from the fruit and leaves of the almond.—3. ROSEÆ, or roses proper, the type of which is the single wild-roses of our hedges. The section is distinguished botanically by the numerous achenes inclosed in a fleshy calycine tube which is contracted at the orifice. They have all a corolla of five equal slightly indented petals, capable of being increased indefinitely by cultivation; numerous stamens; a five-cleft calyx. The pitcher-shaped portion of the calyx becomes the hip as the seeds ripen, and forms a false pericarp, inclosing the numerous bony carpels. Many of the plants have pinnate leaves and prickles on their stems. Most of them are fragrant, and the leaves of some, as the sweet-brier, are replete with a fragrant volatile oil, which appears to be secreted by glands dispersed all over the foliaceous surface of the plant.—4. POTENTILLIDÆ, embracing those plants which agree with the common *Potentilla* in the construction of their flowers—that is, in having a calyx of ten sepals; its tube short, or nearly flat, not inclosing the fruit; a corolla of five petals; and the stamens, which are numerous, forming a ring round an elevated or flat receptacle, on which are placed numerous carpels. By this test the student will find that the section comprises not only herbs, such as the potentilla, geum, tormentilla, and strawberry, but also erect and trailing shrubs, as the raspberry and bramble. These genera, though alike in their flowers and in many of their habits, are otherwise very dissimilar. In the potentilla, for example, the carpels form the prominent part of the so-called fruit, while in the strawberry the receptacle becomes fleshy and edible. Again, in the raspberry, the receptacle is a torus surrounded by the carpels, which swell out and soften, forming the edible portion. The leaves and stems of these genera are also very dissimilar, but the habit of increasing by suckers or runners is prevalent in all.—5. SANGUISORBIDÆ, a section of herbaceous perennials, illustrated by *Sanguisorba officinalis*, or the weed burnet of our pastures. This tribe is distinguished by having one or two achenes inclosed within the dry calyx-tube. The flowers often have no petals, but the clefts of the calyx are coloured, and the flowers are generally furnished with glossy coloured bracts.—6. SPIRÆIDÆ, deciduous shrubs and perennial herbs, represented by *Spiræa Ulmaria*, or meadow-sweet. In this section, the five-cleft calyx is lined with the dilated receptacle, which forms a sort of cup for the carpels, which are in the form of follicles. The beautiful hardy shrub named *Neillia thyrsiflora* belongs to this tribe, which contains a large number of shrubby ornamental *Spiræas*, as well as herbaceous kinds.—7. POMEÆ, an extensive and varied section, the type of which is the common apple (*Pyrus malus*). It comprehends the apple, pear (*Pyrus communis*), the mountain-ash (*P. aucuparia*), the white beam-tree (*P. Aria*), the quince (*Cydonia*), and the hawthorn (*Cratægus*). In all of these genera, which are trees and shrubs, the flowers are remarkably similar; but the habits of the plants, the leaves, and the fruit, present numerous differences.

The properties of the order have already been so far noticed in the preceding detail, that it may be stated of them generally as follows: The fruit of some of the *Chrysobalaneæ* is eaten under the name of the cocoa-plum. The *Amygdaleæ* include the almond, plum, cherry, and sloe; the leaves and kernels contain prussic acid, which, in a concentrated form, is one of the subtilest poisons; but being generally diluted in a natural state with gum, sugar, &c. it is harmless, and serves to give an agreeable flavour to the fruits containing it. The *Roseæ* are chiefly valued for their ornamental flowers, but they also yield valuable extracts—as attar of roses, rose-water, conserve of roses, &c. The fragrant essential oil called attar of roses is distilled chiefly from the common cabbage-rose (*Rosa centifolia*) and its varieties; 20,000 flowers of roses are required to make a rupee weight of the attar, which sells for £10. The general character of the *Sanguisorbidæ* is astringency. The roots of *Spiræa filipendula* and *Ulmaria*, as well as those of some other plants belonging to the *Spiræidæ*, have been used as a tonic. Of the *Potentillidæ*, the roots of several are astringent and febrifugal, and the fruits of such as the raspberry and strawberry are delicious and wholesome. The *Pomeæ*, under cultivation, supply wholesome

and delicious fruits, of which the apple, pear, quince, and service-berry are familiar examples.

MYRTACEÆ.—The order consists of upwards of 60 genera, and about 1300 known species. They are all trees or shrubs, with simple exstipulate leaves, which are for the most part opposite, full of transparent dots, and with an intra-marginal vein round the edge. The substance of the leaf is coriaceous, and the dots are glands, or cysts, full of a fragrant volatile oil. The inflorescence is both terminal and axillary, variable in its form, but generally aggregate—the flowers being regular and united, of a white, red, or sometimes yellow colour, but never blue. The tube of the calyx adheres to the ovary, and is from four to eight cleft, persistent or deciduous. The petals, which are rarely wanting, are equal in number to, and alternate with, the segments of the calyx; the stamens are inserted with the petals, and are twice as many, or (usually) indefinite, and then arranged in several

Pomegranate.

series; the anthers are two-celled, and burst longitudinally. Fruit, baccate or capsular; style and stigma, simple; many-celled, or one-celled by the obliteration of the dissepiments of the carpels. Seeds, generally indefinite, seldom few, and without albumen.

Among the edible fruits belonging to the order may be mentioned the delicious guava, yielded by several species of *Psidium;* the rose-apple and jamrosade, produced by *Eugenia* and *Jambosa.* Of spices yielded by the order, which are all more or less aromatic, we have the clove, which is the unexpanded flower-bud of the *Caryophyllus aromaticus;* all-spice, Pimento or Jamaica pepper, the dried berries of *Eugenia pimento;* and also the dried berries of the common myrtle. It is the volatile oil found in the dots of the leaves, the unexpanded petals, and in almost all the parts of the plant, that gives to them their fine aromatic fragrance. The pomegranate (*Punica granatum*) forms a delicious fruit in warm countries; the pericarp or rind is used in the East as an astringent; and the bark of the root is esteemed an efficient anthelmintic.

Some species of the beautiful genus *Metrosideros* yield hard and heavy timber, which the South Sea islanders prize for their clubs and other weapons of war. The gum-trees of Australia (*Eucalypti*) deserve special notice as among the most valuable economical plants of our Australian colonies. They are distinguished by a remarkable operculate calyx, and their bark separates in layers, giving rise to the statement that the trees of Australia shed their bark instead of their leaves in winter. Their leaves often stand in a vertical position, and are remarkably hard and coriaceous. These trees grow to an enormous size, and yield very durable timber. They supply the place of the European oaks as a source of tannin. *E. resinifera* yields, on incision, an astringent matter, called Botany Bay kino; while several others yield saccharine matter. A peculiar red gum is contained in cavities of the wood of *E. robusta.* The leaves of some species of *Leptospermum* are used in Australia as a substitute for tea.

CUCURBITACEÆ.—This is a large and interesting family of herbaceous plants, containing 56 known genera, and about 300 species. The roots are annual or perennial, fibrous or tuberous; the stems succulent, climbing by means of lateral tendrils formed of the abortive stipules, and furnished with large alternate, palmated rough leaves. The flowers are usually unisexual.

The Cucurbits are natives of all hot climates, but are most abundant in India and South America; a few exist in the northern parts of Europe, and some are found at the Cape of Good Hope. In an economical point of view, the order is of considerable importance, furnishing the well-known esculents—the cucumber, melon, gourd, pumpkin, and calabash; and the purgatives colocynth and elaterium. The general properties of the gourd family may be regarded as bitter and purgative—these qualities pervading more or less all the species, and rendering their fruit either esculent or purgative. The seeds of all are sweet and oily, and from some a considerable quantity of fine-flavoured oil may be expressed. The roots and leaves are sometimes replete with a bitter drastic juice. The fruit of many of the members grows to an enormous size; the calabash, for example, being sometimes found six feet long and eighteen inches in circumference. *Gherkins* are the fruit of the common cucumber, pickled when in a young state. The fruit of *Lagenaria vulgaris* is in common use for water-bottles in the Greek islands and generally in the East. It has probably given rise to the clay water-bottles in form of a round bulb ending in a long neck, which much resemble it in shape, and to which the bottles in use all over the world may be traced as modifications. Many of the ornaments of ancient Egyptian architecture are traceable in a similar manner to vegetable forms peculiar to the region.

CACTACEÆ.—The Indian figs, or Cacti, constitute one of the most singular and interesting orders in the vegetable kingdom. They are unique in their forms and habits, having perennial succulent, angular, or rounded spiny stems. In general, the stems and branches are jointed; the leaves are either very minute, or altogether wanting, their place being supplied by strong spines. They are all natives of tropical America, but thrive well in all hot, dry, and exposed places. Of the more common genera, we may mention the following: *Mammillaria*, so called from the pap-like tubercles which cover its sub-cylindrical stem. Each tubercle is crowned with a little tuft of radiating spines; and the flowers, which are sessile, are ranged in a kind of zone round the plant. The melon cactus (*Melocactus communis*), which has a more or less globose stem, with alternate furrows and ridges,

the latter being armed with tufts of spines; the stem is crowned by a woolly tuft, from which spring the flowers. The hedgehog-thistle (*Echinocactus*) has also a globose stem, but wants the woolly head, and has its flowers springing from the tufts of spines which arm the ridges. Some of the species grow to an enormous size. A plant of *E. platyceras*, growing at Kew, measured 9 feet in height, 9½ in circumference, and weighed upwards of a ton. The torch-thistle (*Cereus*) has the stem angular, the projecting angles being armed with spiny tufts, from which the flowers generally spring. The old-man cactus (*Polocereus senilis*) is so called from its resemblance to an old man's head, being covered with long white hairs. The Peruvian torch-thistles (*Cereus peruvianus* and *hexagonus*) are still more gigantic plants, often attaining a height of forty feet, though their stems be not thicker than a man's arm. The rat's tail cereus (*C. flagelliformis*) is well known from its long whip-like stems, which hang down from the sides of the suspended pots in which it is usually grown. The night-flowering cereus (*C. grandiflorus*), so called from its blossoms opening during night, and fading before morning, has an angular, branched, and climbing stem, throwing out roots at every point. The genus *Rhipsalis* has slender jointed stems, which look like samphire; and the opuntias, which are numerous and useful, are distinguished by their round, flat, leaf-like bodies, united together by joints, and for the most part covered with spines.

The fruit of many of the Cactaceæ is esculent, but is rather insipid, having little of that acidulous flavour which characterises the Currantworts, to which the family is allied. It is upon the *Opuntia cocchinellifera*, the Nopal plant, that the cochineal insect, so valuable in the arts, chiefly feeds. In the south of Europe, the prickly pear (*O. communis*) is reared as a hedge, and also for its fruit, which is edible, and yields a rich carmine pigment; and the Indian fig (*O. tuna*) is grown for similar purposes in Brazil.

GROSSULARIACEÆ.—This is a well-known order, consisting principally of one genus, *Ribes*, which includes all the gooseberries and currants of our gardens. The species, of which there are upwards of eighty, are unarmed or thorny shrubs, with round or irregularly angled stems and branches; simple, lobed, alternate leaves, destitute of stipules and tendrils. The inflorescence is axillary and in racemes. The calyx, which is often coloured, is four or five cleft; petals, perigynous, equal in number to, and alternate with, the segments of the calyx; stamens, of the same number, alternate, and inserted with the petals; filaments, distinct; anthers, two-celled, bursting longitudinally; ovary, one-celled, cohering with the tube of the calyx; ovules, indefinite; fruit, a berry, crowned with the remains of the flower, one-celled, filled with pulp with two parietal placentas; seeds, numerous, suspended among the pulp by filiform funicles; testa, externally gelatinous; albumen, horny.

The order is very conveniently grouped into two sections—namely, the Gooseberries, which have prickly stems, and the flowers either singly, or in clusters of not more than two or three; and the Currants, which are entirely without spines, and the flowers in racemes. There are a few species, such as *Ribes dracantha* and *saxatile*, which may be considered as intermediate, these having the spines and habit of growth of the one, and the racemose inflorescence of the other. The common gooseberry (*R. Grossularia*), the red currant (*R. rubrum*), the black currant (*R. nigrum*), and the flowering currant (*R. sanguineum*), are familiar examples of the order, and all too well known to require any detailed description. The gooseberry is found wild in many parts of Britain; and is reared in the north of England to greater perfection than in any other country.

Gooseberries and currants have agreeable acid fruits, the acidity or sweetness depending upon the relative quantities of malic acid and sugar which they contain. The blackberry has tonic and astringent properties, infusions of the leaves being used for this purpose.

SAXIFRAGACEÆ.—This order consists chiefly of very small herbaceous plants, with alternate or opposite leaves, and is readily distinguished by the peculiar ovary, which is more or less completely inferior, consisting of two carpels which diverge at the apex. As useful plants, they are unimportant, but they are the most charming that greet the eye of the botanist in his mountain rambles. *Saxifraga stellaris* and *S. aizoides* are the great ornaments of Highland streams at a low elevation; while higher up, the rocky banks are covered with a purple carpet of *S. oppositifolia*, or the rarer *S. rivularis*, which attracts many a botanist to the summit of Loch-na-gar. *S. cernua* is confined to the summit of Ben Lawers. But it is not alone the Scottish mountains that are adorned with these 'alpine gems;' *S. Boussingaultii* reaches to nearly 16,000 feet on Chimborazo.

UMBELLIFERÆ.—This is one of the most extensive and important of the natural orders, comprising about 300 genera, and above 1500 species.

Common Hemlock:
c, flower; *d*, seed.

The genera, though presenting many minor differences, are, on the whole, well marked; so that no one who has seen the flower of the parsley and common hemlock can have any difficulty in detecting an umbelliferous plant. The species are for the most part herbs, seldom shrubs, with fistular furrowed stems, loving damp waste places, and varying much in their properties, according to the climate under which they are grown. The leaves are generally divided, sometimes simple; are alternate, and clasp the stem by a broad sheathing petiole. The flowers are white, pink,

yellow, and blue, and in umbels, which are simple or compound, and these are with or without bracts at their base: when seated at the base of the umbel, the bract is called an involucre; when at the base of the umbellules in the compound head, an involucel. The calyx is superior and five-toothed; petals, five, and inserted on the outside of a fleshy disc, which is placed on the top of the ovary; stamens, five, and inserted alternately with the petals; ovary, inferior, and two-celled, with pendulous ovules; styles, two, distinct; stigmas, simple. The fruit (cremocarp) consists of two carpels, united by a common axis, from which they separate when ripe; the external part of the carpels is traversed by linear ridges, which are divided into primary and secondary, there being five of the latter, and four of the former, between them. The ridges are separated by channels, below which are often placed, in the covering of the seed, receptacles or vittæ of an oily matter. The seed is pendulous, usually cohering with the carpel, rarely loose.

Among the more familiar genera may be mentioned the parsnip (*Pastinaca*), the cow-parsnip (*Heracleum*), the celery (*Apium*), the carrot (*Daucus*), the hemlock (*Conium*), the cow-bane (*Cicuta*), and the coriander (*Coriandrum*).

The properties of the order are very various. Some of the plants are harmless and esculent, while others are narcotic poisons; a third set are antispasmodic, owing to the presence of a gum-resin containing a fetid sulphur oil; while a fourth set are carminative, from containing a volatile oil. 1. Among the harmless plants used as esculents may be mentioned the chervil, celery, arracacha, earth-nut, pig-nut, samphire, carrot, fennel, parsnip, parsley, and skirret. 2. Poisonous plants containing acrid and narcotic principles: fool's parsley, water hemlock or cow-bane, spotted hemlock, and hemlock-dropwort or dead-tongue. The last-named plant has been found to be poisonous only in certain localities. 3. Gum-resinous species, usually with a fetid odour: *Narthex assafœtida*, a native of Persia, yields the true assafœtida; *Ferula orientalis* furnishes a fetid resin in Morocco; *Galbanum officinale* and *Opoidia galbanifera* yield galbanum; *Dorema ammoniacum* yields the Persian gum ammoniac; *Opoponax chironum* produces the gum-resin called opoponax. 4. Aromatic and carminative plants, containing volatile oil: caraway, dill, coriander, cummin, carrot, anise, &c.

CAPRIFOLIACEÆ.—A well-known order, consisting of 12 or 14 genera, and about 220 species. They are erect or twining shrubs, rarely trees, having opposite, simple, or pinnate leaves, without stipules; and flowers terminal in corymbs, or axillary. The flowers are white, scarlet, or yellow, and often sweet-scented, as in the common honeysuckle. The order has been divided into two sections—namely, the SAMBUCEÆ, or elder tribe, and the LONICERÆ, or true honeysuckle tribe.

RUBIACEÆ.—This is a large, and in many respects not a well-defined order, composed of small trees, shrubs, and herbs. It has been divided into two orders by some authors: CINCHONACEÆ, containing those plants most resembling cinchona; and GALIACEÆ, or STELLATÆ, those most resembling the galiums or bedstraws. The *Cinchonaceæ* and *Galiaceæ*, indeed, form two well-marked groups of plants, abundantly distinct from each other in habit and in geographical distribution: the one consisting of trees, shrubs, and herbs, with simple opposite leaves and interpetiolar glandular stipules; almost exclusively inhabiting the hotter parts of the world, most of them eminently conspicuous for their economical products and the beauty of their broad foliage and flowers; the other composed entirely of straggling herbaceous plants, with weak angular stems and narrow verticillate exstipulate leaves, inhabiting northern countries, and, with one or two exceptions, alike inconspicuous for use and ornament. Unfortunately, however, fructification does not supply any character whereby those two ideally distinct groups of plants can be clearly separated from each other, and in the limitation of natural orders something more than a difference of habit is considered requisite. The recent discovery of the peculiar axillary glands of *Cinchonaceæ* in *Galiaceæ* serves still further to break up the supposed distinctions between these groups. De Candolle has proposed a further subdivision into thirteen sub-tribes.

By far the greater number of the species are tropical plants, though many are amongst the most common and neglected of British weeds. Madder (*Rubia tinctorum*) is common in gardens, and is much cultivated in Belgium and Holland for its roots, which yield a rich brownish-red dye, called Turkey red. The *Galiums* or bedstraws are familiar plants, growing on hedges, on dry banks, or sides of old ditches, and known by the common name of cleavers, ladies' bedstraw, crosswort, and the like. *Asperula odorata*, another of the order, is the well-known woodruff, which acquires, when dried, a most delicate fragrance. The coffee-tree (*Coffea*), Jesuit's bark (*Cinchona*), the Cape jasmine (*Gardenia*), and ipecacuanha (*Cephäelis*), are also well-known members.

The properties of the order are very varied. The roots of many, as the madders and bedstraws, contain a large quantity of colouring matter; and it is said that fowls fed upon the roots of some plants of this order have their bones dyed of a red colour; in other cases, the plants are acrid, emetic, purgative, or diuretic. The bark (as that of the Cinchona, or Peruvian bark) is sometimes bitter, tonic, and astringent. The ipecacuanha plant (*Cephäelis ipecacuanha*) of South America, the annulated root of which is so valuable in medicine, and by which it is easily propagated, has been lately (1871) introduced into India by the government, for the purpose of cultivation. Many of the plants were grown and sent out from the Royal Botanic Garden of Edinburgh. Quinine, now so extensively used in medicine, is obtained from different species of cinchona, but chiefly from the bark and young shoots of *C. Calisaya.* The cultivation of cinchona is now being successfully carried on in India, and it has been lately introduced, with that object, into Java and Australia. The value of the roasted albumen of the coffee-berry is too well known to require allusion; and the fruits of others of the order have been recommended as answering the same purpose.

COMPOSITÆ.—This is one of the most extensive of the natural orders, containing not fewer than 900 genera, and between 9000 and 10,000 species. The members are herbaceous plants or shrubs, with leaves alternate or opposite, without stipules, and usually simple. What is called the flower is an aggregation of unisexual or hermaphrodite *florets*, collected in dense heads upon a common

receptacle, surrounded by an involucre, as exemplified in the common daisy and dandelion. As the compound leaf is composed of a number of leaflets, so is the composite flower made up of a number of florets arranged on one receptacle, which is furnished with a calyx-like involucre. Each floret is complete in itself, having all the appendages of bracts, calyx, corolla, stamens, and pistil, although the calyx is in a much reduced state, appearing in the form of bristly hairs. The corolla is monopetalous, and either ligulate, tubular, or bilabiate—that is, has two equal lips cut into several lobes. The stamens are equal in number to the teeth of the corolla, and alternate with them ; the anthers grow together, so as to form a kind of cylinder, through which passes the style, ending in a two-lobed stigma. The ovary is inferior, one-celled, with a single erect ovule. The fruit is an achene, which retains the pappus when ripe, and falls without opening ; the appearance of this pappus or down is familiarly illustrated in the head of the ripe dandelion.

The order has been divided into three sections : 1. *Cichoraceæ*, in which all the florets are ligulate and perfect. 2. *Corymbiferæ*, most of the florets tubular, all hermaphrodite, or those of the circumference filiform or tubular, and pistiliferous or ligulate ; style, not jointed. 3. *Cynarocephalæ*, all the florets tubular ; style, jointed. The Composite plants are widely scattered over the globe, forming, according to some authorities, one-twelfth of its vegetable productions. Humboldt states that they constitute one-seventh of the flowering-plants of France, one-eighth of those of Germany, one-fifteenth of those of Lapland, a sixteenth of those of New Holland, a sixth of the North American Flora, and one-half of that of America within the tropics. The Composites are herbaceous in the colder quarters of the globe, and become shrubby as we approach the equator.

The Cichoraceæ are well illustrated by the common lettuce (*Lactuca*), the dandelion (*Taraxacum*), the succory (*Cichorium*), and the sow-thistle (*Sonchus*), which are common British plants. All the members of this section yield a milky juice, which is bitter, astringent, and slightly narcotic. Many of them are used in medicine—as the lettuce, from which the narcotic and diuretic *Lactucarium* is obtained. Many are also used as articles of food ; thus, endive (*Cichorium Endivia*) is employed as a salad ; so is the garden lettuce when young, the root of the sonchus, and perhaps, more than all, the root of *C. Intybus*, or wild succory, which is roasted and largely mingled with coffee under the name of chicory. The Corymbiferæ, which have the central florets tubular, and the outer ones generally ligulate, are illustrated by the daisy (*Bellis perennis*), the chamomile (fig.) (*Anthemis nobilis*), the groundsel (*Senecio*), the tansy (*Tanacetum vulgare*), dahlia, marigold, &c. The juice of this section is watery; sometimes bitter and tonic, and sometimes acrid. Many of them contain volatile oils, which are used for various purposes, and some yield yellow and other dyes. Among the most useful of the section may be mentioned the Jerusalem artichoke, wormwood, chamomile, tansy, and arnica—the last much employed in homœopathic practice ; indeed, most of the Corymbiferæ are of medicinal value. *Cynarocephalæ*.—The plants of this division are bitter and tonic. By cultivation, this bitterness is lessened, and they become edible. The section may be illustrated by the cardoon and common artichoke,

Chamomile.

all the thistles (*Carduus*), the burdock (*Arctium*), the bluebottles (*Centaurea*), the safflower (*Carthamus*). The properties of the artichoke are well known, as are also those of the carthamus, which is used in dyeing as well as in medicine. The thistle is chiefly interesting as being emblematical of Scotland ; but neither antiquaries nor botanists have been able to discover with certainty the species entitled to the appellation of *the* Scotch thistle. *Onopordum Acanthium* adorns the grave of Burns in Dumfries, and is usually employed in national demonstrations ; but Burns had another species in view as the 'bur-thistle'—namely, *Carduus lanceolatus*. Others prefer the milk-thistle ; and so far as the figures on the coins of the Scotch kings indicate a special species, the milk-thistle appears to be the one indicated.

§ COROLLIFLORÆ.

In this section the flowers are dichlamydeous, the petals united into a tube, hypogynous, stamens inserted in the corolla (or in the first four orders arising directly from the receptacle). The plants may usually be recognised by the corolla appearing to consist of one piece, the petals being united (gamopetalous). Many of the orders have regular flowers, but a large number have them two-lipped, and therefore irregular, such as the Foxglove, labiate plants, and Acanthi.

The following are the orders contained in this section :

*Ericaceæ—Heathworts.
*Pyrolaceæ—Winter-greens.
*Montropaceæ—Fir-rapes.
Epacridaceæ—Epacrids.
Ebenaceæ—Ebony order.
*Aquifoliaceæ—Holly order.
Sapotaceæ—Sapotads.
Myrsinaceæ—Myrsine order.
Jasminaceæ—Jasmines.
*Oleaceæ—Olives.
Salvadoraceæ—Salvadora order.
Asclepiadaceæ—Asclepiads.
*Apocynaceæ—Dogbanes.
Loganiaceæ—Strychnads.
*Gentianaceæ—Gentian worts.
Bignoniaceæ—Trumpet-flowers.
Gesneraceæ—Gesnerads.
Crescentiaceæ—Calabashes.
Pedaliaceæ—Pedalium order.
*Polemoniaceæ—Phlox order.
Hydrophyllaceæ—Water-leaves.
Diapensiaceæ—Diapensia order.
*Convolvulaceæ—Bindweeds.
*Cuscutaceæ—Dodders.
Cordiaceæ—Sebestens.
*Boraginaceæ—Borageworts.
Ehretiaceæ—Ehretia order.
Nolanaceæ—Nolana order.
*Solanaceæ—Potato order.
*Atropaceæ—Nightshades.
*Orobanchaceæ—Broom-rapes.
*Scrophulariaceæ—Figworts.
*Labiatæ or Lamiaceæ—Dead-nettles.
*Verbenaceæ—Verbenas.
Stilbaceæ—Stilbids.
Selaginaceæ or Globulariaceæ—Selagids.
Acanthaceæ—Acanthads.
*Lentibulariaceæ—Butterworts.
*Primulaceæ—Primroses.
*Plumbaginaceæ—Leadworts.
*Plantaginaceæ—Ribworts.

ERICACEÆ.—This is an extensive order of shrubs or under-shrubs, with leaves evergreen, rigid, entire, whorled, or opposite, and without stipules. 'The name of the heath family,' as it has been very appropriately remarked, 'conjures up immediately the image of a number of narrow-leaved plants, with globular, ventricose, or bell-shaped flowers; and we are apt at first to think that the family is so natural a one as to require very little explanation.' Did the order include only the heaths, this would be the case; for all the heaths, differing as they do in some particulars, may be recognised at a glance; but as the order includes the Rhododendrons, the Azaleas, and Kalmias, besides several other plants which have not so strong a family likeness to each other as the heaths, it becomes necessary to point out the botanical resemblances which connect them together. The first and most striking of these is the shape of the anthers—each of which appears like two anthers stuck together—and the manner of their opening, which is always by a pore or round hole in the upper extremity of each cell. The filaments also in all the genera grow from beneath the seed-vessel, being generally slightly attached to the base of the corolla. There is always a single style with an undivided stigma, though the capsule has generally four cells, each containing several small seeds. The calyx is four or five cleft, and the corolla is tubular, with a larger or smaller limb, which is also four or five cleft. The above are the connecting points between the various genera which compose the family; but the differences are such as to require a subdivision of the Ericaceæ into the following sub-orders: 1. *Ericeæ*, or those most closely resembling the true heaths, their fruit being loculicidal, rarely septicidal or berried, and the buds naked; 2. *Rhododendreæ*, those allied to the Rhododendrons, their fruits being capsular septicidal; the buds, scaly, resembling cones; 3. *Pyroleæ*, those allied to the winter-green of our woods, and distinguished by having a minute embryo at the base of fleshy albumen, the two preceding having a cylindrical embryo in the axis of the albumen. 1. *Ericeæ.*—This sub-order may be arranged into two sections—namely, the true heaths (*Ericidæ*), having bracteal pedicels of flowers, the corolla of each flower being more or less bell-shaped or globose, with a four-cleft limb, a four-lobed calyx, and eight stamens; and the *Andromedidæ*, which have the corolla more globose, the limb five-cleft, the calyx five-lobed, and ten stamens. In other respects both sections are nearly alike; both have a honey-bearing disc, and both have the leaves, which are narrow and leathery, slightly rolled in at the margin. The stamens appear differently in the several genera; some being capitate, others ending in awn-shaped horns; in some they are concealed by the corolla, in others they are exposed. The style, in some of the genera, projects considerably beyond the corolla, in others it is rather contracted. The more familiar genera are, the common heath of our moors (*Erica tetralix*), common ling or heather (*Calluna vulgaris*), and the Cape heaths, many of which have glutinous, cylindrical corollas. The genera *Andromeda*, *Zenobia*, the strawberry-tree (*Arbutus*), the bearberry of our Highlands (*Arctostaphylos uva-ursi*), and *Gaultheria*, frequent in gardens, are illustrations of the second section. Plants belonging to this sub-order cover large tracts of our own country, are common in North and South America, and abound at the Cape of Good Hope, which has supplied our gardens with hundreds of the most beautiful species of *Erica*. All of them possess bitter, astringent, and diuretic properties; and the berries of some, as well as the flowers, have been used in dyeing. The Arbutus is a very ornamental shrub, the berries of which are edible, and may be used in the preparation of a wine. 2. *Rhododendreæ.*—The plants in this sub-order have all less or more a resemblance to the well-known genus *Rhododendron*, the species of which have generally evergreen leaves, and large showy flowers produced in terminal corymbs. The calyx is small; the corolla, large in proportion, bell-shaped, and deeply five-cleft; the stamens, five or ten; the capsule, five-celled and five-valved. The flowers are generally purple or whitish, though in some they are yellow, pink, or bright scarlet, as in the Nepaul tree-rhododendron (*R. arboreum*). The genus *Azalea* is very nearly allied to the rhododendron; but its species—the Indian and American—differ considerably in their inflorescence and leaves; the latter in some species being deciduous. *Kalmia* and *Menziesia* are familiar garden genera; *Ledum palustre*, or wild rosemary, and the Labrador tea-plant (*L. latifolium*), also rank under this section, whose members have an extensive range, being found abundantly in Europe, Asia, and North America. They are chiefly inhabitants of high cold regions, and in this particular agree with the general habit of the order. The Rhododendreæ possess soporific properties—*R. crysanthum* being used in gout and acute rheumatism. The Azaleas are astringent, and some yield a poisonous honey, well distinguishing these plants from the true heaths, none of which are poisonous. The honey which gave rise to symptoms of poisoning in the Greek soldiers during the celebrated Retreat of the Ten Thousand mentioned by Xenophon, was obtained from *Rhododendron ponticum* and *Azalea pontica*, two ornamental shrubs much cultivated in our gardens and shrubberies. It has been observed that the leaves and flowers of *R. arboreum* poisoned the cattle which partook of them in Kumaon; and the leaves of *R. ponticum* have poisoned sheep and goats in this country. Some species yield a resinous matter having a powerful and oppressive odour. *R. setosum* is the *Tsalu* of the Sikkim Bhoteas and Tibetans, who attribute the oppression and headaches attending the crossing of the loftiest passes of the Eastern Himalaya to the strongly resinous odour of this and *R. anthopogon*, the *Palu* of the natives. The Rhododendrons introduced by Dr Hooker from Sikkim form the most valuable addition to our ornamental plants that has been made for many years. *R. nivale* occurs at elevations of from 16,000 to 18,000 feet on the Tibetan frontier. For eight months of the year, it is buried under many feet of snow; for the remaining four it is frequently snowed and sunned in the same hour. *R. ferrugineum* and *hirsutum* are the roses of the Alps, and form a shrubby belt on the Swiss mountains. 3. *Pyroleæ.*—This sub-order is well illustrated by the winter-green (*Pyrola*), which is common in British woods. The species of Pyrola are evergreen plants, with white flowers, the corollas consisting of five distinct

petals, and which have ten stamens, with anthers opening by a pore: the style is single, ending in a capitate stigma cut into five lobes; the fruit, a five-celled capsule.

OLEACEÆ.—Under this order are reckoned upwards of 20 genera, and about 130 species. They are trees and shrubs with erect or climbing stems, and with leaves opposite, petiolate, simple, seldom ternate or pinnate, and destitute of stipules. The inflorescence is often paniculate; the flowers regular, and sometimes, by abortion, polygamous; calyx, free, divided, and persistent; corolla, hypogynous, four-cleft, and rarely wanting; stamens, two, alternating with the lateral lobes of the corolla when present, or when there are four petals connecting the lateral petals in pairs; filaments, free; anthers, two-celled, bursting longitudinally; ovary, free, two-celled; ovules, pendulous and in pairs; style, sometimes wanting; stigma, entire or bifid; fruit, fleshy or dry, sometimes one-celled by abortion. According to the character of the fruit, the order is sometimes subdivided into the OLEÆ, having it a drupe or berry, and the FRAXINEÆ, having it samaroid.

The principal genera are—*Olea*, the olive; *Fraxinus*, the ash; *Ornus*, the manna-ash; *Ligustrum*, the privet; *Syringa*, the lilac; *Chionanthus*, the fringe-tree; and *Phillyrea*. The olive (*O. Europæa*) is a well-known tree, with small white flowers, and a fleshy drupe like a sloe, from which is expressed the olive oil of commerce. The ash (*F. excelsior*) is a common British tree, with pinnate leaves, the flowers without a corolla, and the fruit a winged samara or key, with one or two seeds. The manna-ash (*Ornus Europæa*), though closely resembling the common ash in its leaves and samara, has loose panicles of white flowers, the corollas of which are divided into four long narrow segments. The privet (*Ligustrum vulgare*), the lilac (*Syringa vulgaris*), and Phillyrea, are too common ornamental shrubs to require particular notice.

Economically, the oliveworts are of great importance. Besides the oil of the olive, so universally used in Europe, the unripe berries are pickled and eaten on the continent to provoke an appetite; and the bark, which is bitter and astringent, is used as a substitute for cinchona. The bark of the common ash, as well as that of several others, is astringent and febrifugal, while the wood of the former is easily worked, and exceedingly tough and durable. What is in the present day called manna is a saccharine cathartic, procured by wounding the bark of *Ornus rotundifolia* and *Europæa*. The sweetness of this substance is not due to the presence of sugar, but to a distinct principle called Mannite, which differs from cane-sugar in not fermenting with water and yeast.

LOGANIACEÆ.—This order consists chiefly of woody plants, with opposite entire, stipulate leaves, natives of the tropics. It is chiefly remarkable from containing *Strychnos Nux-vomica*, the plant from which strychnine is prepared. It is called rat's-bane, poison-nut, or koochla. This tree abounds on the Malabar and Coromandel coasts of the Indian peninsula, and produces a small orange-like fruit full of pulp, in which the seeds are imbedded. The latter alone form the fatal drug; but the wood of the tree is intensely bitter, and is employed in the cure of intermittent fevers and the bites of venomous snakes. Strychnia, the alkaloid upon which the poisonous properties of the seeds depend, is an intensely bitter substance—so bitter, it is said, that its taste can be detected when dissolved in 600,000 times its weight in water. This has led to its use in the adulteration of malt liquors, and there is reason to believe that it is still used for this purpose. *S. toxifera* is the basis of the famous woorali employed by the Red Indians to poison their arrows, which thus cause immediate death when introduced into the slightest wound. *S. Tieuté* yields the upas radja of Java, not that half-mythical upas around which so many fearful fables have been entwined.

CONVOLVULACEÆ.—A well-defined order, containing about 670 species. The members are lactescent herbaceous plants or shrubs, with stems usually twining, and with leaves alternate, undivided or lobed, and exstipulate. The inflorescence is axillary or terminal; peduncles one or many flowered, the partial ones generally with two bracts; calyx, persistent in five divisions, and imbricated as if in more whorls than one—often very unequal; corolla, monopetalous, hypogynous, regular, deciduous; the limb, five-lobed and plaited; stamens, five, inserted into the base of the corolla, and alternate with its segments; ovary, free, with two or four cells; the ovules, definite and erect; style, one, usually divided at the top; stigmas, obtuse or acute; capsule, with the valves fitting at their edges to the angles of a loose dissepiment, bearing the seeds at its base; seeds, large; albumen, mucilaginous.

The more familiar genera are *Convolvulus* and *Ipomœa*, which have the corolla marked with a decided fold or plait, peculiarly imbricated calyx, and are climbing plants, not easily confounded with any other family. The *Convolvulus arvensis* is the wild climber of our hedges; and *C. tricolor*, so common in gardens, is a native of Sicily. The bindweed (*Convolvulus sepium*) is another of our hedge-natives, and is a well-known pest of the farm and garden. The roots of the order abound in an acrid, purgative, milky juice, exemplified in *jalap*—which is obtained from *Exogonium Purga*—and in *scammony*, the concrete juice of the root of *Convolvulus Scammonia*, the roots or tubers of *C. Batatas*, the sweet potato, are edible, as are also those of *Ipomœa macrorhiza*, whose insipid farinaceous tubers are found in the sandy soil of Georgia and Carolina, weighing as much as forty or fifty pounds.

BORAGINACEÆ.—The plants of this order are chiefly herbaceous, have round stems, alternate rough leaves, and flowers in scorpioidal cymes. Corolla, usually regular and five-cleft, imbricate, often with faucial scales. Fruit, two or four distinct achenes; seeds, exalbuminous. Some of the plants of the order yield dyes, such as the alkanet, others form pot-herbs; one maritime species (*Mertensia maritima*) is a vegetable substitute for oysters, having a similar flavour; and another (*Symphytum asperrimum*) is particularly recommended by agricultural writers as a suitable food for pigs. More sentimental associations surround the forget-me-not (*Myosotis palustris*), which is not uncommon in marshy situations in Britain.

NOLANACEÆ, SOLANACEÆ, ATROPACEÆ.—These three groups are sometimes associated under one order; and although tabulated separately, we shall save space by discussing their characteristics together, for they have many points

of structure in common. They are herbaceous plants or shrubs, with alternate leaves, and with angular or rounded stems; calyx, five (rarely four) parted and persistent; corolla, with the limb having the same number of lobes as the calyx, somewhat unequal, and deciduous; estivation, folded or imbricate; stamens, alternating with the segments of the corolla, sometimes one abortive; anthers, bursting longitudinally, or by terminal pores; ovary, two or more celled, rarely one-celled; ovules, usually indefinite; style, continuous; stigma, obtuse, very rarely lobed; fruit, either a capsule opening variously, a berry with the placenta adhering to the dissepiment, or a nuculanium, with five spurious-celled nucules, which have one seed in each; seeds, sessile.

The *Solanaceæ* closely resemble each other in their flowers, and also in their berry-like fruit, which is always crowned by the persistent calyx; seeds, albuminous; embryo, curved. The estivation is valvate or induplicato-valvate. The genus *Solanum*, to which belongs the bitter-sweet (*S. Dulcamara*), the garden nightshade (*S. nigrum*), and the potato (*S. tuberosum*), has the anthers opening by pores like the heaths; whereas all the other members have a slit down each cell, as the tomato, or love-apple (*Lycopersicum esculentum*), with its edible fruit; the capsicum (*C. frutescens*, &c.), whose dry inflated berry yields the cayenne-pepper of commerce; and the winter-cherry (*Physalis Alkekengi*), also with edible berry-like fruit. To the *Atropaceæ* belong the deadly nightshade or dwale (*Atropa Belladona*), which furnishes the deadly poison of that name; and the Barbary or box-thorn (*Lycium barbarum*). They are dangerous in their qualities, the leaves and flowers being narcotic and poisonous. They are distinguished from the preceding principally by the more or less imbricated estivation of the corolla; it is never valvate. The flowers are also more funnel-shaped, with a longish tube and spreading limb. The principal genera are—*Nicotiana*, *N. Tabacum*, being the Virginian tobacco of commerce, and *N. persica* is the source of Shiraz or Persian tobacco, so much esteemed by smokers. *Petunia*, which furnishes some of our best known garden favourites; *Nierembergia*, a genus of ornamental green-house plants; *Hyoscyamus*, the poisonous henbane; *Datura*, *D. Stramonium*, being the common thorn-apple; and *Brugmansia* and *Salpiglossis*, all more or less prized for their showy funnel-shaped flowers, some of which are highly fragrant. The plants of this order display marked narcotic properties, and cause dilatation of the pupil. *Nolanaceæ*.—'This tribe,' says Loudon, 'is principally known by the genus *Nolana*, the species of which are annual plants, natives of Chili and Peru, which have of late been much cultivated in British gardens. The flowers of *N. atriplicifolia*, one of the commonest kind, very much resemble those of the *Convolvulus tricolor*, and the leaves are large and juicy like those of the spinach. On opening the corolla there will be found five stamens, surrounding four or five ovaries, which are crowded together on a fleshy ring-like disc. These ovaries, when ripe, become as many drupes, enclosing each a three or four celled nut, which is marked with three or more grooves on the outside, and has three or more little holes beneath. All the species of Nolana have the same peculiarities in their seed-vessels, though they differ in many other respects.'

SCROPHULARIACEÆ.—The Figworts, of which the common foxglove may be taken as the type, form rather an extensive order, consisting of about 170 genera, and 1800 species. The plants are herbaceous, rarely shrubby, with round or square stems; the leaves being simple and exstipulate, opposite or whorled, seldom alternate, and either sessile or with footstalks. The inflorescence is very variable, being axillary or united, usually in spikes, racemes, or in panicles; calyx, inferior, persistent, and often unequal; corolla, tubular or inflated, with a short limb, which is flat or erect, nearly equally divided, or labiate; stamens, definite, two or four (didynamous), rarely five, filaments, free; anthers, two-celled; ovary, two-celled; style, simple; stigma, obtuse, rarely bifid; fruit, a dry capsule, rarely baccate.

Foxglove.

The following genera may be mentioned as illustrative of the order: *Scrophularia*, weeds common in Britain. *Digitalis*, the foxglove of our waysides and gardens; *Antirrhinum*, the well-known snapdragon; *Linaria*, the toad-flax of our hedges and banks; *Euphrasia*, the eyebright; *Veronica*, including the brooklime and the speedwells; *Rhinanthus*, the yellow rattle, *Verbascum*, the mullein; and *Calceolaria*, *Buddlea*, *Mimulus*, and others, now favourites in every flower-garden. The form of the flowers in the different genera varies considerably, as may be seen by examining the foxglove, the speedwell, and calceolaria—plants at the command of every one. The stamens also present considerable differences: in the foxglove (*Digitalis purpurea*) there are two long and two short; in *Pentstemon* there are five, the fifth being long and slender, and without an anther; in *Calceolaria* and *Veronica* there are only two. Various attempts have been made to subdivide the order—as, for example, into two sections, the one including the genera having four anther-bearing stamens, and the other those having only two-anthered stamens. Mr Bentham divides it into three sub-orders, according to the inflorescence, each of which is again subdivided into several tribes.

The majority of this family contain a principle more or less acrid, purgative in some, and poisonous, as in the foxglove, unless taken in small doses. The meadow eyebright (*Euphrasia officinalis*) is slightly astringent and aromatic, without the deleterious qualities of the other genera. Cows are said to be fond of *Melampyrum pratense*; and Linnæus says the best and yellowest butter is made where it abounds. One or two species of Linaria and Calceolaria are named as yielding colours for the dyer. *Mimulus luteus* affords an interesting example of an exotic plant—from America—becoming speedily diffused throughout Europe in a naturalised state. It is now not

uncommon in ditches. Its stigma, formed of two lips, displays peculiar irritability.

LABIATÆ.—A very large natural order, remarkable for the uniformity of structure and properties which prevails among the members. The *labiate* or lipped corolla immediately suggests the mint, sage, thyme, dead-nettle, horehound, and lavender, with which every one must be more or less familiar. They are herbs or under-shrubs, with quadrangular stems, and opposite, divided or undivided, exstipulate leaves, replete with receptacles of aromatic oil. The flowers are in opposite, nearly sessile, axillary verticillasters, resembling whorls, as in the dead-nettle; sometimes solitary; calyx, tubular and persistent; corolla, bilabiate, the upper lip (*a*) being entire or bifid, the lower (*b*) three-cleft, the upper in estivation overlapping the lower; stamens, four, didynamous, the upper sometimes wanting; ovary, deeply four-lobed, seated on a fleshy disc, each lobe containing one erect ovule; style, simple; stigma, bifid; fruit, from one to four small nuts inclosed within the persistent calyx.

Labiatæ.

The following plants well exemplify the order: *Lamium album*, the white dead-nettle of our wall-sides; *Salvia officinalis*, the common garden sage; *Rosmarinus officinalis*, the well-known rosemary shrub; *Thymus Serpyllum*, the wild thyme; *Lavandula vera*, the sweet-scented lavender; *Mentha viridis*, spearmint, and *M. piperita*, peppermint; *M. sylvestris* is the Greek Heduosmon, translated mint in Scripture; *Nepeta Glechoma*, the ground ivy; *Marrubium vulgare*, the true medicinal horehound; *Ballota nigra*, black horehound, well known for its heavy oppressive smell; *Prunella vulgaris*, self-heal; *Ajuga reptans*, the common bugle; with basil, marjoram, betony, hyssop, and other culinary and medicinal herbs.

ACANTHACEÆ.—There are nearly 100 genera enumerated under this order, and upwards of 1400 species of herbs and shrubs, principally inhabiting tropical regions. Leaves, simple, opposite, and without stipules; inflorescence, terminal or axillary; flowers, showy, in spikes with two or three bracts to each; calyx, in four or five divisions, and persistent—but in many of the species inconspicuous or obsolete, its place being supplied by the large bracts; corolla, monopetalous, and usually irregular, with the limb ringent or bilabiate, and deciduous; stamens, two or four, and in the latter case didynamous; anthers, one or two celled, sometimes bearded, as in Acanthus, and bursting longitudinally; style, simple; stigma, one or two lobed; fruit, a two-celled capsule, elastically two-valved; seeds, supported on a filiform podosperm. The elastic dehiscent capsules, wingless seeds with hooked dissepiments, and imbricated flowers, are distinguishing features.

Examples of the genera are—*Acanthus*, *Thunbergia*, *Goldfussia*, *Lankesteria*, *Ruellia*, and *Justicia*. The species of Acanthus are found chiefly in the south of Europe; they are plants with graceful foliage, and the leaves of the *A. mollis* is said to have furnished Callimachus with patterns for the capital of the Corinthian pillar. The corolla varies considerably in the different genera; being bilabiate in Justicia, funnel-shaped in Ruellia, and campanulate in Thunbergia, the species of which are exotic climbers.

Acanthus.

The properties of the order are little known. The Arabs use the leaves of an Acanthus by way of salad; *Justicia pectoralis*, boiled in sugar, yields a syrup used in the West Indies as a stomachic; and *J. paniculata* is said to be the basis of the famous French tonic, *Drogue Amère*. A valuable deep blue dye is said to be obtained from one of the East Indian Ruellias.

MONOCHLAMYDEÆ.

The plants in this division have either no floral envelope, or have one only. In the former case, the pistil and stamens are naked; in the latter, they are surrounded by a calyx, there being no parts corresponding to the petals of a true corolla. The following are the orders:

ANGIOSPERMÆ.

Nyctaginaceæ—Marvel of Peru order.
*Amaranthaceæ—Amaranths.
*Chenopodiaceæ—Goosefoots.
Basellaceæ—Basella order.
*Scleranthaceæ—Knawel order.
Phytolaccaceæ—Phytolaccads.
Petiveriaceæ—Petivera order.
*Polygonaceæ—Buckwheats.
Begoniaceæ—Begoniads.
Lauraceæ—Laurels.
Atherospermaceæ—Plume Nutmegs.
Myristicaceæ—Nutmegs.
Monimiaceæ—Monimia order.
Proteaceæ—Protea order.
*Elæagnaceæ—Oleaster.
Penæaceæ—Penæa order.
*Thymelæaceæ—Mezereons.
Aquilariaceæ—Aquilaria order.
Chailletiaceæ—Chailletia order.
Samydaceæ—Samyda order.
Homaliaceæ—Homalium order.
*Santalaceæ—Sandal-woods.
*Aristolochiaceæ—Birthworts.
Nepenthaceæ—Pitcher plants.
Datiscaceæ—Datisca order.
*Empetraceæ—Crowberries.
*Euphorbiaceæ—Spurgeworts.
Scepaceæ—Scepa order.
*Callitrichaceæ—Starworts.
*Ceratophyllaceæ—Hornworts.
*Urticaceæ—Nettleworts.
Artocarpaceæ—Bread-fruits.
*Ulmaceæ—Elms.
Stilaginaceæ—Stilago order.
Lacistemaceæ — Lacistema order.
Podostemonaceæ—River-weeds.
Chloranthaceæ—Chloranthads.
Saururaceæ—Lizard's tails.
Piperaceæ—Peppers.
*Myricaceæ—Gale order.
*Salicaceæ—Willows.
Altingiaceæ—Liquidambars.
*Betulaceæ—Birches.
*Corylaceæ—Hazels and Oaks.
Casuarinaceæ—Beefwoods.
Platanaceæ—Plane-trees.
Juglandaceæ—Walnuts.
Garryaceæ—Garrya order.
Rafflesiaceæ—Rafflesia order.
Cytinaceæ—Cistus Rapes.
Balanophoraceæ—Balanophoras.

GYMNOSPERMÆ.

*Coniferæ — Pines or Cone-bearers.
*Taxaceæ—Yews.
Gnetaceæ—Jointed Firs.
Cycadaceæ—Cycad and Zamia order.

ANGIOSPERMÆ.

CHENOPODIACEÆ.—Chiefly herbs with herbaceous (greenish) flowers. The embryo is coiled round mealy albumen, or spiral without albumen; ovary, free, one-celled; stamens, inserted into the base of the perianth. Many of the species are used as pot-herbs, such as Spinach, Orach, and English mercury (*Chenopodium Bonus-Henricus*). The seeds of *C. Quinoa* are used as food. The Beet (*Beta vulgaris*) yields a large proportion of sugar, and in the form of mangold-wurzel is an important forage plant throughout Europe.

LAURACEÆ.—An important order, comprising about 450 species. They are tropical trees, with elegant foliage and aromatic properties, having exstipulate, alternate (seldom opposite) leaves, with inconspicuous flowers. The perianth is from four to six cleft, the limb sometimes obsolete; estivation, imbricate. The male and female flowers are distinct: the former have four, six, or eight stamens, opposite the segments of the perianth; the latter have four or more abortive stamens, furnished with glands, but without anthers, a one-celled, one-seeded ovary, with a simple style and an obtuse-crested stigma. The fruit is fleshy and indehiscent, naked, or covered by the enlarged and fleshy perianth. The two or four celled anthers, with the valves curling upwards when ripe, and the filaments furnished with kidney-shaped glands at their base, are characteristics of the order.

The chief genera are—*Laurus*, the sweet bay; *Sassafras*, the sassafras-tree; *Persea*, the avocado-pear; *Camphora*, the camphor-tree; *Cinnamomum*, the cinnamon-tree; *Cassytha*, the Dodder-laurel; *Tretranthera*, and *Cryptocarya*. The true laurels have two anthers, and naked fruit; the cassia, cinnamon, and camphor have four anthers, and the fruit covered. The plants contain essential oil in abundance, which imparts to them a peculiar sweet, though strong penetrating odour, and a warm and pleasant taste; hence they yield some of our most grateful stimulants and spices. Cinnamon, cassia, camphor, benzoin, and sassafras are products of the family; the roots of the sweet bay yield a violet dye; and a concrete oil, used in candle-manufacture, is obtained from the fruit of *Laurus glauca*. The branches of *Laurus nobilis*, or sweet bay, were used to crown the victors in the ancient games. This plant seems to be the *ezrach* of the Bible, translated 'green bay-tree.'

ARISTOLOCHIACEÆ.—There are only six or eight genera in this order, the members of which are herbaceous plants or shrubs, of climbing habit. The characters are—flowers, hermaphrodite; perianth, tubular, adherent with the ovary, and divided into three segments; stamens, from six to twelve epigynous, sometimes free and distinct, in other cases adhering with the style and stigma; ovary, three to six celled; style, short; stigma, six-rayed; fruit, capsular, dry, or succulent, three to six celled, and many-seeded; seeds, thin, flat, and of a dark-brown colour.

The chief genera are—*Aristolochia*, the birthwort; and *Asarum*, the wild-ginger of North America. Many of the species are natives of Europe; but they abound in the tropical regions of South America; *Arist. Clematitis* (common birthwort) and *Asar. Europæum* (Asarabacca) are the only two found in Britain, and are doubtfully native.

The birthworts are heating and stimulating in

Aristolochia.

their properties, and act chiefly on the skin and kidneys. The prepared root of *Arist. serpentaria* (Virginian snake-root) is used in ague, typhus fever, and in gout—being one of the ingredients of the celebrated Portland powder. The snake-root is regarded as an antidote against serpent-bites. A drop or two of the juice, if introduced into the mouth of one of these reptiles, has the power of stupefying it, so that it can be handled with impunity; and a few drops swallowed almost instantly cause death. The roots of the species of *Asarum* have bitter and acrid properties, and a disagreeable odour like that of the stapelias. *Asarum canadense* has an aromatic flavour, and is often used by the country-people in lieu of the true ginger.

EUPHORBIACEÆ.—In Britain, this order is represented by the small weedy spurges of our gardens and waste grounds, but exhibits a nobler aspect in hot regions, where the tall cacti-like columnar species attain gigantic proportions. The juice is usually acrid and milky, and the fruit formed of three globose carpels in union. The purgative resin Euphorbium is supplied by *E. officinarum* and other species. *Hura crepitans* is the sand-box tree, whose fruit bursts with a loud noise. *Ricinus communis* yields castor-oil. The vegetable tallow of China is derived from *Stillingia sebifera*. The seeds are beaten down and boiled to separate the tallow, which fuses at 80°, and is used for candles. *Aleurites triloba* yields Eboe-oil, used by artists. *Croton Tiglium* seeds yield croton-oil. *Janipha manihot* is the cassava or manioc plant of the West Indies. *Jatropha Curcas* produces the physic-nut. *Oldfieldia Africana* is the tree which supplies the African teak or oak.

URTICACEÆ—ARTOCARPACEÆ.—These are extensive orders of plants, which, to the uninitiated, may appear very dissimilar—as illustrated, for example, by the common nettle, the hop, the hemp, the pellitory of the wall, the bread-fruit tree, the cow-tree, upas, mulberry, common fig, banyan, and India-rubber tree, all of which, though exhibiting different habits and products, are not only strikingly alike in their essential characters,

but also in their general properties. They are much simplified by subdivision into two orders—namely, *Urticaceæ* and *Artocarpaceæ*—the former including the herbaceous species—as the nettle, hemp, and hop, with watery juice; and the latter the ligneous species—as the bread-fruit, mulberry, and fig, which have their juice milky. Bearing this distinction in mind, the following may be stated as the characteristics common to both: Trees, shrubs, or herbs, with alternate leaves, sometimes covered with asperities or stinging hairs, and furnished with membranous stipules, which are deciduous or convolute in vernation; flowers, usually monœcious, sometimes diœcious; perianth, membranous, lobed, and persistent; stamens, definite, distinct, inserted into the base of the perianth, and opposite its lobes; anthers, turned backwards with elasticity when bursting; ovary, superior, simple; ovule, solitary, erect, or pendulous; stigma, simple; fruit, a simple indehiscent nut, as in the nettle and hemp—or consisting of achenes immersed in a fleshy receptacle, or the persistent fleshy perianths, as in the bread-fruit, or inclosing them within its cavity, as in the fig. 'The unisexual flowers,' says Dr Lindley, 'simple lenticular fruit, and superior radicle and stipules, afford the essential characteristics of this order, which cannot well be mistaken for any except *Chenopodiaceæ;* and the plants of that order never have stipules, or rough or stinging leaves.'

The chief genera in the order URTICACEÆ are —*Urtica*, of which *U. dioica* is the common stinging-nettle; *U. urens*, the smaller stinging-nettle; and *U. pilulifera*, the Roman nettle; *Humulus lupulus*, the cultivated hop; *Cannabis sativa*, the fibrous hemp of commerce; and *Parietaria erecta*, the pellitory of the wall. The members of this order are widely scattered over the world, and increase apparently with the progress of civilisation; some of them—as, for example, the nettles—following in the footsteps of man. The chief genera of the order ARTOCARPACEÆ are—*Artocarpus*, of which *A. incisa* is the bread-fruit of the South Sea Islands; and *A. integrifolia*, the jack-tree of the East India Islands; *Galactodendron utile*, the cow-tree or palo de vaca of South America; *Antiaris toxicaria*, the upas-tree of Java, about which so many fabulous stories have been told; *Morus*, of which *M. nigra* is the common black mulberry, *M. rubra*, the red, and *M. alba*, the white mulberry, the leaves of which are so much esteemed for feeding silkworms; *Ficus*, of which *F. Carica* is the common edible fig, *F. Sycamorus*, the sycamore fig, the wood of which is very durable, and is supposed to have been used in the construction of mummy-cases; *Urostigma*, of which *U. Indica* is the spreading banyan, *U. elasticum* the India-rubber tree, and *U. religiosum* the sacred fig or pippul-tree of India. *Bœhmeria* (*Urtica*) *nivea*, the China nettle, is the source of that beautiful fabric for handkerchiefs, &c. which has of late years come into use under the name of China-grass and China nettle-fibre. Large quantities of the fibre are produced in the East, and find a ready sale in European markets, and especially among European residents in hot countries, for whose clothing this extremely fine fibre is peculiarly adapted.

The Urticaceæ have watery juice, which is acrid and astringent, and the fibres of their stems are all less or more tenacious. The leaves of the hemp are narcotic; the hop (fig.) has bitter, aro-

Hop.

matic, and stomachic properties, and its effluvia are said to be narcotic. The stinging property of the common nettle is well known. In the Artocarpaceæ, the juice is milky, and on exposure to the air, becomes tough and elastic. Their fruit is edible, but their juice is generally acrid and poisonous; except in that of the Galactodendron, which is wholesome and nutritious. The elaboration of a tough elastic product seems to be characteristic of the whole order—making its appearance in the stem of the hemp, in the inspissated juice of the India-rubber tree, or in silk, the best of which is derived from silkworms which feed on the leaves of the mulberry.

BETULACEÆ.—A small order of trees and shrubs, abounding in the temperate and colder regions of the globe. They have alternate simple leaves, with the primary veins often running straight from the midrib to the margin, and deciduous stipules. The flowers are in catkins, unisexual, and monœcious; the males having small scales in place of a perianth, or, in Alnus, a four-leaved membranous perianth. Stamens distinct, opposite the scales, scarcely ever monadelphous; anthers, two-celled; ovary, two-celled; ovules, definite, pendulous; style, single or none; stigmas, two; fruit, membranous, indehiscent, by abortion one-celled; seeds, pendulous, naked.

The chief genera are *Betula*, the birch, and *Alnus*, the alder, the species of which abound in every northern country. The common white birch (*B. alba*) is an elegant tree, thriving in almost any sort of soil, and becoming stunted and dwarfish only in the arctic regions, or at great elevations. The weeping-birch is a still more graceful tree, grown in lawns and parks for its fine drooping branches and neat foliage. *B. nana* is the dwarf birch of high and exposed situations, being found on the Scottish mountains and in some countries approaching to the very limits of perpetual snow. *B. nigra* is the black birch of North America, the timber of which is used by cabinet-makers; and *B. papyracea* is the paper birch, whose bark

is used by the Esquimaux and others in the construction of canoes. The common alder (*A. glutinosa*) is a quick-growing tree, found in swampy flats and by the borders of streams; its wood resists well the action of water, and is useful for piles; the Rialto at Venice is built on alder-piles, as well as many houses in Amsterdam; the hoary alder (*A. incana*) is seldom found south of the sixtieth parallel; the notch-leafed alders (*A. sinuolata* and *A. glauca*) are both American species.

The bark of the order is astringent and bitter. A decoction of birch-bark is used by the Laplanders in the preparation of reindeer skins; and the empyreumatic oil derived from it is used by the Russians in tanning, which gives the peculiar odour of their leather. The sweetish sap obtained by tapping the birch in spring is the chief ingredient in birch-wine; the leaves, which, when young, are highly odorous, are also used in imparting dyes of various shades of yellow. *B. lenta* yields sugar.

CORYLACEÆ.—The Corylaceæ or Cupuliferæ are so named from the cup-like shape of the persistent involucre in which their fruit or nuts are placed—as, for example, the acorn. The order includes many genera of well-known trees and shrubs—as the oak, Spanish chestnut, beech, hazel, and hornbeam. Their leaves are alternate, simple, and stipulate; their venation well marked, and often rigid; flowers, unisexual; the males in catkins, and the females in clusters or in catkins; the male flowers have from five to twenty stamens inserted into the base of the scales, or of a membranous perianth, generally distinct; in the females, the ovaries are crowned by the rudiments of an adherent perianth, seated within a coriaceous involucre of various figure, and with several cells and several ovules, most of which are abortive; ovules, twin or solitary, pendulous; stigmas, several, nearly sessile, and distinct; fruit, a bony or leathery nut, of one cell, and more or less inclosed in the involucre.

The following are the most familiar genera: *Quercus*, of which *Q. pedunculata* and *sessiliflora* are the British oaks; *Q. suber*, the cork-tree; *Q. Ilex*, the evergreen oak; *Q. rubra*, the scarlet oak of America; *Q. infectoria*, the gall-yielding oak; and *Q. coccifera*, the kermes oak. *Fagus*, of which *F. sylvatica* is the common beech of our woods; and *F. ferruginea*, of North America, has edible fruit. *Castanea*, to which belong *C. vesca*, the edible sweet chestnut; and *C. pumila*, the dwarf Virginian chestnut. *Corylus*, of which *C. Avellana* is the common hazel-nut or filbert, which yields an oil used by artists and watch-makers. *Carpinus Betulus*, the hornbeam of our hedges; and *Ostrya Virginica*, the iron-wood of America. The hornbeams are by some botanists ranked under the Birch tribe, on account of the involucre not forming so complete a cupule as the other genera; but this seems too minute a distinction, as the involucre is not more leafy than it is in some of the filberts. The members of the family abound in Europe, Asia, and North America, and generally in temperate regions, more sparingly in South America; they are altogether absent from the south of Africa.

The bark in all the species is bitter and astringent, and is used for dyeing, tanning, and for medical purposes. In a few, the fruit is bitter and disagreeable; but in the majority it is farinaceous, and frequently contains an oily matter, used in domestic economy. Their fruit, as well as their bark and timber, is of the highest value to man. The gall-nut is an excrescence of the oak caused by the puncture of an insect; it is used in medicine, and in the manufacture of ink and black dyes.

GYMNOSPERMÆ.

CONIFERÆ.—One of the most important, as it is one of the best defined, of the natural orders. Its members are trees or shrubs, with a symmetrically branched trunk abounding in resin, and are familiarly illustrated by the Scotch pine, the spruce and silver firs, the larch, the cedar, the araucaria, the arbor vitæ, the cypress, and the juniper. The ligneous tissue of their wood is marked with circular discs having a central punctation; their leaves are linear, needle-shaped, or lanceolate, entire at the margin. The characters afforded by the fructification are: Flowers, unisexual; males in deciduous catkins, monandrous or monadelphous, each floret consisting of a single stamen, or of a few; females in cones, whose scales arise from the axil of membranous bracts supplying the place of ovaries; destitute of a proper style or stigma; ovules, naked, in pairs on each scale, with large micropyles at their apices; fruit consisting of a cone formed of the hardened scales, which become enlarged and indurated, and occasionally of the bracts also; seed, with a hard crustaceous testa. In speaking of the Coniferæ, it has been not inaptly remarked that 'the flowers are quite different from what is generally understood by that name, being in fact nothing but scales; those of the male containing the pollen in the body of the scale, and those of the female producing the ovules or incipient seeds at the base.'

Well defined as the order obviously is, there are minor distinctions which warrant its subdivision into the following sections—namely, ABIETINEÆ, the true pines and firs; and CUPRESSINEÆ, the cypresses. In the firs, the fruit is a cone, the scales of which open, and more or less recurve, when the seeds are ripe; the ovules are inverted; the pollen, oval, or curved: in the cypresses, the fruit is also a cone, but rounder, and with fewer scales, occasionally succulent, forming a galbulus; ovules, erect; pollen, spheroidal. Of the Abietineæ the following are characteristic members: *Pinus sylvestris*, the Scotch pine; *Abies excelsa*, the spruce-fir; *Picea pectinata*, the silver fir; *Larix Europæa*, the common larch; *Cedrus Libani*, the cedar; and *Araucaria imbricata*, the Chili pine—all of which are evergreens, with the exception of the larch. The Cupressineæ are well represented by *Cupressus sempervirens*, the evergreen cypress; *Thuja occidentalis*, the American arbor vitæ; *Taxodium distichum*, the deciduous cypress; *Juniperus communis*, the juniper of our moors; *J. sabina*, the savin-tree, as well as by the newer genera, *Saxe-Gothæa*, *Fitzroya*, &c.

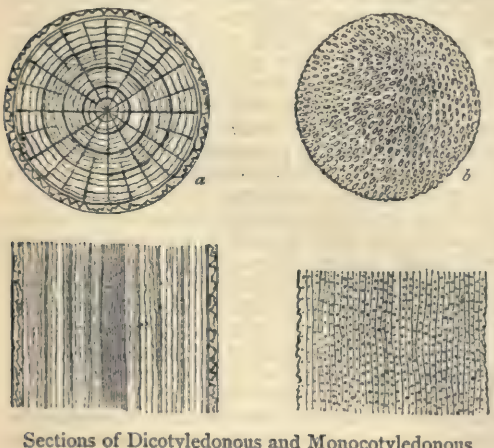
The high importance of this order is derived from its timber, which in all is straight, easily worked, and durable. *Wellingtonia gigantea*, the mammoth tree of California, forms a lofty trunk 112 feet in circumference, and upwards of 350 feet in height. Many valuable additions have

been made to this order of late years by Douglas, Jeffrey, Murray, Brown, and others. Vast forests of pines occur in North America, which have yielded many species well adapted to our climate, such as *Abies Douglasii*, *Pattoniana*, *Pinus Balfouriana*, *M'Nabiana*, *Jeffreyi*, &c.; and indeed almost every gentleman's estate exhibits examples of this order, not only from America, but from almost every region in the world. The deodar and cedar, from the East; firs, cypresses, and junipers, from the Far West; araucarias, from Chili and the antipodes; and cryptomerias, from Japan, form by far the most interesting, the most useful, and the most ornamental of our forest trees, whether planted merely with a view to the raising of timber, or for the purpose of beautifying the landscape. (See ARBORICULTURE.) Many plants of the order are also valuable for their resinous productions; several kinds of pitch, tar, turpentine, gums, and balsams being procured from them. The large seeds of some are edible and wholesome; the succulent cones, or, as they are familiarly called, *berries* of the juniper are largely used in the preparation of gin; and the main ingredient in spruce-beer is an extract from several species of Abies. Great tanning-powers exist in the bark of the larch; the savin, juniper, and others, possess stimulating and diuretic properties.

TAXACEÆ.—The yews are nearly related to coniferæ, and are usually associated with them. They differ in not producing true cones. The wood of many species is also peculiar, having spirals on the woody tubes, as well as discs; but this we have recently ascertained to be also the case in some firs—such as *Abies Douglasii*.

ENDOGENOUS OR MONOCOTYLEDONOUS PLANTS.

This class includes those plants whose leaves have their veins placed parallel—as the palms, the grasses, the hyacinth and crocus, and whose stems have no distinction of pith, wood, bark,



Sections of Dicotyledonous and Monocotyledonous Stems.

concentric circles, and medullary rays, like the Exogens (*a*), but consist merely of a confused mass of tissue (*b*). Their seed contains an embryo, having only one seed-lobe or cotyledon; hence the term Monocotyledon. Their trunks increase inwardly, instead of by external concentric layers; hence also the term Endogen. They are divided into three sections—DICTYOGENÆ, differing from all the others in having the leaves more or less net-veined, and usually articulated with the stem. PETALOIDEÆ, or FLORIDÆ, those having a perianth—such as the orchis, lily, palm, &c. GLUMIFERÆ, those which are destitute of a perianth, but have glumes or husks instead, like the grasses. The trees of this division are strictly tropical; the herbaceous species are found all over the globe.

§ 1. DICTYOGENÆ.

*Dioscoreaceæ—Yam order.
Smilaceæ—Sarsaparilla order.
*Trilliaceæ—Trillium order.
Roxburghiaceæ—Roxburghia order.
Philesiaceæ—Philesia order.

§ 2. PETALOIDEÆ.

*Hydrocharidaceæ—Frog-bits.
*Orchidaceæ—Orchids.
Apostasiaceæ—Apostasia order.
Burmanniaceæ—Burmannia order.
Zingiberaceæ—Ginger order.
Marantaceæ—Arrow-roots.
Musaceæ—Bananas.
*Iridaceæ—Iris order.
*Amaryllidaceæ—Amaryllis order.
Hypoxidaceæ—Hypoxids.
Hæmodoraceæ—Blood-roots.
Taccaceæ—Tacca order.
Bromeliaceæ—Pine Apples.
*Liliaceæ—Lilies.
*Melanthaceæ—Colchicum order.
Gilliesiaceæ—Gilliesia order.
Pontederiaceæ—Pontederia order.
Xyridaceæ—Xyris order.
Philydraceæ—Waterworts.
Commelynaceæ—Spiderworts.
Mayacaceæ—Mayaca order.
*Juncaceæ—Rushes.
Palmaceæ—Palms.
*Alismaceæ—Water-plantains.
*Juncaginaceæ—Arrow grasses.
*Butomaceæ—Flowering-rushes.
Pandanaceæ—Screw-pines.
*Typhaceæ—Bulrushes.
*Araceæ—Arum order.
*Orontiaceæ—Sweet Flags.
Pistiaceæ—Duck-weeds.
*Naiadaceæ—Pond-weeds.
Triuridaceæ—Triuris order.
*Restiaceæ—Restio order.
*Eriocaulonaceæ—Pipeworts.
Desvauxiaceæ—Bristleworts.

§ 3. GLUMIFERÆ.

*Cyperaceæ—Sedges.
*Gramineæ—Grasses.

DICTYOGENÆ.

DIOSCOREACEÆ.—These are twining, somewhat shrubby plants, with unisexual flowers in spikes, natives of the tropics, except *Tamus communis*, or Black Bryony, which represents the order in temperate climates. Various species of *Dioscorea* yield edible tubers, which are known by the name of yams, and are used like potatoes. *D. Batatas* is the Chinese Potato. *Testudinaria Elephantipes* is the Elephant's-foot, Hottentot's-bread, or Tortoise plant, of the Cape.

PETALOIDEÆ.

ORCHIDACEÆ.—This order consists of terrestrial or epiphytal herbaceous plants with enlarged roots and stems. The roots in epiphytal species are clothed with an outer layer of spiral cells, which apparently serve the purpose of absorbing moisture from the atmosphere, and thus enabling the plant, which has no roots in the soil, to subsist and develop itself. The perianth consists of six segments in two rows, one differing in form from the rest, and called the labellum. The pollen-cells do not occur in the form of distinct grains, but are aggregated together in simple or compound *masses*, which become detached collectively. The flowers often resemble the forms of insects, as the bee orchis of Kent, and the more gaudy butterfly orchid of the tropics. The singular forms and intense colours of their flowers recommend these plants to the attention of horticulturists. Of the 3000 existing species, few are conspicuous for their uses. Species of *Eulophia* furnish salep; and the fragrant vanilla, used in confectionary and in the

preparation of chocolate, is obtained from *Vanilla planifolia* and *aromatica.*

BROMELIACEÆ.—This family consists of about a dozen genera, and more than 170 species of plants, with scarcely any stem, and sometimes epiphytic in their habit. Their leaves are rigid, channeled, and often spiny or toothed at the margin. The perianth is tubular, its parts in two rows; the outer, or calyx, in three clefts, rigid, and persistent; the inner, petaloid and deciduous; stamens, six, inserted into the tube of the perianth; ovary, free or cohering, and three-celled; ovules, indefinite; style, single; stigma, three-parted, often twisted; fruit, capsular or succulent, three-celled, and many-seeded.

The principal genera are—*Bromelia*, *Ananassa*, *Billbergia*, *Pitcairnia*, *Tillandsia.* They are natives of moist warm climates. The common pine-apple (*A. sativa*) receives its English name from the circumstance of its fruit being covered on all sides with small triangular scales, resembling the cone of a pine-tree. What is called the fruit is, in fact, the fruits of the same spike cohering into one mass, by means of their succulent bracts.

The order has several important uses. Several of the species are esteemed for their showy blossoms; and the tough leaf-fibres of many produce excellent cordage. Some of the Tillandsias, which hang their black thread-like festoons from the trees of Brazil, are collected and used for stuffing mattresses, saddles, &c. Most of the genera yield a fine aromatic odour; and from their habit of retaining water in the sheathing axes of their leaves, are said to be specially grateful to the traveller in the regions where they abound.

LILIACEÆ.—A very extensive, and, to the florist, one of the most important of the natural orders. Taking the common white lily as the type, there is a great resemblance in all the Lilyworts, not only in their habits and forms, but also in their essential characters; but botanists have somewhat perplexed themselves by subdivisions founded upon minute differences. It must be confessed that the limits of the order are not very clearly defined. The plants may be generally characterised as having usually scaly or tunicated bulbs; and leaves not articulated with the stem, either sessile or with a narrow petiole. In some of the genera, the flowers are erect and single, as in the tulip; in others, they are erect, but in umbels, as in the orange-lily; and in others they are in racemes and drooping, as in yucca; or single and drooping, as in the fritillary; or with the segments curved back, as in the martagon lily. Perianth, coloured, regular, and divided into six segments, occasionally tubular; stamens, six, inserted into the segments of the perianth; anthers, opening inwards; ovary, superior, three-celled, and many-seeded; style, one; stigma, simple or three-lobed; fruit, either a three-celled, three-valved capsule, or fleshy, and then occasionally tripartite. The seeds of the Asphodeleæ have a black, crustaceous, brittle testa; in the Tulipeæ and Hemerocallideæ the testa is brown and spongy.

Liliaceous Flower.

The following plants may be mentioned as illustrative of the principal genera: *Lilium chalcedonicum*, the scarlet martagon lily, supposed to be the Krinon, or lily of the field of the New Testament; *Tulipa sylvestris*, the wild yellow tulip; *Allium cepa*, the onion; *Fritillaria Meleagris*, the fritillary; *Hyacinthus orientalis*, the garden hyacinth; *Endymion nutans*, the bluebell; *Asparagus officinalis*, the garden asparagus; *Muscari racemosa*, the grape hyacinth; *Erythronium dens-canis*, the dog's-tooth violet; *Phormium tenax*, the New Zealand flax; *Aloë*, the aloe; *Hemerocallis*, the day-lily; *Scilla*, squills; *Asphodelus*, king's spear; *Ornithogalum umbellatum*, the star of Bethlehem or doves' dung of Scripture. The Lilyworts are found in every quarter of the globe, being more abundant, however, in temperate than in tropical climates, where they exist chiefly in arborescent forms.

The properties of the order present considerable differences. All the Asphodeleæ contain a bitter stimulant principle, and have a viscid juice, as is exemplified by the onion, garlic, leek, and chives. The roots of some are purgative, as the aloe; while those of several lilies are eaten in Siberia. Gum-dragon is the styptic juice of *Dracæna Draco*, which yields a gum called Dragons' Blood; New Zealand flax is the tough fibre of the leaf of *Phormium tenax;* squills is a well-known demulcent; and the succulent suckers of asparagus are largely eaten as a vegetable. *Xanthorhœa hastile* and *arborea* are the grass-trees of New South Wales, which yield a resin used by the natives for fixing wooden handles to stone hatchets or hammers.

PALMACEÆ.—An important order of arborescent plants, with lofty, usually unbranched trunks, bearing a tuft of leaves on the summit. The leaves are large, pinnate or fan-shaped; flowers, small, arranged on a simple or branched spadix, which is inclosed in a one or many valved spathe; florets, bisexual or polygamous; perianth, six-parted, and persistent, its parts in a double row—the three outer segments often smaller, the three inner sometimes deeply connate; stamens inserted into the base of the perianth, usually six, seldom three, and in a few polygamous species, indefinite; ovary, one or three celled, or deeply three-lobed; ovules, three, rarely one; fruit, a nut, drupe, or berry; albumen, cartilaginous or hard, often ruminate, with a central cavity.

Palm.

The principal genera are—*Cocos*, the coco-nut; *Phœnix*, the date-palm; *Sagus*, the sago-palm; *Calamus*, the rattan canes; *Areca*, the betel-nut; *Borassus*, the Palmyra-palm; *Ceroxylon*, the wax-palm; *Elais*, the oil-palm; *Lodoicea*, the double coco-nut; *Phytelephas*, the vegetable ivory-palm; and *Hyphœne*, the doom-palm of Egypt. They are strictly inhabitants of the tropics, to the natives of which they are undoubtedly the most useful order of vegetation.

The properties of the Palms are numerous and varied—wine, oil, wax, flour, sugar, salt, thread, utensils, habitations, and food, being obtained from numerous species. *Coir*, which is worked into mats and cordage, is the dry fibrous pericarp of the coco-nut.

BUTOMACEÆ.—A small order of aquatic plants, having very cellular leaves, furnished with parallel veins, and handsome umbellate flowers of a purple or yellow colour. Calyx, three-sepaled, usually herbaceous; corolla, three-petaled and coloured; stamens, definite or indefinite; ovaries, superior, three, six, or more, either distinct or united; follicles, many-seeded; seeds, minute, attached to the whole inner surface of the fruit.

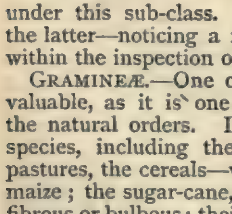
The genera are—*Butomus*, *Limnocharis*, and *Hydrochleis*, which abound respectively in the marshes of Europe, South America, and the East Indies. *B. umbellatus*, the flowering rush, an enneandrous plant, is found in ditches and by river-sides in some parts of Britain, growing from two to three feet high, with sword-shaped leaves, and umbels of rose or purplish white flowers. *Limnocharis Plumieri*, a native of Brazil, has yellow flowers, and the apex of each leaf is furnished with a curious pore, apparently for the discharge of the superabundant moisture which constantly distils from the plant.

Flowering Rush.

The order is said to possess acrid and bitter properties; and most of the species yield a milky juice.

GLUMIFERÆ.

The plants in the section Glumiferæ of the Monocotyledons are destitute of a regular calyx and corolla, having instead green or brown scales to cover the stamens and pistil. The glume or chaff of the oat (see fig.) is a familiar example of this kind of envelope. The Sedges (CYPERACEÆ) and the Grasses (GRAMINEÆ) are the only orders ranking under this sub-class. We can merely glance at the latter—noticing a few of the genera which lie within the inspection of every one.



GRAMINEÆ.—One of the most important and valuable, as it is one of the most extensive, of the natural orders. It comprehends 4000 known species, including the common grasses of our pastures, the cereals—wheat, barley, rye, oats, and maize; the sugar-cane, rice, &c. Their roots are fibrous or bulbous; their culms or stems cylindrical and hollow, except at the joints, where they become solid, the whole culm generally covered with a silicious coating; leaves alternate, and though sheathing the stem, not united round it; flowers in spikelets, and arranged in a spiked, racemed, or panicled manner. The characters of the fructification are —flowers, either solitary or arranged in spikes, usually hermaphrodite, sometimes monœcious or polygamous, consisting of imbricated bracts, of which the most exterior are called *glumes*, the inferior immediately inclosing the stamens, *paleæ*, and the innermost at the base of the ovarium, *scales:* glumes, usually two, alternate, sometimes single, often unequal; paleæ, two, alternate, the lower or exterior simple, the upper or interior supposed to be composed of two united by their contiguous margins, and usually with two keels; scales, two or three, sometimes wanting; stamens, hypogynous; anthers, versatile; pericarp, usually undistinguishable from the seed, membranous; albumen, farinaceous.

The Grasses are scattered all over the globe, and are the most directly useful of all vegetation both to man and to the lower animals. The following well-known plants may be taken as illustrative of the order: *Triticum vulgare*, common wheat, which, according to the experiments of Fabre, appears to have originated from a small weedy grass (*Ægilops ovata*), not uncommon on the shores of the Mediterranean. *Hordeum distichum*, common two-rowed barley; *Secale cereale*, rye; *Avena sativa*, common oat; *Zea mays*, maize or Indian corn; *Saccharum officinarum*, the sugar-cane; *Oryza sativa*, rice; *Bambusa arundinacea*, the bamboo; *Phleum pratense*, cat's-tail or Timothy grass; *Anthoxanthum odoratum*, sweet-scented vernal grass; *Dactylis glomerata*, cock's-foot grass; *D. cæspitosa*, the tussac-grass; *Andropogon Schœnanthus*, the lemon-grass; *Gynerium argenteum*, the Pampas-grass; *Phalaris canariensis*, the canary-seed; Sorgham species, the guinea-corn; *Festuca pratensis*, meadow-fescue; *Lolium perenne*, rye-grass; *Briza media*, quaking-grass; *Alopecurus pratensis*, meadow fox-tail grass; and *Holcus lanatus*, woolly soft grass. The cereal grains are plants of very ancient cultivation, and not being now found in a wild state, the origin of some of them is doubtful. Though allied in many respects to the Sedges, the Grasses are readily distinguished by their round hollow-jointed stems, and leaves that sheathe, but do not completely surround, the stem like a tube. The Grasses have a thin silicious coating on their stems, which seems intended to furnish them with greater strength and durability than could have been procured by simple ligneous fibre.

Sugar-cane.

ACROGENOUS OR ACOTYLEDONOUS (FLOWERLESS) PLANTS.

This class of vegetation is readily distinguished by none of its members bearing proper flowers—hence the terms *Cryptogamia* and *Flowerless.* The higher forms exhibit a peculiar kind of tissue, called scalariform vessels, as well as spiral vessels; but the lower forms consist of cellular tissue only. They exhibit very different degrees of organisation—the highest (*ferns*) having both stems and leaves (*fronds*), and the lowest consisting of simple-jointed threads, or even mere individual cells. Between these two extremes there are various

conditions of stem and leaf—the two most frequently graduating into each other, and forming neither true leaf nor stem, but thin expansions, termed *thalli*. Cryptogamic plants do not originate from seeds, containing embryos, like the flowering-plants, but are reproduced by means of spores—bodies which in their simplest form consist of a single cell, but which are very varied in morphological character in different families. There are two sub-classes.

§ 1. ACROGENÆ.

*Filices—Ferns.	*Equisetaceæ—Horse-tails.
*Lycopodiaceæ—Club-mosses.	*Musci—Mosses.
*Marsileaceæ—Pillworts.	*Hepaticæ—Liverworts.

FILICES.—In this order the different parts of the plant spring from a *rhizome*, or root-stock; the elegant fronds or leaves being either separate and independent, or uniting by their stalks so as to form a sort of trunk, as in the tree-ferns. The fronds are furnished with forked veins, and are usually pinnatifid, and more or less compound; sometimes nearly simple and entire; in their vernation they are circinnate—that is, they unroll from the stem outwards in the form of a crosier. The reproductive organs appear on the mature plant in the form of *sori*, or brown membranous-looking spots, usually either upon the backs of the fronds, or on their margins. These sori either lie under a small shield-like *indusium*, or they are naked; or they are arranged along the margin of the leaf, which curls over them, and supplies the place of the indusium. Each sorus consists of a number of brownish bodies, called *thecæ*, or *sporangia*, each being in reality a case containing a number of minute *spores*, which are the true reproductive bodies. (For details of the development of these spores into plants, see VEGETABLE PHYSIOLOGY, page 75.)

The Ferns are divided into the following sub-orders: 1. POLYPODIACEÆ; sporangia in variously shaped sori on the back or margin of the frond, each having an elastic ring or rachis (vertical and incomplete, or horizontal and complete), by means of which the ripe sporangium is torn so as to set the contained spores free. 2. OSMUNDACEÆ; sporangia on a transformed contracted frond, with a terminal or dorsal ring more or less complete, reticulated, and opening vertically. 3. OPHIOGLOSSACEÆ; sporangia in spikes, sessile on a contracted frond, exannulate, two-valved (vernation of frond straight). 4. DANÆACEÆ; sporangia dorsal in masses, exannulate, splitting irregularly by a central cleft. The first sub-order is illustrated by the following genera: *Polypodium*, the polypody, which has naked sori; *Lastrea*, the shield-fern; *Cystopteris*, the bladder-fern; *Asplenium*, spleen-wort; *Pteris*, the common brake; *Athyrium*, to which belongs the lady-fern of our woods; *Adiantum*, maidenhair; and *Scolopendrium*, hart's-tongue, the frond of which is tongue-shaped and simple. The second sub-order is represented by *Osmunda*, the Royal fern; *Anemidictyon*, and *Lygodium*, the climbing-fern. The third sub-order contains *Botrychium*, the grape-fern or moon-wort; and *Ophiglossum*, the adder's-tongue; and the fourth sub-order, a few exotic genera. The Filices are widely distributed, delighting in humid soil and shady situations—some growing on trees.

Tree-fern.

The fronds of the family generally contain an astringent mucilage, and are thus considered as pectoral; the roots of some have recently been used successfully as anthelmintics and purgatives; and *Aspidium fragrans* has been employed as a substitute for tea. The young leaves and rhizomes of some New Zealand species are edible; and the fronds of the common brake, when burned, yield a considerable quantity of alkali.

Lycopodiaceæ (Club-mosses), *Equisetaceæ* (Horse-tails), and *Marsileaceæ* (Pillworts), are usually classed as FERN ALLIES. They display considerable variety of structure, and will well repay careful study.

MUSCI.—The Mosses present many points of interest. They are minute plants, with erect or creeping stems and small leaves, all their tissues cellular. At certain seasons, little flower-like heads are produced, some containing antheridia (so named from their resemblance to anthers), and others less conspicuous, consisting of pistillidia, which represent the female parts. At maturity, each antheridium opens at the apex, and emits a granular gelatinous mass; this consists of minute spermatozoa, which find their way into, and impregnate the pistillidia, and thus give rise to the development of the latter into an urn-shaped theca or spore-case, containing spores capable of germinating into new plants.

Mosses grow usually in shady situations, and are abundant in moist, temperate countries. They are divided into three sub-orders—Andreæaceæ, Sphagnaceæ, and Bryaceæ. The first is illustrated by the split-mosses (*Andreæa*), which are common on the Scottish hills; of the second, *Sphagnum*, bog-mosses is the only genus; while the third embraces the genera *Bryum* and *Hypnum*, and most other British mosses.

§ 2. THALLOGENÆ.

The orders under the Thallogenous sub-class of Cryptogams are:

*Lichenes—Lichens.	*Algæ—Sea-weeds.
*Fungi—Mushrooms.	*Characeæ—Charas.

LICHENES.—Lichens form not the least interesting section of the Cryptogamia, and their value on the score of utility is by no means unimportant. They are familiar objects to all in the form of apparent discolorations and incrustations on old walls and rocks; but some of them hang in festoons from the branches of trees (*Usnea*, *Alectoria*), while others (*Peltidea*) spread their thalli among mosses and herbage in shaded situations. They grow slowly, and attain an extreme age, as some of those growing on the primitive rocks of our highest mountain-ranges must be. 'The hoary Usneas, Ramalinas, and Physcias, like the gray beard of an old man, silently but eloquently proclaim time's ravages, and illustrate the constant succession of life upon death, growth upon decay, which is going on around us.' In their reproductive organs, they approach the Fungi, but are well distinguished by the presence

in their tissue of gonidia containing chlorophyl, which are capable of originating new plants.

The Lichens yield valuable dyes. Orchil, a red dye, supposed to have supplied the purple of ancient Tyre, is produced by *Roccella tinctoria*, a Southern European species which was discovered in the Cumbray Islands, in the west of Scotland, by Professor Balfour in 1855. *Cladonia rangiferina* is the Reindeer Moss, an important forage-plant in Lapland. Species of *Gyrophora* (*Tripe de Roche*) are edible, and furnished Franklin and his companions with food for many weeks in arctic regions. *Cetraria islandica*, the Iceland moss, contains starch and a bitter principle. *Lecanora tartarea*, the rock-moss, supplies the cudbear dye; and *Parmelia parietina* yields a yellow dye.

FUNGI.—The Fungi, or Mushroom family, which are among the lowest forms of vegetation, are extremely diversified in their size, shape, colour, and consistence. The common field-mushroom is one of the best known, and may be cited as a type of the family; but the puff-ball, truffle, moril, as well as the mould on cheese and stale bread, the mildew on trees, the rust on corn, the substance called dry-rot, and many other minute appearances of a similar nature, are all fungi. In the field-mushroom (*Agaricus campestris*), the plant consists first of some filamentous filaments or spawn, which look like roots, then the stipe or stalk, surmounted by the pileus or cup. 'When the mushroom first appears, the stalk is covered by a thin membrane, called the veil, which unites the cup to the lower part; but as the mushroom grows, this veil is rent asunder, and it either entirely disappears, or only a small portion of it remains round the stalk, which is called the *annulus* or ring. Under the cup are gills or lamellæ, which are of a dark reddish brown; and attached to these are the thecæ, containing the spores.' Many—as the moulds, &c.—are mere microscopic jointed filaments, or filaments surmounted by little ball-like receptacles which contain the sporules, or are mere spherical or filamentous cells, which increase with astonishing rapidity, each cell containing a number of undeveloped ones.

Among the more familiar genera are—*Agaricus*, the mushroom; *Tuber*, the truffle; *Morchella*, the morel; *Lycoperdon*, the puff-ball; *Puccinia*, the mildew; *Clavaria*, the yellow meadow fungus; *Podisoma*, the jelly-looking masses often found on juniper and savin bushes; and *Tubercularia*, the small, red, pimple-like fungus found on rotten sticks and trunks of trees. The Fungi are scattered everywhere—springing from the ground, yet without roots; under the ground, as the truffle; on all decaying organic substances; and even on living animals. What is called yeast is a spherical-celled fungus, having a nucleated development.

The plants of this order are not more diversified in form than in properties. Some are wholesome and palatable—as the mushroom, moril, truffle, &c.; others, similar to these in appearance, are deadly poisons. Many of the minuter fungi—as moulds, smuts, rusts, &c.—are noxious to the human system. Ergot forms a powerful and dangerous medicine. German tinder is prepared from a species of puff-ball, which, after being dried, is impregnated with nitre. The Siberian fungus (*Amanita*) is used to induce intoxication. The vinegar plant is one of the most singular forms of fungi; it is an abnormal state of *Penicillium glaucum* developed in saccharine fluid, which it has the property of converting into vinegar suited for table use.

ALGÆ.—The Algæ form a highly interesting family of plants, and are specially important to the physiologist, for it is in these that the phenomena of growth and reproduction are most successfully studied. This order—which has been wisely split up into *several orders*, concerning which our space will not permit of full details—embraces the very simplest forms of vegetation, as well as many having a complicated structure. The Algæ are not confined to the sea; many occur in fresh water and on the dry land. They are classified as follows: 1. MELANOSPERMEÆ or FUCACEÆ; brown-coloured sea-weeds. 2. RHODOSPERMEÆ or CERAMINACEÆ; rose-coloured sea-weeds. 3. CHLOROSPERMEÆ or CONFERVACEÆ; green-coloured sea and fresh-water weeds. 4. DIATOMACEÆ, Brittleworts; unicellular, in the form of frustules, usually coated with silica, and containing brown, rarely green, contents. 5. DESMIDIEÆ; unicellular, without silica, containing always green cell-contents. The first contains many of our large species of common sea-weeds; the second, those beautiful kinds so highly prized for albums; the third, those green filamentous species so common in stagnant waters, some of which fill up lakes with their interlaced masses of filaments; the fourth, those minute silicious bodies found in such amazing quantities in all parts of the world; and the fifth, the analogous non-silicious species, which display perhaps the most beautifully symmetrical forms of the vegetable kingdom.

Such, according to our limits, is an outline of the Natural System of Botany; which, though as yet not fully developed, is more interesting and instructive than any artificial method, however elaborate and complete. Undeveloped as we must admit it to be, harsh and difficult as much of its nomenclature is, unnecessarily multiplied and complicated as its orders and tribes really have been, it has still the germs of truth and nature within it, and only requires a cordial and patient elaboration, on the simple principles of its great founder, to render it what it professes to be—an exposition of the system upon which Nature has proceeded in the creation of the Vegetable Kingdom. Our brief synopsis can at most but convey a very general notion of vegetable life and relationship, and only introduce the student to the technical phraseology and mode of procedure: for further acquaintance with the subject, we cannot refer to more accessible sources than the excellent works published by Professor Asa Gray, Professor Lindley, and Professor Balfour.

HUMAN PHYSIOLOGY.

HUMAN PHYSIOLOGY is the science which treats of the functions of the body and the manner in which these are performed. By a function we mean the action performed by any part of the body. For example, one of the functions of the liver is to secrete bile, while that of the stomach is to digest food. It is the object of the present paper to describe as briefly as is compatible with clearness the most important of these functions. The functions of the human body may be conveniently classified into three great divisions: 1. The Function of Nutrition, or the nourishment of every part of the body, so as to enable each part to perform its special function; 2. The Function of Innervation, or the actions performed by the nerves, spinal cord, and brain; and 3. The Function of Reproduction, or the perpetuation of the species by offspring.

I. THE FUNCTION OF NUTRITION.

This function is a complex process. To keep up the integrity and vigour of the body, food must be procured, chewed or masticated, mixed with saliva, swallowed, digested in the stomach, the nutritious material absorbed by special organs in the bowels, called *villi*, and from them carried to various glands, where it is elaborated into blood. The blood is then conveyed through the body, giving up to the tissues what they require for nourishment, and carrying away materials resulting from their decay. Thus rendered impure, the blood must have the noxious materials removed. For this purpose, several organs, such as the lungs, the liver, the skin, the kidneys, and the lower bowel, are set apart. Thus the blood is constantly replenished with nutritious matters, and constantly being purified, so as to fit it for supplying each individual particle or cell of the body with exactly the material it requires. Bone requires earthy salts, muscle requires albumen, the nervous system requires fat, and so on.

The process of nutrition is complex only in the higher animals. In the amœba, a little animal which is nothing more than a mass of jelly-like living material, we find no trace of organs, and nutrition is carried on by any part of the body. But as we ascend in the scale of animal life, one organ after another is added, such as a digestive sac, glands for secretions to act on the food, a special fluid—the blood, an organ and vessels for circulating this fluid; and so on, till we come to the higher animals, where we find great differences in parts, and corresponding differences in function. We will divide nutrition into the following thirteen stages, namely:

1. FOOD, OR ALIMENT.

A living being is always in a state of change. His skin gives off water, either in the form of sweat, or as invisible vapour; his kidneys act similarly, the water in both cases containing salts and other matters in solution; and his lungs are always exhaling, not only watery vapour, but the gas known as carbonic acid, as may be readily shewn by breathing into lime-water, which soon assumes a milky appearance, in consequence of the formation of carbonate of lime. Moreover, the body, which has an almost constant temperature of about 98·4° F. is always giving off heat. The production of heat indicates chemical changes in the body, accompanied by waste of material. If this condition of things were to go on indefinitely, the weight of the body would gradually diminish. To retain the body in its normal state, we must therefore supply it with three things—*atmospheric air*, *water*, and *food*. We have placed them in the order of their importance.

Various classifications of the food of man have been proposed; but the following is simple and practical: (1) the *aqueous*, (2) the *albuminous*, (3) the *fatty*, *oily*, or *oleaginous*, (4) the *saccharine*, (5) the *gelatinous*, and (6) the *saline* groups. All our daily food is referable to one or more of these classes. The *aqueous* group includes not only water, but all fluids (except oils) used as drink, and it must be recollected that all our so-called solid foods contain a large percentage of water. The *albuminous* group (often termed the protein) is typified by the white of egg, and includes the gluten of flour, the chief constituents of flesh and cheese. These substances contain the four elements, carbon, hydrogen, oxygen, and nitrogen, and also a little sulphur or phosphorus, or both. The albuminous foods chiefly nourish the muscles, but they contribute, along with fat or oil, to almost every tissue. The *fatty* group includes all animal and vegetable fats or oils. They are composed of carbon (ranging from 60 to 80 per cent.), hydrogen, and a little oxygen. The *saccharine* (often termed the starchy or amyloid) group contains all the varieties of sugar, starch, dextrine, and gum; like the preceding group, they are composed solely of carbon, hydrogen, and oxygen. Both the fats and sugars belong to the group termed by chemists *hydrocarbons*, because they contain carbon or charcoal, and oxygen and hydrogen, in the proportions, or nearly in the proportions, necessary to form water. They contribute chiefly to the adipose or fatty tissue of the body. The *gelatinous* group is represented by cow-heel, isinglass, and such-like substances, yielding jellies and soups that stiffen on cooling; while the *saline* group includes mineral matters, especially common salt, and phosphates of the alkalies, and of lime, &c. The saline or mineral matters form bone, tooth, &c. and they are found in variable proportions in almost every fluid and solid in the body. It must be remembered, however, that a mixture of all of these constituents of food is essential to the formation of a nutritious diet, and, moreover, that there must always be a certain amount of sapidity or flavour in the food. We should

turn with disgust from a mess consisting of these constituents, even in proper proportions, if it were not properly cooked. The best example of a natural food is milk. It contains water, albumen in the form of caseine or cheese, fat in the form of butter, sugar, and various salts. Hence it is nature's food for all young animals of the mammalian group.

A daily amount of food varying from 33 to 35 ounces of dry food is sufficient to maintain the health of an adult man, not engaged in active labour, and of this a fourth or fifth part should be animal food; but in special cases much more or less may be taken with advantage. The arrangement and form of the teeth in man indicate that he should live on a mixed diet of animal and vegetable food; though, no doubt, there are examples on record of individuals who have lived in good health for many years entirely on either animal or vegetable food. By mixing these in proper portions, we are nourished on a smaller bulk of food than if we lived on either one or the other.

2. MASTICATION.

Mastication is effected in the cavity of the mouth by means of the teeth, which fit into sockets in the upper and lower jaw-bones. The upper jaw is immovable, or only movable with the entire head; but the lower jaw, with its teeth, is capable of moving upwards, downwards, backwards, forwards, and laterally, by means of the powerful muscles of mastication. It is by the varied movements of the lower teeth against the upper, through the action of these muscles, that food is broken down or masticated. In the adult there are 32 teeth, 16 in each jaw, and 8 on each side. There are from before backwards, beginning in the middle line of the jaw, 2 incisors or cutting teeth on each side; 1 canine or eye-tooth, for seizing; 2 premolars or bicuspids, for tearing; and 3 molars or grinders, for crushing and breaking up the food. The body and greater bulk of each tooth consists of a substance called *dentine*, composed of branching tubes; the top or crown is covered by a cap of *enamel*, a very hard substance, made of small hexagonal prisms; and the fang or root is protected by a layer of a material resembling bone, called *crusta petrosa*, or cement. In the centre of each tooth there is a cavity containing a pulpy matter, in which are nerves and blood-vessels.

3. INSALIVATION.

Insalivation is effected by the admixture of the secretions of the three pairs of salivary glands (the parotids, the sub-maxillaries, and the sub-linguals), and of the mucus secreted by numerous small glands beneath the lining of the cheeks, gums, and tongue, called *buccal* glands, with the triturated food. The common saliva formed by the combined secretion of these various secreting organs, is a colourless, slightly turbid, viscid, inodorous, and tasteless fluid. In the normal state, its reaction is alkaline. Saliva does not contain more than five or six parts of solid constituents to 995 or 994 parts of water. The daily quantity of saliva secreted by an adult man is estimated at about 48 ounces, but the activity of the salivary glands is dependent upon various influences and conditions. Thus, movement of the lower jaw, as in masticating, speaking, or singing, increases the secretion — acrid and aromatic substances and hard dry food also increase it. It is also under the influence of mental emotions and desires, through the nervous system, for the sight of a feast or tempting dish may make one's 'mouth water.'

The uses of the saliva in reference to digestion are partly mechanical and partly chemical. The chemical use of the saliva is to convert the starchy portions of the food into grape-sugar, and thus to promote its absorption. It also assists in speech and swallowing. The public speaker cannot articulate when his mouth becomes dry, and we cannot swallow a perfectly dry powder.

4. DEGLUTITION.

Deglutition is the act by which the food is transferred from the mouth to the stomach. The mouth leads into a cavity called the pharynx. Between it and the mouth is the pendulous or soft palate, which is a movable muscular partition that separates the two cavities during mastication. As soon, however, as the latter act is accomplished,

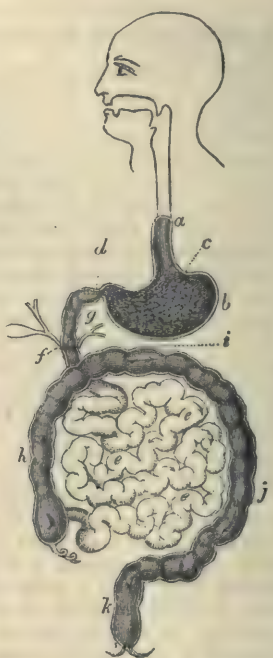


Fig. 1.—Human Alimentary Canal:

a, œsophagus; *b*, stomach; *c*, cardiac orifice; *d*, pylorus; *e*, small intestine; *f*, biliary duct; *g*, pancreatic duct; *h*, ascending colon; *i*, transverse colon; *j*, descending colon; *k*, rectum.

and the bolus is pressed backwards by the tongue, the soft palate is drawn upwards and backwards, so as to prevent the food passing into the nose. The opening of the windpipe is closed by a lid called the epiglottis. The bolus or pellet of food having arrived near the œsophagus or gullet (which is continuous inferiorly and posteriorly

with the pharynx), is driven into it by the action of certain muscles, which almost surround the pharynx, and are termed its constrictor muscles. All voluntary action ceases as soon as the food is pressed backwards by the tongue into the pharynx. It is impossible to recall the pellet, and it is necessarily carried on (without even our cognisance) into the stomach. This involuntary mechanism is called a *reflex* action. All reflex actions require a stimulus to call the parts into action. The stimulus in this case is the contact of the food with the back of the tongue and throat. It will be found on experiment that the reader cannot perform the action of swallowing if nothing, not even saliva, is in his mouth.

5. DIGESTION IN THE STOMACH.

The whole of the alimentary canal below the diaphragm, or muscular partition which separates the cavity of the chest from that of the abdomen or belly, possesses the following points in common, in relation to structure. The stomach, the small intestine, and the large intestine, are all lined by mucous membrane, have a muscular coat consisting of two sets of distinct fibres—namely, circular fibres which surround the tube or viscus after the manner of a series of rings, and longitudinal fibres running in the same direction as the intestine itself—and are invested with a smooth, glossy, serous membrane, which, while it retains the viscera in their proper position, also permits their necessary movement with a minimum of friction.

The human stomach is an elongated curved pouch, lying immediately below the diaphragm. It is very dilatable and contractile, and its function is to retain the food until it is duly acted upon and dissolved by the gastric juice, which is secreted by glands lying in its inner coat, and then to transmit it, in a semi-fluid state, into the first part of the small intestine, called the duodenum. Its average capacity is about five pints.

The mucous membrane, or lining coat of the stomach, is thick and soft, and lies in irregular folds, in consequence of the contraction of the muscular coat, unless when the organ is distended with food. On opening the stomach, and stretching it so as to remove the appearance of folds, we perceive numerous very shallow pits or depressions. The rest of the thickness is chiefly made up of minute tubes, running vertically towards the surface of the stomach, and secreting the gastric juice from the blood in the capillaries or minute blood-vessels which abound in the mucous membrane. These tubes are lined half-way down with epithelial cells, and the bottom is during digestion filled with molecular matter and a few cells. Other tubular glands are also found in the stomach, which are believed to secrete mucus.

When food is introduced into the stomach, it is subjected to three actions—first, to heat, the temperature of the stomach being, during digestion, about 99° F.); second, to a slow movement round and round, so as to bring the food into contact with the lining; and, third, to the chemical action of a special fluid—the gastric juice.

The food on entering the stomach first passes into the cardiac end, thence along the greater curvature from left to right to the pyloric end, and from thence along the lesser curvature from right to left.

The changes in the mucous membrane are—The inner surface of the healthy fasting stomach is of a paler pink than after the introduction of food, which causes the exudation of a pure, colourless, viscid fluid, having a well-marked acid reaction. This fluid, which is the gastric juice, collects in drops, which trickle down the walls, and mix with the food. Its two essential elements are—1. A free acid, which in some cases seems to be hydrochloric alone, and in others a mixture of hydrochloric and lactic acids; and 2. An organic matter called pepsine, which is highly nitrogenous, and allied to the albuminates.

The uses of this fluid are not only to dissolve but also to modify the nitrogenous elements of the food (such as albumen, fibrine, caseine, and, in short, all animal food except fat, and the albuminous principles of vegetable food), converting them into new substances, termed *peptones*, which, although they coincide in their chemical composition, and in many of their physical properties, with the substances from which they are derived, differ essentially from them in their more ready solubility in water, and in various chemical relations.

The gastric juice exerts no action on the fats and the carbon-hydrates (sugar, starch). If the fats or starches are in cells, the walls of which are formed of albumen, the walls are dissolved, and the contents set free.

The process of gastric digestion is slow. According to Beaumont's researches on Alexis St Martin, a man who had an injury which left a permanent opening into his stomach, guarded by a little valve of mucous membrane, the mean time required for the digestion of ordinary animal food, such as butcher-meat, fowl, and game, was from two hours and three-quarters to four hours.

What becomes of the matters that are thoroughly dissolved in the stomach? The albuminates, &c. which are converted into peptones, are for the most part taken up by the blood-vessels, and by another set of vessels called the lacteals. The rapidity with which aqueous solutions of iodine of potassium, the alkaline carbonates, lactates, citrates, &c. pass into the blood, and thence into the urine, saliva, &c. shews that the absorption of fluids must take place very shortly after they are swallowed; and there is little doubt that the blood-vessels (capillaries) of the stomach constitute the principal channel through which they pass out of the intestinal tract into the blood.

There can be no doubt that the stomach is admirably adapted for the digestion of the food introduced into it, because it has been shewn by numerous experiments that digestion will go on in gastric juice out of the stomach, but that it requires three or four times longer a period than when performed by the stomach itself. In the stomach, in most individuals, rice and tripe are digested in one hour; eggs, salmon, and venison in one and a half hours; tapioca, liver, fish, in two hours; lamb, pork, and turkey in two and a half hours; beef, mutton, and fowl, three and a half hours; and veal in four hours. There are, however, considerable differences in various individuals, or even in the same individual at different times.

6. DIGESTION IN THE BOWELS.

After the food, by digestion in the stomach, has been converted into a semi-fluid mass called the chyme (*chymos*, juice), it passes into the intestine. The length of the human intestine is usually about twenty-five feet. As a general rule it may be stated that the intestines of herbivora are much longer than those of carnivora. This is due to the nature of the food. In those animals, such as the ox, which live on a food very different, physically and chemically, from the tissues of the individual, a complicated digestive apparatus and a long intestinal tube will be found; whereas those which live on food readily converted into their own tissues (such as a weasel, which preys on the blood of other animals), have a simple digestive apparatus and a short tube.

The human intestine consists of a convoluted tube, which, from a great change in calibre in two different parts, is divided into (1) the small intestine, and (2) the great intestine. The small intestine is about twenty feet in length, and is divided by anatomists into three portions—the *duodenum*, *jejunum*, and *ileum*, the latter opening into the great intestine. The whole of this tube is connected with the back of the abdominal cavity by a thin web, called the *mesentery*, on which blood-vessels, nerves, and absorptive vessels called lacteals, ramify before penetrating and supplying the bowel. When the small intestine is slit open, it presents a large number of transverse folds, which are simply doublings of the mucous membrane, so as in little space to increase the surface for absorption. It has also a peculiar velvety appearance, which is due to the fact that it is covered over by innumerable small projections termed *villi*. They are more numerous in the upper than in the lower portions of the bowel. When examined by the microscope, they are found to be prolongations of the mucous membrane, shaped like the finger of a glove, and each is covered by a layer of epithelial cells. In the centre we find the commencement of the true absorbent vessel, called a *lacteal*, and surrounding it a network of vessels of very minute size. The villi in the small intestine are to a certain extent comparable to the delicate rootlets of a plant. The latter absorb moisture and soluble nutriment from the soil, while the former are bathed in a nutritious fluid, the chyme, and absorb readily fluids by the blood-vessels, and fatty matters by the lacteals. We find also scattered in large numbers over the mucous membrane, minute tubular glands called *Lieberkühnian glands*, after the anatomist Lieberkühn, who first described them. In the upper part of the duodenum, there are a few glands, like small clusters of grapes, called Brunner's glands, the function of which is unknown.

The great intestine, about five or six feet in length, is so termed because it is so much wider than the smaller one. It is also divided into three parts: the *cæcum*, which is a wide pouch, often of great size in herbivorous animals, and into which the small intestine opens, the entrance being guarded by a valve; the *colon*, which forms the greater part of the large intestine; and the *rectum*, which is situated entirely in the pelvis, and terminates in the anus. The great resembles the small intestine in general respects.

There is abundant evidence that the function of the villi is connected with absorption, and mainly with the absorption of fatty matters. 1. The villi exist only in the small intestine where the absorption of food goes on. 2. They are turgid, enlarged, and opaque during the process of digestion and absorption, and small and shrunken in animals that have been kept fasting for some time before death.

The function of the muscular coats is to propel the food along the bowel. This they perform by alternate contractions and relaxations, and thus a wave-like motion is produced. This motion may be readily seen in the intestines of an animal recently killed, and is termed a peristaltic action.

When the food, reduced to a pulpy mass in the stomach, termed chyme, passes into the duodenum, it is mixed with three fluids: 1, the bile; 2, the pancreatic juice; and 3, the intestinal juice.

The *bile* is an alkaline fluid secreted by the liver, and, after having been collected in the gall-bladder, finds its way into the upper part of the small intestine by a duct, which usually unites with that of the pancreas, and opens by a common orifice. As it flows from the liver, the bile is a thin greenish-yellow fluid, sometimes olive-brown; but when acted on by the gastric juice, it acquires a distinctly yellow or green hue, hence the appearance of vomited bile. Its main use seems to be to promote the digestion of fatty matters, and it accomplishes this end by a peculiar physical action both on the fats and on the intestinal walls, disintegrating the former, and impressing on the latter (by moistening the villi) a peculiar condition which facilitates the absorption of fatty matters. The bile separates nutritious matters from those which are non-nutritious, while it stimulates the muscular movements of the bowels and arrests putrefaction in the fæces.

The *pancreatic juice* is secreted by a long, narrow, flattened gland called the pancreas, or sweetbread, which lies deeply in the cavity of the abdomen, immediately behind the stomach. It is a lobulated or racemose gland, consisting of an immense number of small pouches grouped round the extremities of small ducts. These ducts unite with others, becoming larger and larger, until the great duct of the gland is formed.

The secretion is a colourless, clear, somewhat viscid, and ropy fluid, devoid of any special odour, and exhibiting an alkaline reaction. It contains a peculiar principle called pancreatine.

The function of the pancreatic juice is to emulsionise the fat of the chyme, and thus promote its absorption. If the duct of the pancreas be tied, and fat be taken as food, a large amount of it will appear in the fæces; and the same result has been seen in the human being in cases of diseased pancreas. The pancreatic juice also converts any starchy matter, which may have escaped the action of the saliva, into grape-sugar.

Of the last of the fluids poured into the intestine, the *intestinal juice*, we know little. It is the aggregate secretion of the various glands which occur in the walls of the smaller intestine. It is a colourless, or sometimes yellowish, ropy, viscid fluid, which is invariably alkaline. It seems to unite in itself the leading properties of the pancreatic and gastric juices; that is to say, it resembles the former in converting starch into

sugar, and the latter, in dissolving flesh and other albuminous bodies.

The line of demarcation between the small and large intestine is very obvious, and by the peculiar arrangement of the ileo-cæcal valve, which guards the entrance of the small into the great intestine, matters are allowed to pass forward with facility, while regurgitation is impossible. The contents of the large intestine differ very materially from those which are found in the small intestine, and constitute the fæces. They are more solid and homogeneous, and are often moulded into a definite shape. The only essential change which the contents undergo in this part of their course is, that they increase as they pass onward in solidity, in consequence of the absorption of fluid from them by the mucous membrane. They are propelled onwards into the rectum by the vermicular action which has been already described, and are at last expelled by a voluntary effort.

The fæces consist partly of undigested materials and partly of matters which are derived from the mucous membrane of the great intestine. It is in the great intestine the chyme first acquires a fæcal odour, which increases in intensity as the material passes along the bowel. This odour is not due simply to putrefaction, but to the presence of peculiar effete matters, which are thrown off by the lining membrane of the bowel.

7. ABSORPTION OF NUTRITIOUS MATTER.

As the chyme is propelled along the alimentary canal, the watery portion, holding various substances in solution, is absorbed by the blood-vessels, while the fatty matter is taken up by the lacteals. It is believed that this absorptive action is really a physical process dependent on osmotic action. The whole of the nutritive material thus separates itself into two parts: one which passes directly into the blood, and the other which enters the lacteals, and in these becomes a milky fluid called the *chyle*. It is important to remember that all the blood circulating in the digestive organs must pass through the liver before entering the general circulation, and from it the cells of the liver select and elaborate their secretions. But the chyle passes into the blood indirectly. It is first conveyed to numerous glands in the neighbourhood of the intestines, called mesenteric glands. Before entering these glands it is a milky fluid, essentially molecular; but after it has passed through the glands it is found to contain small, round, biconcave discs, termed chyle corpuscles, along with much molecular matter. The lacteal vessels proceeding from these glands unite with corresponding sets of vessels from the lower limbs, called lymphatics, in a wide cavity opposite the last dorsal vertebra, the *receptaculum chyli*. From this cavity a duct, the thoracic duct, ascends through the thorax, receives branches from the left arm and left side of the head, and unites with the venous system at the root of the neck on the left side, the point of junction being where the left internal jugular vein unites with the great vein of the left arm, the left subclavian. The lymphatics of the rest of the body unite to form the right lymphatic duct, which joins the venous system at a corresponding point on the opposite side. The whole of the chyle, therefore, passes into the blood at the root of the neck; from thence it goes through the right side of the heart to the lungs, where the corpuscles probably acquire colour, and become the coloured corpuscles of the blood.

8. SANGUIFICATION.

By this term we mean the making of blood. In the lowest animals, such as in the amœba, we find no circulating nutritious fluid. When we ascend higher in the scale we find a colourless fluid containing molecules moving in certain definite directions by the action of cilia in the general cavity of the body, as in a sea-anemone. Still higher we meet with a colourless fluid circulating in vessels, frequently communicating with the body-cavity, and propelled by a special contractile organ, as in the sea-urchin or ascidian; and at last we meet with a coloured fluid, circulating in vessels separate from the body-cavity, and having a propelling organ, or heart, of more or less complex structure, as in all the vertebrata. This fluid, in the higher animals and in man, is derived from three sources: 1st, from materials absorbed in the primary digestion of the food in the alimentary canal; 2d, from the secretions of certain glands called blood-glands, found in various parts of the body; and, 3d, from materials re-introduced into the blood from the tissues, which are products of the decomposition and solution of portions of these tissues consequent on their vital activity. The so-called blood-glands are—the spleen, a large organ found almost in juxtaposition with the left end of the stomach; the suprarenal capsules, two organs found in the lumbar region, one on the top of each kidney; the thymus, a gland found in the thorax, immediately behind the breast-bone, of larger size before birth and during the earlier years of life than during adult life; the thyroid, a gland existing in front of the box of the larynx; the pituitary and pineal glands, found in the brain; the glands of Peyer, in the mucous membrane of the small intestine; and lastly, the lymphatic glands, which we find in many parts of the body, such as in the groin, the armpit, the neck, &c. and which we readily recognise as hard 'kernels' during the inflammation of any adjoining part. All of these glands agree in certain points of their anatomy; they have no ducts to carry off the secretion, except we regard the numerous lymphatics by which they are supplied as such; they consist essentially of shut sacs, containing numerous molecules, nuclei from which cells may be developed, and fully formed cells resembling white blood corpuscles; and finally, they are richly supplied with blood-vessels, lymphatics, and nerves. That they are really connected with the formation of blood, more especially of the colourless corpuscles, is probable from the fact, that in a disease known as leucocythæmia, in which there is a great increase in these cells, we find also that one or more or all of the blood-glands are much enlarged.

9. THE BLOOD AND ITS CIRCULATION.

The blood is the most important and most abundant fluid in the body, and deserves the popular term of the 'vital fluid.' With the exception of a few tissues, such as the centre of the cornea of the eye, the nails, and the hair, it pervades every part of the body, as may be

shewn in the case of the skin by puncturing any part of it with a needle. The total quantity is estimated at about one-eighth of the weight of the body, or about 20 lbs. in a man of average size. Its colour is red, but it varies from a bright scarlet in the arteries to a dark purple in the veins. When, however, a minute drop is examined under the microscope, it is seen to be made up of, first, a clear colourless fluid; and, secondly, of a multitude of small solid bodies or corpuscles, which float in the plasma. This plasma, called liquor sanguinis, is composed of water richly charged with materials derived (through the chyme) from the food; namely, albumen, fibrine, various fats, &c. The greater part of the blood—about 70 per cent.—is made up of water. It contains a very small amount of fibrine, about 7 per cent. of albumen, 14 per cent. of corpuscles, and the remainder consists of extractive matters, fats, and various salts. The great majority of the corpuscles are of a yellowish-red colour, and by their enormous number seem to impart a red hue to the blood; while a few are white or colourless. The red corpuscles have a diameter of about $\frac{1}{3200}$th of an inch, being about $\frac{1}{4}$th of that fraction in thickness; and in form they are circular biconcave discs, and in freshly drawn blood they arrange themselves by contact of their flat surfaces into little rolls like piles of coins. The colourless corpuscles are larger, globular in form, and present a granulated appearance. Recently it has been shewn that these are little masses of living protoplasm, capable of spontaneous movement, and that they are identical with the corpuscles found in purulent matter or pus. In all classes of animals the colourless corpuscles are alike; but the form of the coloured corpuscles varies, being oval in fishes, reptiles, and birds. In all mammals they are circular, with the exception of the camels and llamas, where they are oval. Shortly after its removal from the body, the blood begins to thicken or coagulate, and soon separates into two distinct parts, one of them being a dark-red jelly or clot, which is the heavier of the two, and sinks; while the other is a clear straw-coloured fluid, called the serum, which covers the clot. This depends on the formation of a substance called fibrine, which forms a meshwork of fine molecular fibres, entangling the corpuscles. When a coagulum appears, fibrine is produced by the union of two substances present in solution, one called fibrinogen, and the other termed fibrino-plastic substance, the latter probably being a substance known as globulin, which forms a large part of the coloured corpuscles. This remarkable property of coagulation is the chief cause of the arrest of bleeding from a wound.

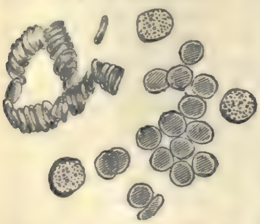

Fig. 2.—Blood Corpuscles highly magnified.

The blood is in constant motion in a definite direction during life, and the motion is known as the *circulation*. Its true course was discovered by Harvey, about 1620. The organs of circulation are the heart, arteries, veins, and capillaries. The course of the blood through these organs will be best elucidated by the aid of a diagram, which is equally applicable for all other mammals as well as for man and for birds. The shaded part of fig. 3 represents structures filled with impure or venous blood, while the unshaded portion represents structures in which pure oxygenated arterial blood occurs. In this diagram we observe a dotted circle, representing a closed bag or sac, termed the pericardium, and inclosing the four cavities *c*, *v*, *c'*, *v'*, of which the heart is composed. Two of these cavities, *c* and *c'*, are for the purpose of receiving the blood as it flows into the heart, and are termed the ***auricles;*** while the two cavities, *v* and *v'*, are for the purpose of propelling the blood through the lungs and general system respectively, and are termed the *ventricles*. The vessels that transport blood into the auricles are termed *veins;* and the vessels through which blood is driven onwards from the ventricles are known as *arteries*. The diagram further shews that what we commonly term the heart is in reality *two distinct hearts* in apposition with each other; one, shaded in the figure, which is called the right, or venous, or pulmonary heart; and the other, unshaded, which is called the left, or arterial, or systemic heart, the last name having been given to it because the blood is sent from it to the general system; just as the right heart is termed pulmonary from its sending blood to the lungs. We will now trace the course of the blood as indicated by the arrows in this diagram, commencing with the right auricle, *c*. The right auricle contracting upon the venous or impure blood which has been returned from the body, and with which we suppose it to be filled, drives its contents onwards into the right ventricle, *v*, through an opening between these two cavities, called the right auriculo-ventricular opening, which is guarded by a valve, named tricuspid, from its being composed of three pointed membranous expansions, which almost entirely prevents the regurgitation or reflux of the blood from the ventricle into the auricle. The ventricle, *v*, being now filled, contracts; and, as the blood cannot return into the auricle, it is driven along the shaded vessel, the dividing branches of which are indicated by *f*. This vessel is known as the pulmonary artery, and conveys the blood to the lungs. At its commencement it is guarded by valves, termed, from their shape, the semilunar pulmonary valves, which entirely prevent the blood which has once been propelled into the pulmonary artery from re-entering the ventricle. The pulmonary artery gradually divides into smaller and smaller branches, which ultimately merge into capillaries. In these capillaries, which are freely distributed over the external surface of all the air-cells (of which the lung is mainly composed), the venous blood is

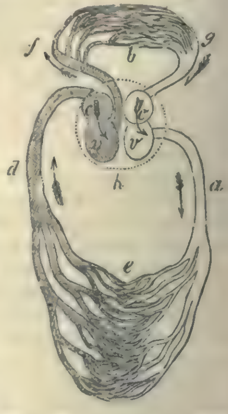

Fig. 3.—Mode of Circulation in Man and other Mammals, and in Birds: *h*, heart; *v*, right ventricle; *v'*, left ventricle; *c*, right auricle; *c'*, left auricle; *a*, aorta; *d*, vena cava; *e*, greater circulation; *b*, smaller circulation; *f*, pulmonary artery; *g*, pulmonary veins.

brought in contact with atmospheric air, gives off its carbonic acid gas (which is its principal impurity), and absorbs oxygen, by which processes it is converted into pure or arterial blood. The capillaries, *b*, in which the blood is arterialised, gradually unite to form minute veins, which, again, join to form larger vessels, until finally the blood is collected into four vessels, known as pulmonary veins (two from each lung), which pour their contents into the left auricle. Only one such vessel, *g*, is shewn in the figure, because the main object of this diagram is to illustrate the mode and general direction in which the blood circulates, not to indicate the special vessels through which it flows in different parts of the body. The blood, now fitted for the various purposes of nutrition, enters the left auricle, *c'*, which, by its contraction, propels it into the left ventricle, *v'*, through the left auriculo-ventricular opening. This opening, like the corresponding one in the right heart, is guarded by a valve, which, from its form, is termed the mitral valve, and which entirely prevents the reflux of the blood. The left ventricle, *v'*, contracts and drives its contents into the large artery, *a*, which represents the aorta—the great trunk—which, by means of its various branches (none of which are indicated in the diagram), supplies every portion of the body with pure arterial blood. From the aorta and its various subdividing branches the blood passes into the capillaries, *e*, which occur in every part of the system. In these capillaries it undergoes important changes, which may be considered as almost exactly the reverse of those which occur in the pulmonary capillaries; it parts with its oxygen, becomes charged with carbonic acid, and, as it leaves the capillaries and enters the minute veins formed by their union, presents all the characters of venous blood. The veins gradually unite till they form two large trunks, termed the superior and inferior *venæ cavæ*, which pour their contents into the right auricle—the point from which we started. Only one of these great veins, *d*, is indicated in the diagram. We thus perceive that there is a complete double circulation; that there is a lesser circulation effected by the blood in its passage from the right to the left heart through the lungs, and that there is a great circulation effected by that fluid in its passage from the left heart, through the system generally, to the right heart.

The heart is situated in very nearly the centre of the cavity of the chest. Its form is somewhat conical, the lower end tapering almost to a point, and directed rather forwards and to the left. This lower portion alone is movable, and, at each contraction of the heart, it is tilted forwards, and strikes against the walls of the chest between, in man, the fifth and sixth ribs, or a little below the left nipple. All the large vessels connected with the heart arise from its base, and serve, from their attachment to the neighbouring parts, to keep that portion of it fixed.

The substance of the heart is composed of a spiral arrangement of no less than seven layers of muscular fibre. When the ventricles contract, the blood is propelled from them, not in a direct manner, but with a sort of spiral motion, as if it were really wrung out of the heart.

But although the heart is the chief organ for propelling the blood, there are other forces at work. When the right ventricle contracts, blood is propelled into the aorta, which, however, contained blood at the time. This blood is pushed forwards, and the aorta dilates. When the propulsive power has ceased, the aorta, being a very elastic tube, recovers its original calibre. In doing so, it assists in forcing the blood onwards. Thus by successive portions of the larger arteries acting in the same manner, dilating with the impulse, and regaining their size by elasticity, the original mechanical force of the heart, which throws blood into the aorta in a series of successive jets, is converted into a uniform wave-like flow, which we term the pulse. The *pulse*, which beats about seventy times per minute, is the change produced in the diameter and length of an artery when it receives the wave of blood. The tissues also exert an attractive influence on the blood, drawing it forwards; and, consequently, we find that wherever we have activity of growth in any part of the body, there is a determination of blood to that part. We see this in the congestion which precedes the annual growth of a stag's horn. After the blood has passed through the capillaries and into the veins, the power of the heart has reached a minimum. The blood is now forced along the veins to the heart, chiefly by the pressure of the muscles. The veins are provided with valves, which are so arranged as to allow the blood to flow only towards the heart; and, consequently, when a muscle contracts and presses on a vein, the blood is propelled forwards. Thus muscular exercise assists occasionally in removing venous congestions. Lastly, the movements of respiration affect the circulation; inspiration, by increasing the flow of blood along the great vessels to the heart; while expiration has the contrary effect.

10. RESPIRATION.

The organs and process of respiration now claim our attention. We have already stated that the blood of the arteries differs in colour from that of the veins, the former being of a bright scarlet tint, while the latter is purplish in colour. The *arterial* represents pure, and the *venous* impure blood; the change from the former to the latter having taken place in the capillaries which form the bond of union between the termination of an artery and the beginning of a vein. The chemical differences between arterial and venous blood are slight, except in relation to the gases held in solution in these fluids. The two kinds of blood differ widely in this respect, there being a smaller quantity of oxygen, and a greater quantity of carbonic acid in venous than in arterial blood.

The organs by which the impure and dark venous blood is converted into pure, bright scarlet arterial blood, fit for nourishing the various tissues of the body, are the lungs, and the agent by which this change is effected is the oxygen of the air we breathe. In their simplest form, as they occur in certain reptiles, they are mere air-sacs, existing as two elastic membranous bags, having small honey-comb-like depressions on their inner surface, communicating with the external air by a tube known as the windpipe, or *trachea*, which opens through the larynx or organ of voice into the throat. These bags are lined by a delicate, thin, and moist

mucous membrane, in which is imbedded a network of capillaries, through which all the blood is in turn driven by the heart. The moist partition between the blood in this network and the air in the interior of the lungs, is so thin as to allow an interchange between the gases of the blood and the gases of the air; that is to say, oxygen passes from the air in the air-cells into the blood, while carbonic acid gas and aqueous vapour pass outwards from the lungs into the air in the air-cells. This is a purely physical phenomenon, dependent on the laws of diffusion and admixture of gases through animal membranes.

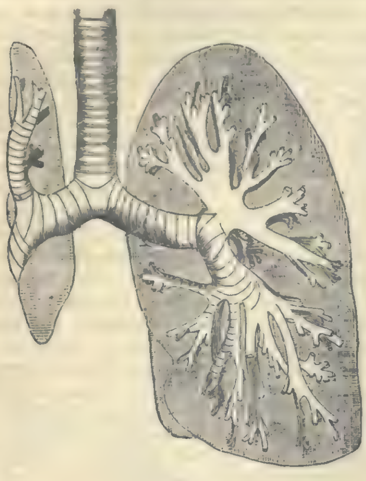

Fig. 4.

In the higher animals and in man, these essential parts are much complicated and modified in a variety of ways. The anatomical details may be considered under the following heads. *Firstly*, the lungs must afford by their internal arrangement an immense extent of internal mucous membrane, covered by vascular network, through which, as in the simpler form, the blood flows in innumerable minute streamlets, only separated by an extremely thin membrane from the atmospheric air that has been inhaled; *secondly*, there must be such an arrangement of the circulating system, that fresh blood may be perpetually driven from the right side of the heart through the lungs, and onward to the left side of the heart; and *thirdly*, there must be arrangements for the frequent and regular change of the air contained in the lungs.

We shall first consider the lungs and the passages leading to them. The back of the mouth or pharynx is connected with the outer air in two ways—namely, by the nasal passages and nostrils, and by the mouth. Through either of these channels, the air may pass to and from the lungs, but the nostrils are, properly speaking, the entrances to the respiratory system. Behind the root of the tongue, we find a chink or aperture, the *glottis*, bounded laterally by two folds of membrane called the *vocal chords*, which may be more or less widely separated from each other. This chink or aperture is guarded by a leaf-like lid, the *epiglottis*, which can be closed when expedient, so as to prevent the entrance of particles of food, drink, &c. The glottis opens downwards, into a box-like chamber called the *larynx* (which is the organ of voice), and leading downwards from the larynx runs the *trachea*, or windpipe, which is kept permanently open for the passage of air, by cartilaginous rings, that surround the anterior two-thirds of it. These are united, and the back of the tube is formed by a fibrous membrane or muscle. The windpipe, which is easily felt by the hand, and lies just below the projecting part of the larynx, popularly known as Adam's Apple, is about four and a half inches in length, and about three-fourths of an inch wide. Passing into the cavity of the chest, it divides into two branches, which are termed the right and left *bronchi*. Each bronchus enters the lung of its own side, and divides into a great number of smaller tubes, called the *bronchial tubes*, which again go on subdividing. These finest tubes end in elongated dilatations, averaging $\frac{1}{70}$th of an inch in diameter, which are called the *air-cells*. If we can conceive a bunch of grapes with its stem and all its minute branches, and the grapes attached to the ends of them to be hollow, we get a good idea of the mode in which the lung is constructed, except that it does not represent all the sacculation or partitioning of the terminal cells. It is in consequence of the air included in these cells that the lungs have their soft spongy feeling, and crackle when compressed between the fingers. Each lung is invested by its own investing serous membrane, termed the *pleura*, which serves the double purpose of facilitating the movements necessary in the act of respiration, and in suspending each lung in its proper position.

The blood is being perpetually changed and driven in a constant current through the lungs by the action of the heart, the venous or impure blood being collected in the right ventricle, and thence conveyed by the pulmonary artery into the lungs. In these, again, it gives off carbonic acid and aqueous vapour, and absorbs oxygen (as already described); and after these changes, it is collected, and returned to the left auricle by four vessels called the pulmonary veins.

The mode in which the air is renewed in the lungs next requires notice. This is effected by the respiratory movements, which consist in alternate acts of inspiration and expiration, with an intervening pause before the process is renewed. An adult man in a sitting position performs the respiratory act from thirteen to fifteen times in the minute, but much more rapidly if taking exercise. At each inspiration, about 30 cubic inches of air are inspired, and at each expiration nearly the same volume is exhaled, difference being allowed for temperature, which in the exhaled air may equal that of the blood. From 300 to 400 cubic feet of air thus pass through the lungs of a man at rest in the course of twenty-four hours, and these are charged with carbonic acid, and deprived of oxygen to the extent of nearly 5 per cent.; or, to put it in another form, about 18 cubic feet of the one gas are taken in, and of the other gas are given off. The quantity of carbon thus excreted in the form of carbonic acid gas is nearly represented by eight ounces of pure charcoal. The amount of watery vapour separated by the lungs varies from six to twenty ounces daily, according to the

diet, exercise, temperature, humidity of the air, &c.

The mechanical means by which these changes are effected are partly to be sought for in the elasticity of the lungs themselves, and partly in the mobility of the sides and bottom of the cavity of the chest, which is thus enabled to alter its size with each respiratory act. The sides of the chest are mainly formed by the ribs, which are so attached to the spine as to be freely movable upwards and downwards by two sets of intercostal muscles. Again, the *diaphragm*, the great muscular partition between the chest and the belly, is always convex to the former; but when it contracts, the convexity is lessened, and consequently the capacity of the chest is increased.

A knowledge of the respiratory process explains the great benefit to be derived from efficient ventilation. Ten thousand parts of ordinary atmospheric air contain from 2 to 4 parts of carbonic acid. If this gas be present to the extent of $1\frac{1}{2}$ to 3 parts in 1000, headache and giddiness are felt; and if it be increased to 20 parts in 1000, death will in all likelihood be the result. To secure a proper degree of dilution of carbonic acid in a small room, so as to render the air fit for respiration, about 2000 cubic feet of fresh air should be introduced every hour.

11. THE NOURISHMENT OF THE TISSUES.

The various tissues of the body, such as muscle, bone, nerve, or brain, are nourished by the blood. But as this fluid is almost the same in chemical composition in different parts of the body, and as the tissues differ much in this respect from each other, we must adopt the theory that each tissue has an elective power in itself, whereby it selects from the blood exactly the material it requires for its growth. To secure healthy nutrition, we must have an adequate supply of blood. If any part of the body is not supplied with abundance of blood, its actions are enfeebled; and if the supply be cut off altogether, it soon weakens and dies. The blood must also be healthy in quality. If affected by disease of any organ, so that certain injurious materials are not eliminated, the general nutrition of the body speedily suffers. To secure proper nutrition, a part must, thirdly, be subject to the influence of the nervous system. Disease of the spinal cord causes paralysis of the lower limbs, and the muscles become soft, flabby, and diminish in size. Section of a nerve supplying a part is often followed by destruction of the part by ulceration. Finally, the part itself must be in a healthy condition to secure proper growth. Any tissue which has acquired any peculiarity of structure by previous disease, retains this peculiarity for many years; but in course of time the tissue tends to revert to its original condition. This explains such phenomena as the perpetuation of cicatrices, and the influence of the vaccine virus. In the latter case, the virus stamps a peculiar quality on the blood and tissues, which modifies any subsequent attack of small-pox. Growth is dependent essentially on the supply of material to the tissues by the blood, and on the amount of waste of tissue. If the supply exceeds the waste, as in childhood, the body increases in weight and power; if the supply and waste are equal, the body may remain in a stationary condition for many years, as in middle life; and if the supply is much less than the waste, the body loses weight and strength, as in old age.

12. SECRETION.

Secretion is that function by means of which certain fluids are separated from the blood for further service in the economy. Various of these secretions, such as the saliva, gastric juice, pancreatic juice, &c. have been already described, but here we may briefly refer to the process of secretion generally. However complicated the structure of the various secreting glands may be, it is found, on minute examination, to consist of a delicate membrane, called a basement membrane, having blood-vessels richly distributed under its attached surface, and actively growing cells on its free surface. By foldings and reduplications of these elements of structure, all secreting glands are formed. The cells, however, are the active agents. They select from the blood the materials necessary, and form the secretion. Recent researches have shewn that these cells are directly influenced by the nervous system. The secretion is found in their interior. They are developed, grow, live a certain time, drop off from the membrane, and, becoming ruptured, the secretion is set free. Thus secretion is not opposed to growth, as at one time supposed: it is dependent on the growth of certain cells.

13. EXCRETION.

During the vital activity of the tissues, new particles are assimilated by the process of growth already described. On the other hand, certain materials are worn out, and becoming soluble, pass into the blood. These effete matters must be removed from the blood, and cast out of the body, so that this important fluid may be kept in a healthy condition. This process of removal is the function of excretion. There are five great channels of excretion:

1. *The Lungs.*—The lungs, as already described under Respiration, separate from the blood carbonic acid and watery vapour.

2. *The Liver.*—This organ is the largest and heaviest gland in the body, weighing, on an average, 65 oz. avoirdupois. It is situated on the right side, beneath the lower ribs. It consists of five lobes, of a dark reddish colour, and these lobes are divided into lobules. The lobules are bound together by areolar tissue, and their structure is similar. The liver is supplied with the blood from which it derives its secretions by the portal vein, a vessel which collects all the blood circulating in the stomach, spleen, and intestines. The portal vein divides and subdivides in the liver, till it forms a plexus of minute vessels between and in the lobules, from which originate the radicles of the hepatic vein, a vessel which carries the blood from the liver to the ascending *vena cava.* The connective tissue of the liver, and its vessels and nerves, are supplied by a special artery, the hepatic artery. The proper secreting structure of the liver consists of numerous compressed cells, about the $\frac{1}{1000}$th of an inch in diameter, called hepatic cells. These cells secrete materials from the blood, which they elaborate into bile. This secretion passes into minute ducts, the hepatic

ducts, the exact mode of origin of which is at present obscure. These ducts convey the bile out of the liver; and after it has become inspissated and mixed with mucus, from small mucous glands in the larger ducts, and from the gall-bladder, it is poured into the duodenum. The liver performs at least three functions: first, the secretion of bile; second, the formation of fat; and third, the formation of animal starch or glycogen. The bile is to be regarded chiefly as an excretion rich in hydro-carbons, but during its passage from the economy, it performs certain functions referred to under Digestion. It is highly probable that part of the bile is re-absorbed into the blood, but its ultimate function is unknown. The amount formed daily is about 3½ pounds; but the quantity is liable to great variation.

The formation of animal starch by the liver is called its *glycogenic function*. It is supposed that this starch, formed in the cells of the liver, is converted by the blood of the hepatic vein into sugar, which is carried to the lungs, where it is decomposed into carbonic acid and water. This, however, is a point not yet conclusively settled.

3. *The Skin.*—This organ, continuous at various points with the internal mucous surfaces, covers the whole body, and consists of two layers: first, a hard epithelium, composed of cells more or less flattened, called the epidermis; and second, of the *derma*, or *cutis vera*, or true skin, which is formed of connective and elastic tissue. Underneath the true skin, we find a layer of fat. We find in the skin two kinds of glands. The sudoriparous or sweat glands, consist of a tube, coiled into a ball at the deeper part, and communicating with the surface by a spiral duct. The sebaceous glands are small racemose glands, which usually open into the hair follicles, and secrete an oily fluid for lubricating the hairs and surface of the skin. The chief excretion of skin is sweat, an acid watery fluid, which is usually carried off from the surface in the form of vapour. The amount varies greatly: from five pounds in the twenty-four hours, to one pound. That the separation of this excretion is important, is proved by the fact, that if the skin be varnished over, so as to prevent exhalation, death may speedily ensue. All the various modifications of epidermis, such as hair, horn, nail, hoof, &c. may also be regarded in the light of excretions, but space compels us merely to allude to this fact.

Fig. 5.—Vertical Section of the Skin of the Sole:

a, cuticle; *b*, papillary structure; *c*, *cutis vera*, or true skin; *d*, sweat-gland lying in a cavity on the deep surface of the skin, and imbedded in globules of fat. Its duct is seen passing to the surface. Magnified about 30 diameters.

4. *The Kidneys.*—The human kidneys are situated in the loins, one on each side of the spine. A well-developed healthy kidney weighs about six ounces. When cut open, we find a cavity communicating with the ureter, the excretory duct of the kidney, and we observe also that the organ consists of two substances, which are named, from their position, the external or cortical, and the internal or medullary substance. The medullary part consists of straight tubules, which divide in two as we pass outwards to the cortical part, while in the latter, the tubes are extremely convoluted. In the cortical part of an injected kidney, there are numerous small round balls of capillaries called Malpighian bodies, after the celebrated anatomist who first observed them. In man they are about the $\frac{1}{120}$th of an inch in diameter. They consist of a mass of minute capillaries supplied with blood by an afferent vessel, and having also an efferent vessel to carry the blood away. Each of these little balls is embraced by the dilated end of one of the uriniferous tubes, as seen in the preceding figure. The function of the kidney is to excrete urine, a fluid rich in nitrogenous materials. The urine is an amber-coloured liquid, having a specific gravity of 1020, a slightly acid reaction, a saltish taste, and an odour peculiar to itself. The chief substance in the urine of man is urea, of which about an ounce is excreted daily, while, during the same time, about eight grains of uric acid are separated. In reptiles, however, the amount of urea is small, while uric acid is largely present. These substances are derived from the waste of the nitrogenous tissues, uric acid being formed before urea. In rapid-breathing, warm-blooded animals, uric acid is rapidly oxidised to urea, and consequently only a small amount of the acid appears in the urine; whereas, in slow-breathing, cold-blooded animals, the oxidation is incomplete. Man being omnivorous, partakes of enough of food rich in carbon to prevent the complete oxidation, and therefore a small amount of uric acid is always found in his urine. The kidneys also separate inorganic matters, such as chlorides, sulphates, phosphates, &c. These are much modified as to amount by the nature of the diet, and the amount of fluid taken with them.

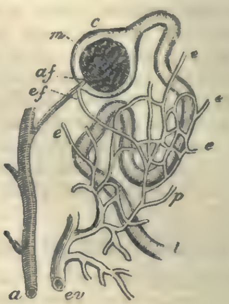

Fig. 6.—Plan of the Renal Circulation:

a, terminal branch of the artery, giving the terminal twig, *af*, to the Malpighian tuft, *m*, from which emerges the efferent vessel, *ef*. Other efferent vessels, *e*, *e*, *e*, are seen proceeding from other tufts, and entering the capillaries surrounding the uriniferous tube, *t*. From this plexus of capillaries the emulgent vein, *ev*, springs.

5. *The Intestines.*—The excretions from the bowel consist not only of the non-nutritious materials of food, bile, mucus, and mineral matters,

but also of fetid effete matters removed from the system by the lower bowel.

II. THE FUNCTION OF INNERVATION.

The vital processes included under the function of nutrition belong to the class of functions known as *vegetative*, because certain of them are common to vegetables as well as to animals. These functions have as their object the preservation of the plant. The animal has, however, another set of organs, by the use of which it becomes conscious of a world external to itself. By means of certain functions, which, from their occurrence in animals

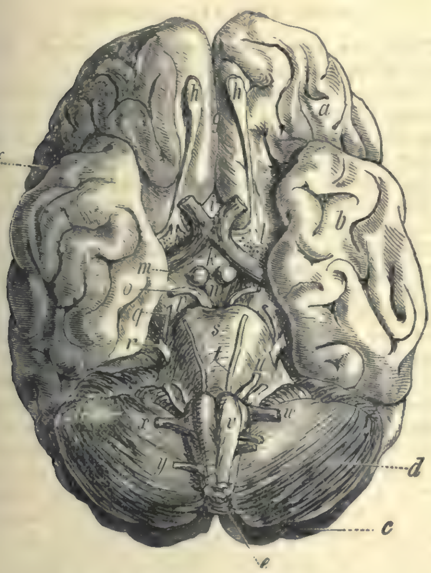

Fig. 7.—Human Adult Brain:

a, anterior lobe of cerebrum; *b*, middle lobe; *c*, posterior lobe of cerebrum, appearing behind; *d*, cerebellar hemisphere; *e*, medulla oblongata; *f*, fissure of Sylvius; *g*, longitudinal fissure; *h*, *h*, olfactory bulbs; *i*, optic commissure—the optic nerves are seen interchanging fibres; *l*, three roots of olfactory process; *m*, white round bodies (*corpora albicantia*), the terminations of the anterior portions of fornix; *n*, where the vessels perforate the brain substance, hence called posterior perforated space; *o*, third pair of nerves coming to supply muscles of the eyeball, from *p*, the crus cerebri; *q*, fourth nerve, turning round from the valve of Vieussens; *r*, fifth pair; *s*, pons varolii; *t*, sixth pair of nerves; *u*, seventh pair, portio dura for muscles of face, and portio mollis for hearing; *v*, posterior pyramids of cerebellum, seen to interchange fibres; *w*, and two below, are eighth pair—viz. glosso-pharyngeal, vagus or pneumo-gastric, and spinal accessory nerve; between *w* and *v* is the small prominence called olivary body; *x*, *y*, two roots of ninth pair of nerves, motor nerve of tongue.

only, are termed *animal*, all the higher creatures, and especially man, are endowed with Sensation, Motion, and Volition. These powers are due to the presence of a Nervous System, including two sets of nerves and nerve-centres—namely, the *cerebro-spinal system* and the *sympathetic system*.

The former consists of the *cerebro-spinal axis*, composed of the brain and spinal cord, and the *cerebral* and *spinal nerves* connected with this axis; while the latter consists chiefly of a double chain of ganglia or nervous masses, lying at the sides of the spinal column, and united with one another and with the spinal nerves by connecting threads of nervous tissue. The sympathetic system influences the heart and blood-vessels, and the intestines. It has the power of stimulating the action of the heart by acting on ganglia in its substance. It maintains the blood-vessels in a certain state of contraction.

The cerebro-spinal axis lies protected in the cavity of the skull and spinal column, and is covered by three membranes, which serve for protection and for the supply of blood.

Nerve-matter is of two kinds, white and gray, and may be readily seen by cutting through the brain of a sheep or of any other animal, when it will be observed that there is an outer layer of gray matter, while the interior is white. In the spinal cord these relations are reversed, the gray matter lying in the centre. The nerves consist entirely of the white tissue. The microscope shews that the gray matter is made up of round, oval, or star-like cells with a nucleus, and sending off prolongations, which either unite with those of other similar cells, or are continued as nerve-tubes. These cells, termed nerve-cells, vary much in size, from the $\frac{1}{5000}$th to the $\frac{1}{400}$th of an inch. The white matter consists of tubes, transparent as glass when examined alive; but immediately after death, shewing two well-defined lines on each side of a broad clear space. They thus appear to consist of two parts—a central part, which probably conducts the nervous influence, surrounded by a substance, of different chemical constitution, which may act as an insulator of the nervous force. A nerve consists of many of these tubes running alongside of each other, and here and there plexuses are formed by certain tubes diverging and running from one nerve to another. The function of the nerve-tube is to receive an impression of any kind, mechanical, chemical, thermal, or volitional, thereupon to generate an influence, and to conduct this influence to or from a nerve-centre. The rapidity of the nerve-current is from 75 to 120 feet per second; incomparably slower than light, or electricity. The nerve-cells either receive or originate nervous force.

The brain consists of the *cerebrum*, or brain proper, which occupies the whole of the upper and front parts of the cavity of the skull; the *cerebellum*, or little brain, lying beneath the hinder part of the cerebrum; and the *medulla oblongata*, or oblong marrow, which may be regarded as a continuation of the spinal cord within the cavity of the cranium, and as forming the connection between the brain and cord. The cerebrum and cerebellum are almost completely bisected into two lateral halves by a deep longitudinal fissure; and the surface of the former is divided by a considerable number of tortuous furrows, nearly an inch deep, into convolutions. As the gray matter is extended into these furrows, its quantity is thus vastly increased.

At the base of the cerebrum, and connected with it, there are two large ganglionic masses of gray and white matter, called the *corpora striata;* behind these, other two bodies of a similar nature, the *optic thalami;* and still farther back, four bodies, two on each side, the *corpora quadrigemina*. All these parts of the brain are connected with each other by numerous tubes. The tubes from the spinal cord pass upwards in the medulla oblongata; those from the posterior part of the cord going chiefly to the cerebellum, while those from the anterior pass to the cerebrum. In the cerebrum,

cerebellum, and ganglia, we also find tubes running from their anterior to their posterior ends, while other tubes run transversely, and unite corresponding parts on opposite sides of the brain. Thus there is evidently community of function.

The functions of these different parts may be briefly stated to be as follows: 1, the *cerebrum* is the seat of Sensation, Volition, Emotion, and of those intellectual powers which constitute MIND; 2, the *cerebellum* is probably the regulator of muscular movements; 3, the *corpora striata* is a great centre of voluntary movement, not of volition, but of the nervous mechanism by which, when we will with the cerebrum, the influences are sent along the spinal cord to the various muscles; 4, the *optic thalami* perform the same function with regard to sensation; 5, the *corpora quadrigemina* receive visual impressions by the optic nerves from the retina of the eyes, and transmit these to the cerebrum, where there is then the consciousness of sight; and 6, the *medulla oblongata*, and an adjoining part called the *pons Varolii*, are the seat of the nervous influences which regulate swallowing, breathing, and other important involuntary movements. The parts of the brain last mentioned (6) are absolutely essential to life. The other parts may be cut or mutilated without instant death, but this surely follows in a few moments injury to the medulla.

Nerves have different functions. When an influence travels along a nerve to a muscle, it excites the muscle to contract, and the former is then called a *motor* nerve; when it travels to the brain and causes a sensation, we call such a nerve *sensory*. Most nerves contain both sensory and motor tubes. Some are purely sensory, as certain parts of the fifth cranial nerve; others purely motor, as the facial, or seventh cranial nerve; while all the spinal nerves are senso-motory. Certain nerves respond only to particular stimuli. For example, the optic nerve is affected only by vibrations of rays of light. Such are called *special sensory* nerves, and include those of sight, hearing, taste, smell. The nerves of touch are those of common sensibility distributed to the skin.

Twelve pair of nerves are given off from the brain, and thirty-one from the spinal cord.

The *spinal cord* or *marrow* is a cylindrical column of soft nervous tissue, extending from the base of the skull, where it is continuous with the *medulla oblongata*, to the region of the loins, where it tapers off to a thread in the lowest part of the vertebral canal. Its average length is eighteen inches. It is not only divided by two fissures in the middle, but each half is again divided longitudinally into three equal parts by two parallel series of nervous filaments, which are the anterior and posterior roots of the spinal nerves. The posterior root presents a swelling or ganglion, immediately beyond which the two coalesce into the trunk of a nerve which, after emerging through a hole called the intervertebral foramen, is distributed into branches to the parts it is destined to supply with nervous filaments; as, for example, the muscles of the trunk and limbs and the surface of the body. These roots have separate functions, the anterior being composed of motor, while the posterior contain sensory tubes. Hence if the anterior root (in a vivisection operation) is divided, or if the column of the cord from which it springs is diseased, loss of motion in the part which it supplies is the result; while if the posterior root were similarly acted on, there would be loss of sensation. The anterior columns of the medulla decussate (that is, send nerve-tubes across to the adjoining column); while many of the tubes of the posterior columns decussate all the way up the back of the cord. Consequently, injury to the right anterior column causes loss of motion on the same side, while injury to the right posterior column paralyses sensation as regards the opposite side of the body. The decussation of the anterior columns in the medulla also explains how a clot of blood in the right hemisphere of the brain, as in apoplexy, causes loss of motor-power on the left side of the body.

THE SPECIAL SENSES.

There are five senses—namely, *touch*, *taste*, *smell*, *sight*, and *hearing*.

Touch.—The sense of touch, including that of different degrees of heat, is possessed by the skin, by the walls of the mouth and nostrils, and by the tongue, but it is most highly developed on the tips of the fingers. The essential organs of this sense are the true skin, containing capillaries, and the terminations of sensory nerves. On examining the surface of the true skin by a magnifying-glass, we can see a regular arrangement of papillæ, or cone-like projections about $\frac{1}{100}$th of an inch in length. In many of these papillæ there are found small round or oval bodies made of hard fibrous tissue, and having a nerve-tube coiled round them, and sometimes penetrating into their interior. These are called *touch-bodies*. They serve as resisting structures against which the nerve may be pressed, and thus the sense of touch may be intensified. When one of those nerves is pressed by the contact of any foreign body, an influence is produced which travels to the brain, where we become conscious of the impression. This consciousness, however, we refer not to the brain, but to the part affected; a subjective power, which is probably the result of experience.

Taste.—The organs of taste are in the mucous membrane of the tongue, especially at its back part. The nerves of taste are the lingual branch of the fifth cranial nerve and the glosso-pharyngeal, the former supplying the anterior two-thirds, and the latter the posterior one-third of the tongue. The mucous membrane of the tongue presents papillæ of various forms, called *filiform*, or thread-like; *fungiform*, or mushroom-like; and *circumvallate*. The circumvallate are about thirteen or fifteen papillæ set in the form of a V with its point backwards, and each resembles a fungiform papillæ surrounded by a wall. These last-named structures are regarded as the essential organs of taste. They derive their nerves chiefly from the glosso-pharyngeal nerve. The contact of a sapid body with the surface of the tongue is not sufficient to evoke the sense of taste. The substance must be dissolved, and to effect its solution nature provides a special fluid—the saliva. In febrile diseases, in which the tongue is dry and coated, the sense of taste is either dormant or perverted. Taste is more acute in some persons than in others. It is sometimes blended in a remarkable way with smell, giving rise to the peculiar sensation we call flavour. The sensations produced by

the contact of mustard, pepper, &c. with the tongue are not those of taste, but rather exaggerated forms of touch.

Smell.—The organ of the sense of smell is the mucous membrane lining a part of the nasal cavities supplied with nerves from the *olfactory* bulbs or first pair of cranial nerves. Attached to the side-walls of each nasal cavity are two delicate scroll-like bones, called turbinated bones, which to a great extent divide each cavity into three spaces, lying one above the other. The two uppermost of these constitute the true olfactory chambers, while the lowest passage is merely used for respiratory purposes. The whole of this bony framework is covered by moist mucous membrane, having imbedded in it flat elongated plates attached to the ramifications of the olfactory nerves. By the contact of certain substances with these, a sensation of smell is produced. According to Graham, 'all odorous substances are in general such as can be readily acted on by oxygen.' Animal effluvia keep near the soil, hence the bloodhound runs with the nose to the ground. The sense of smell is extremely delicate in most individuals. It is soon blunted, and consequently many who live among disagreeable odours do not perceive them. A distinction must be drawn between a smell proper, like that of a violet, and the irritation produced by the fumes of ammonia. The close stuffy sensation experienced on entering an ill-ventilated crowded apartment, is due chiefly to interference with the free play of respiration.

Sight or Vision.—The sensation of light results from the influence produced on the sensitive expansion of the filaments of the optic nerve by vibrations of a delicate and subtle substance known as

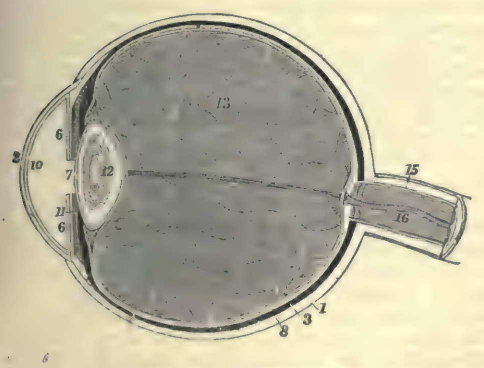

Fig. 8.—A longitudinal section of the Coats of the Eye:

1, the sclerotic, thicker behind than in front; 2, the cornea; 3, the choroid; 6, the iris; 7, the pupil; 8, the retina; 10, the anterior chamber of the eye; 11, the posterior chamber; 12, the crystalline lens, inclosed in its capsule; 13, the vitreous humour, inclosed in the hyaloid membrane, and in cells formed in its interior by that membrane; 15, the sheath; and 16, the interior of the optic nerve, in the centre of which is a small artery.

'ether.' But the falling of light upon the optic nerve itself will produce no sensation. An intermediary apparatus is necessary—the retina, which is an expansion of nervous matter placed behind the optic nerve.

The *globe of the eye* is placed in the anterior part of the orbit, in which it is held in position by its connection with the optic nerve posteriorly, and with the muscles which surround it, and by the eyelids in front. It is further supported behind and on the sides by a quantity of fat.

The eyeball is composed of several investing membranes, and of certain transparent structures, which are inclosed within them. These transparent structures act as refractive media of different densities, so that rays of light entering the eye are so bent as to come to a focus on the retina. Thus a distinct image is formed. These refractive structures are from before backwards—1st, the cornea, like transparent horn; 2d, the aqueous humour, like water; 3d, the lens, like glass; and lastly, the vitreous humour, like clear jelly.

The outermost coat of the eye is the *sclerotic* (from *skleros*, hard). It is a strong, dense, white, fibrous structure. Posteriorly, it is perforated by the optic nerve. This coat, by its great strength and comparatively unyielding structure, maintains the inclosed parts in their proper form, and serves to protect them from external injuries.

The *choroid coat* is a dark-coloured vascular membrane, containing pigment cells. In front, it ends by means of the ciliary processes, which consist of about sixty or seventy radiating folds. These fit into depressions in the suspensory ligament of the lens, and assist in keeping it in its proper position.

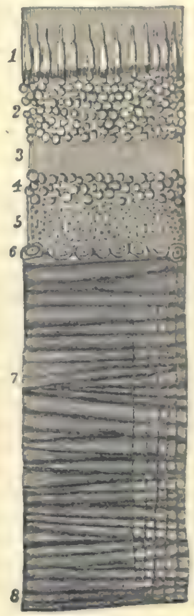

Fig. 9.—A Vertical Section of the Human Retina:

1, the layer of rods and cones (Jacob's membrane); 2, the external granular layer; 3, the intervening layer between 2 and 4, the internal granular layer; 5, finer granular layer; 6, layer of nerve-cells; 7, fibres of the optic nerve; 8, limitary membrane.

The *iris* may be regarded as a process of the choroid, with which it is continuous. It is a thin flat curtain, hanging vertically in the aqueous humour in front of the lens, and perforated by the pupil for the transmission of light. It is composed of unstriped muscular fibres, one set of which being arranged circularly round the pupil, and, when necessary, effecting its contraction; while another set lie in a radiating direction from within outwards, and by their action dilate the pupil. Thus more or less light may be admitted into the eye, and its function is like that of the diaphragm in many optical instruments.

The varieties of colour in the eyes of different individuals and of different kinds of animals, mainly depend upon the colour of the pigment, which is deposited in cells in the substance of the iris.

Within the choroid is the *retina*. With the naked eye it is seen to be a delicate semi-transparent sheet of nervous matter, lying immediately behind the vitreous humour, and extending

from the entrance of the optic nerve nearly as far as the lens. On examining the retina at the back of the eye by an instrument called an ophthalmoscope, we observe, directly in a line with the axis of the globe, a circular yellow spot called, after its discoverer, the yellow spot of Sömmering. The only mammals in which it exists are man and the monkey. It is the point of distinct vision. When we read a book, we run the eye along the lines so as to bring portions of the line successively on the yellow spot. If, on the other hand, we carefully fix our attention on a word in the middle of the line, we see the word distinctly, because it is on the yellow spot, while the words towards each end of the line are less distinct, being on other portions of the retina.

The structure of the retina, as revealed by the microscope, is seen in fig. 9.

The *transparent media* through which rays of light must pass before they form on the retina the images of external objects are:

Immediately behind the transparent cornea is the *aqueous humour*, which fills up the chamber between the cornea and the lens. It is nearly pure water, with a trace of chloride of sodium.

The *crystalline lens* lies opposite to and behind the pupil, close to the iris, and its posterior surface is received into a depression on the forepart of the vitreous humour (see fig. 8). In form, it is a double-convex lens, with surfaces of unequal curvature, the posterior being the most convex, and the curvature is also less at the centre than towards the margin.

The *vitreous humour* lies in the concavity of the retina, and occupies about four-fifths of the eye posteriorly.

The appendages of the eye are:

1. The *muscles* by which the eye is moved are four straight (or *recti*) muscles, and two oblique (the superior and inferior). By the duly associated action of these muscles, the eye is enabled to move (within definite limits) in every direction.

2. The *eyelids* are two thin movable folds placed in front of the eye, to shield it from too strong light, and to protect its anterior surface. The eyelashes intercept the entrance of foreign particles directed against the eye, and assist in shading that organ from an excess of light.

3. The *lachrymal apparatus* consists of the lachrymal gland, by which the tears are secreted; two canals, into which the tears are received near the inner angle of the eye; the sac, into which these canals open; and the duct, through which the tears pass from the sac into the nose. The constant motion of the upper eyelid induces a continuous gentle current of tears over the surface, which carry away any foreign particle that may have been deposited on it.

The various uses of the different structures of the eye are readily understood. Assuming a general knowledge of the ordinary laws of geometrical optics, we will trace the course of the rays of light proceeding from any luminous body through the different media on which they impinge. If a luminous object, as, for example, a lighted candle, be placed at about the ordinary distance of distinct vision (about ten inches) from the front of the eye, some rays fall on the sclerotic, and being reflected, take no part in vision; the more central ones fall upon the cornea, and of these some also are reflected, giving to the surface of the eye its beautiful glistening appearance; while others pass through it, are converged by it, and enter the aqueous humour, which probably, also, slightly converges them. Those which fall on and pass through the outer or circumferential part of the cornea are stopped by the iris, and are either reflected or absorbed by it; while those which fall upon its more central part pass through the pupil. The rays now impinge upon the lens, which, by the convexity of its surface, and by its greater density towards the centre, very much increases the convergence of the rays passing through it. They then traverse the vitreous humour, whose principal use appears to be to afford support to the expanded retina, and are brought to a focus upon that tunic, forming there an exact, but inverted image of the object.

Accommodation of the Eye to Distance.—It will be found on experiment that we cannot see a distant and a near object at the same moment. For example, if we look through a railing at a distant church spire, and fix our attention on the spire, we do not distinctly see the railing; and *vice versâ*. This was early observed; but, until recently, the mechanism by which the eye accommodates or focuses itself for different distances was unknown. Cramer was the first to point out that if we bring a candle-flame near the eye in a dark room, we may see three images—1st, an erect image reflected on the cornea; 2d, an erect image on the anterior surface of the lens; and 3d, an inverted and very faint image on the posterior surface of the lens. He also shewed that when the eye looks quickly at a near object, after having been for some time directed to a distant one, the middle image moves forward nearer to the first, and also becomes smaller, shewing that for near vision the anterior surface of the lens becomes more convex. Helmholtz afterwards, by means of an instrument called the ophthalmometer, measured the sizes of those reflections, and, from certain data, calculated by mathematical formulæ the radii of curvature of the reflecting surfaces; and he shewed conclusively that the accommodation of the eye for different distances is effected by changes in the curvature of the anterior surface of the lens. The physiological explanation is as follows:

The lens, which is elastic, is kept habitually in a state of tension by the pressure of the suspensory ligament, and consequently has a flatter form than it would take if left to itself. When the ciliary muscle contracts, it relaxes the ligament, and thereby diminishes its elastic tension upon the lens. The lens, consequently, becomes more convex, returning to its former shape when the ciliary muscle ceases to contract.

There are two common forms of defective vision which require notice—namely, short-sightedness or *myopia*, and long-sightedness or *presbyopia*. They are due to an abnormality either in the curves or in the density of the refracting media. In *short-sightedness* from too great a refractive power from either cause, the rays from objects at the ordinary range of distinct vision are brought too soon to a focus, so as to cross one another, and to diverge before they fall on the retina; the eye in this case being able to bring to the proper focus on the retina only those rays which were previously diverging at a large angle from a very near object. The correction for this deficiency is accomplished by interposing between the eye

and indistinctly seen objects a *concave* lens, with a curvature sufficient to throw the images of external objects at the ordinary distance of distinct vision backwards upon the retina. In *long-sightedness*, on the other hand, there is an abnormal diminution of the refractive power, so that the focus is behind the retina. This defect is corrected by a *convex* lens, which increases the convergence of the rays of light.

Position of Objects on the Retina.—In consequence of the bending of rays of light by the refractive media, the image of an external object is inverted on the retina, and yet we see objects erect. The probable explanation is, that the mind may perceive as correctly from an inverted as from an erect image. When we glance at a column from top to base, we move the eyeball downwards so as to bring successive parts on the yellow spot, and it is the feeling of movement which informs us which is top and which is base, not the inverted position on the retina, of which we are really unconscious.

Single Vision with two Eyes.—This phenomenon is explained by the fact that there are corresponding points on the retina, so that when, by the regular action of the muscles of the eyeball, an image is formed on a corresponding point in each eye, the mind is conscious of one image. If we alter the direction of the axis of one eye by pressing gently on the ball, an image is formed on a point of the retina of that eye which does not correspond, and consequently we squint, or see two images.

Hearing.—The organ of hearing is composed of three portions, the external, middle, and internal ear. The external ear consists of the auricle, which

Fig. 10.—General view of the External, Middle, and Internal Ear, shewing the interior of the auditory canal, tympanic cavity, and Eustachian tube:

a, the auditory canal; *b*, the tympanum; *c*, the Eustachian tube, leading to the pharynx; *d*, the cochlea; and *e*, the semicircular canals and vestibule, seen on their exterior by the removal of the surrounding bony tissue.

presents elevations and depressions, the functions of which are to receive and reflect the vibrations of the air which constitute sound, and to transmit these by a tube, partly cartilaginous, partly bony, called the auditory canal, to the middle ear. The middle ear is named the tympanum or drum. It is a cavity in the petrous or hard portion of the temporal bone. It is shut off from the auditory canal by the membrane of the drum, a thin structure capable of vibrating when acted on by the vibrations of the air. The tympanum communicates with the back of the throat by the Eustachian tube, the function of which is to equalise atmospheric pressure on both sides of the vibrating membrane. When this tube becomes stopped mechanically by enlargement of the tonsils, partial deafness is the result, and when cleared so as again to allow air to pass into the tympanum, hearing at once returns to its normal state. Across the tympanum, we find a chain of small bones, one of which, the malleus, or hammer, is attached by a long handle to the drum; this unites by a joint with another, the incus, or anvil; which in turn bears the stapes, or stirrup, the base of this being fixed to a small oval membrane closing an aperture, called the fenestra ovalis, which communicates with the internal ear. The function of this

Fig. 11.—Ossicles of the Left Ear, as seen from the outside and below:

m, head of the malleus; *g*, the slender process, or *processus gracilis*; *h*, the manubrium or handle; *sc*, the short crus, and *lc*, the long crus of the incus; *a*, the position of the lenticular process, through the medium of which it articulates with the head of the stapes; *s*, the base of the stapes. Magnified three diameters.

chain of bones is to convey vibrations from the membrane to the internal ear. The internal ear, or labyrinth, so called on account of its complexity of structure, is the essential part of the organ of hearing, because here we find the filaments of the auditory nerve which are ultimately to receive impulses originally produced by vibrations of the air, and which are conveyed by the intermediate structures already described. It is made of three parts—the vestibule, or central part; the semicircular canals, three in number, which communicate posteriorly by five openings with the vestibule; and the cochlea, so called from its resemblance to a snail-shell. Each of these parts is excavated from the substance of the bone, and forms the bony or osseous labyrinth; but within this we have a fibrous structure, exactly corresponding in shape, the membranous labyrinth. The osseous is separated from the membranous labyrinth by a fluid called the *perilymph*, and within the membranous portion there is another fluid, called the *endolymph*. The terminations of the auditory nerve are distributed on the walls of the membranous portion, and by the presence of the two fluids just mentioned, the most delicate vibrations of the air communicated directly to the drum and chain of bones, or indirectly through the bones of the head, are conveyed to the nerves. The structure of the cochlea is very remarkable. It consists of a central pillar, round which a tube makes two and a half coils. This tube is divided into two compartments

by a partition, partly bony, partly membranous. The upper portion communicates with the vestibule, and, from its fancied resemblance to a stair, has been called *scala vestibuli*. Suppose we ascended this stair to the apex of the cochlea, we would there find a small opening communicating with the lower compartment, which has been called the *scala tympani*. It received this name because at the bottom it communicates with the tympanum by a round opening, called the *fenestra rotunda*, closed by a thin membrane. The cochlear branch of the auditory nerve enters the base of the pillar just mentioned, and distributes branches to the membranous portion of the scalæ. But this is not all. Between the two scalæ or staircases, in a triangular space, there is a remarkable organ, called the *Organ of Corti*. This is a complicated anatomical structure, which space will not allow us fully to describe here, but essentially it consists of three or four thousand jointed rods, apparently capable of vibrating, and presenting, when viewed from above, an appearance somewhat like the key-board of a piano.

We know little regarding the functions of the different parts of the internal ear. That they have different functions, we infer from the structure being so dissimilar, and also from the facts of comparative anatomy. In the animal kingdom, the vestibule first appears; to this are superadded the semicircular canals; and lastly, the cochlea, which increases in complexity from the lower orders of the mammalia up to man, in whom it is one of the most complicated organs of the body. The vestibule probably enables us to experience a sensation of sound as such; the semicircular canals may, as suggested by Wheatstone, assist in determining the direction of sounds; while there are many arguments in favour of the view, that the cochlea, as we find it in man, with a highly elaborated organ of Corti, may be the mechanism by which we appreciate musical sounds, which act so powerfully in exciting the emotions.

The range of hearing, like that of vision, varies in different persons. Some are insensible to sounds that others hear. Many cannot hear the chirp of a grasshopper or the squeak of a bat, two of the shrillest sounds in nature. The range of the ear is much greater than that of the eye in detecting movements which produce vibrations. Thus we hear the sound produced by a vibrating rod or string long after we have ceased to see the movements. The range of the human ear is probably nine or ten octaves.

The Muscular Sense.—There is still another sense, called the muscular sense, or sense of weight. If we close our eyes, and hold a weight on the palm of the outstretched hand, we experience a peculiar sensation. It is not referable to any of the five senses, except, perhaps, to touch. But it is not simple touch. We are conscious of an effort to sustain the weight, and of a firm condition of the muscles of the arm. This sensation is the muscular sense. It is the sensation we experience when any groups of the voluntary muscles are called into action, and by it we become aware of the condition of these muscles. By means of this sense, we stand erect, we walk, balance ourselves on a narrow ledge, throw stones or weapons, play on many instruments, &c.; and it adds largely to our feelings of pleasure.

VOICE AND SPEECH.

There is a great difference between voice and speech. Voice is produced by vibrations of two thin folds of membrane called the vocal cords, placed in the larynx, at the top of the trachea or windpipe: speech is the modification of voice into sounds connected with certain ideas produced by the action of the brain, which we wish to communicate to our fellow-men. Many animals have voice; none, except man, have articulate speech expressive of ideas. The organ of voice is the larynx (behind the *Pomum Adami*), the structure of which is very complicated, and cannot be here described. It consists of various cartilages and muscles, the object of which is to tighten or relax the margins of two folds of membrane, called the *vocal cords*. By the vibrations of these cords voice is produced, and by tightening or relaxing, separating or approximating them, we obtain various modifications of voice. When a high note is sounded, the cords are tense and close together; and, on the contrary, when we sing a deep bass note, they are relaxed and wide apart. The quality and compass of the voice differ in individuals. In men, the highest is the tenor; the lowest, the bass; the intermediate, the barytone. In women, the corresponding notes are the soprano, the contralto, and the mezzo-soprano. The difference between the deep bass of a man and the shrill soprano of a woman, is, that in the man the cords are longer and less tense than in the woman.

Speech is voice so modified by the action of the throat, tongue, cheeks, and lips, as to mean or indicate objects, properties, ideas, &c. This is language. If we breathe quietly, without causing the vocal cords to vibrate, and modify by the action of the mouth, &c. the volume of air expelled, we produce *whispering*.

III. FUNCTION OF REPRODUCTION.

The third great function of animal life is reproduction, by which the species is perpetuated. It is beyond the scope of this article to treat of this subject, and reference is accordingly made to special works on Anatomy and Physiology.

ZOOLOGY.

ZOOLOGY (from Greek *zōon*, an animal, and *logos*, a discourse) treats of the form and structure of animals, and the characters by which they may be distinguished from each other.

All natural bodies may be divided into two great groups—mineral or inorganic, and living or organic. The organic are again subdivided into vegetables and animals. Hence arises the division of all natural objects into three great kingdoms—namely, the *Mineral*, *Vegetable*, and *Animal*.

Inorganic substances never *live*. Chemically, they may be simple or compound, such combinations usually forming binary or ternary compounds. Their physical condition may be solid, fluid, or gaseous; but they are homogeneous in texture, that is, any detached portion exactly resembles the remainder in composition and properties. They may be amorphous, without distinct forms; or crystalline, that is, having distinct geometrical forms, bounded by plane surfaces, which have a definite relation to each other. They increase by the addition of like particles to their surface, which is termed *accretion* or *juxtaposition*. Their atoms are at rest, unless set in motion by some physical force acting from without: they initiate no change or motion.

An *organic being* either *lives* or has lived during some part of its existence. Chemically, it consists of few elements, which unite to form ternary and quaternary compounds. It consists of solid and fluid parts, which exercise a reciprocal action on each other. It is bounded by curved lines, and has convex and concave surfaces. Each organised being, under the influence of life, assumes a characteristic, though not absolutely definite shape. It increases or grows by receiving into its interior matter which it elaborates and assimilates. The old particles are being constantly removed, and replaced by new ones, so that all its parts are in constant motion, and are ever changing. It arises from some pre-existing organism of the same kind, by means of a *germ*, which becomes separated, and enjoys an individual existence.

We do not know 'life' apart from matter; some material substratum or 'physical basis' is required for its manifestation. This, according to Huxley, is furnished by what he calls *protoplasm*, which is a homogeneous, structureless substance, endowed with contractility, and having a chemical composition nearly allied to that of albumen: it is composed of carbon, hydrogen, oxygen, and nitrogen. This term *life* indicates a very special property indeed; and at present, looking at it from a purely material point of view, we are scarcely justified in regarding *life* as more than that condition of an organised being in which the products of chemical and physical changes taking place within it are stamped with a *specific form*. By the term 'moulding of specific form' is meant the building up of a complicated and heterogeneous organism, which repeats the characters which have been transmitted to it through a germ, by a parent, every molecule of every part having thus a direct relation in form, in position, and in composition, to every other molecule of the body.

It is impossible to draw a distinct line of demarcation between vegetables and animals, as the lowest forms of both kingdoms seem to meet and merge into each other. It was on this account that Professor Ernst Haeckel of Jena constructed a fourth kingdom, called by him 'Protista,' into which he proposed to put all the organisms of doubtful affinity. But this, at present, seems scarcely justifiable. Of course, the conspicuous members of the vegetable kingdom can never be confounded with the higher animal forms. In the latter, the presence of a nervous system, the possession of a mouth and digestive cavity, as well as the power of voluntary locomotion, are sufficient to distinguish them from the former, in which all these are absent. In the simplest groups in each kingdom, however, these grand distinctions are lost. *Chemically*, plants consist chiefly of ternary compounds—that is to say, compounds consisting of three elementary ingredients, as starch and cellulose, which are different combinations of oxygen, hydrogen, and carbon. In an animal, quaternary, and still more complex compounds, as albumen, fibrine, and gelatine, make up the bulk of the body; while ternary compounds, though, indeed, not wanting, play a subordinate part. The *general plan of nutrition* is strongly contrasted in the two kingdoms; but in some low animal forms, as the Gregarinæ, nutrition is effected by absorption through the external surface, just as is the case in plants. Most plants are permanently fixed in the ground by roots, but some low forms of algæ are locomotive; and although most animals can move about from place to place, others are incapable of progression, as the branched and tree-like sponges. It may be said, in a general sense, that *organs of relation* are present in animals, and absent from plants. But some phenomena connected with climbing plants, and with the process of fertilisation, are very difficult to explain without admitting some low form of a general harmonising and regulating function, comparable to such an obscure manifestation of reflex nervous action as we have in Sponges and other animals in which a distinct nervous system is absent.

Plants can secrete and store in their leaves and other parts a substance called 'chlorophyl,' by means of which, under the influence of light, they absorb carbonic acid from the atmosphere, decompose it, and, when the carbon is in a nascent state—that is, just liberated from combination—can combine it with the elements of water (hydrogen and oxygen), or with the elements of water and ammonia, likewise reduced to a nascent state by the same agency. The plant thus gains from the air and from the soil certain elementary substances, chiefly carbon, oxygen, hydrogen, and nitrogen. These, under the guidance of a vital property, and through the

medium of protoplasm contained in its cells, it combines into still more complex organic compounds, which contribute to the development or maintenance of the special specific form of the organism of which it is a part. Plants can assimilate no elementary substance except oxygen, unless it is presented to them in the nascent condition.

An animal stands in exactly the same relation to the binary compounds, carbonic acid, water, and ammonia, which, along with salts, form the food of plants. An animal cannot assimilate these substances directly; they must first be elaborated to the condition of ternary and quaternary compounds, which can be done only by the cells of plants. This is the broad and practical distinction between the vegetable and the animal kingdom. Plants possess the power of absorbing, modifying, and organising inorganic substances; while animals are entirely dependent for their support upon the organic substances thus prepared.

The pale growing parts of plants have precisely the same vital properties and relations as animal protoplasm. It is only in cells in which protoplasm elaborates and incorporates with itself colouring-matter (endochrome), which seems to be a more powerful catalytic agent, capable of disengaging the component atoms of the more stable binary compounds, when loosened by the vibrations of light, that the special function of the vegetable cell is manifested. Further, in the interior of the cells of some plants, as *Chara*, the movements of the protoplasm are so special and characteristic as to prove its absolute identity with the protoplasm of the Rhizopods.

A living being is a complicated machine, which does a great deal of various work. One of the higher animals, to take an example, is made up of a great many parts, each of which does its own special part of that work—thus, the stomach digests, and the eye sees. These several parts are called *organs*, and the thing which an organ does is called its *function*. If we remove these organs, performing each its function, one by one, the whole animal disappears. The animal body therefore consists of the sum of its organs.

Living beings may be studied under three principal aspects—the Morphological (*morphē*, form, and *logos*, a discourse), the Physiological, and the Distributional.

Morphology, which treats of the *form* and structure of living beings, includes anatomy, both naked-eyed and microscopic; to the latter, the term Histology (*histos*, a web, and *logos*) has been applied. It also embraces Embryology, or the study of the forms of living beings in all stages of development, from their earliest or immature condition, till they reach their mature or adult state.

Physiology treats of the *functions* of the organism as a whole, or of its separate component parts, organs, or tissues; of what an animal *does*, or of what its different parts do. The functions of an organism are divisible into—1. Function of Nutrition. 2. Function of Generation or Reproduction. 3. Function of Irritability or Correlation.

The *function of nutrition* has reference to the support and maintenance of the body. Matter is introduced into the interior of the body; there it undergoes certain changes, which assimilate it to, and fit it to be incorporated with, the textures which compose the body. *The function of reproduction* serves the purpose of perpetuating the species. The function of nutrition and the function of reproduction have been called the functions of 'organic' or 'vegetative' life, because they are possessed both by plants and animals. *The functions of relation*—including irritability, consciousness, sensation, and volition, with all the movements depending upon the will—bring the organism into connection with the outer world, and the outer world into connection with the organism, so that thus the one reacts upon the other. This group of functions is possessed by animals alone, so that they have been called the 'functions of animal life.'

Distribution treats not only of the areas of the globe over which organisms are distributed, and the conditions under which they exist, but it also relates to the history of life in bygone ages, as furnished to us by the evidence of fossil remains. The former is called distribution in space, or geographical distribution; the latter, distribution in time.

Classification.—On looking at the multitude and variety of animal forms around us—such as we are familiar with as inhabitants of this country, or as natives of other climates collected for our observation—the mind naturally associates together those which have the greatest general resemblance, and separates these (although differing in some degree amongst themselves) from those with which they have greater dissimilarity. Now, it is necessary that some system of arrangement or classification should be adopted, by bringing together those animals which most closely resemble each other, not so much in external appearance as in *internal structure*, in order that the mind shall be the better able to grasp the facts of zoological science. A classification, therefore, will be correct in proportion to the number of ascertained facts upon which it is founded. Zoologists, in seeking to classify animals, are in the habit of using several terms, one of the most important being *species*. It is by no means easy to define this term. It is generally understood to mean an assemblage of animals that resemble each other in all essential points of structure, and which are supposed all to have descended from the same parent stock. A test to which much importance has been assigned, is founded on the supposed fact, that when the animals of different species breed together, their offspring is barren. This offspring is called a *hybrid*—thus, a mule is a hybrid between a horse and an ass. This, however, is not an absolutely satisfactory or conclusive test of specific identity, as hybrids between undoubtedly distinct species have been known, though rarely, to breed and produce fertile offspring.

Until lately it has been the almost universal belief among naturalists that species are permanent within very narrow limits of variation; that is to say, that any group of animals which present the same specific characters, characters which lead an educated observer to set them down as the same thing — for example, all common partridges, or, to take a variable species, all domestic dogs—are descended from an ancestry which can by no possibility include anything except partridges or dogs, and can never, under any circumstances, or through the lapse of any amount of time, give origin to anything except dogs or partridges. This view, of course, involves

the admission of the special creation of a single progenitor for each species, or of two, according as the sexes may be united or distinct. As Edward Forbes expresses it (*Natural History of the British Seas*, page 8): 'Every true species presents in its individuals certain features, *specific characters*, which distinguish it from every other species; as if the Creator had set an exclusive mark or seal upon each type.' From time to time, however, naturalists of high eminence, and among them the celebrated French zoologist Lamarck, dissented from this view, and contended that the weight of evidence was rather in favour of a gradual development of the whole animal series from the simpler to the more complex; a development comparable in certain respects to the development of the individual from the germ to maturity.

The 'doctrine of evolution' has assumed various forms more or less plausible. It will be sufficient here to give a slight sketch of the latest of those speculations, the one which has received the widest acceptance, and exerted the most powerful influence upon the current of human thought—the 'Darwinian theory' of the origin of species by natural selection.

This speculation—for it cannot be said to have assumed any more definite form—is based upon the known phenomena of variation.

It is very evident that offspring have a tendency to resemble their parents very closely in form and structure; and this resemblance, in all cases within our experience, brings parent and offspring within the limit of the same species.

It is equally evident that offspring have a tendency to differ individually from their parents to a certain degree, but this variation is slight, involving no specific distinction; and in no case, so far as we are at present aware, interfering with the power of reproduction, or with the fertility of the succeeding generation.

The range of variation of the individuals composing a species is thus very definite, and is limited by the circumstances under which the group of individuals is placed. Except in man and in domesticated animals, in which it is artificially increased, this individual variation is usually so slight as to be inappreciable, except to a practised eye; and any extreme variation which passes the natural limit in any direction clashes in some way with surrounding circumstances, and is dangerous to the life of the individual. The normal line or 'line of safety' for any species lies midway between the extremes of variation.

If at any period in the history of a species the conditions of life of a group of individuals of the species be gradually altered; if, for example, the temperature of the region which they inhabit be changed, or if there be an alteration in the amount or kind of food, with the gradual change of circumstances, the limit of variation is contracted in one direction and relaxed in another; it becomes more dangerous to diverge towards one side, and more desirable to diverge towards the other, and the position of the lines limiting variation is thus altered. The 'normal line' along which the specific characters are most strongly marked is consequently slightly deflected, some characters being more strongly expressed at the expense of others. This deflection, carried on for ages in the same direction, must eventually carry the divergence of the varying race far beyond any limit within which we are in the habit of admitting identity of species. Those individuals in which the favourable variation is most marked will have the advantage in this struggle for life; will be the stronger and the more comely, and will naturally select one another as partners for the perpetuation of the race; thus continuing and exaggerating the favourable peculiarity from generation to generation.

We must admit that variation is a *vera causa*, capable, within a limited period, under favourable circumstances, of converting one species into what, according to our present ideas, we should be forced to recognise as a different species. And such being the case, it is, perhaps, conceivable that during the lapse of a period of time—still infinitely shorter than eternity—variation may have produced the entire result. There is no doubt great difficulty in imagining that, commencing from the simplest living being, the present state of things in the organic world has been produced solely by the combined action of 'atavism' and 'variation;' and many are still inclined to believe that some other law than the 'survival of the fittest' must regulate the existing marvellous system of extreme and yet harmonious modifications. Still, we are probably justified in saying that there is now scarcely a single competent general naturalist who is not prepared to accept some form of the doctrine of evolution. But the process must be infinitely slow. It is difficult to form any idea of ten, fifty, or a hundred millions of years, or of the relation which such periods bear to changes taking place in the inorganic world. But if it be possible to imagine that this marvellous manifestation of Eternal Power and Wisdom involved in living nature can have been worked out through the law of 'descent with modification' alone, we shall certainly require the longest row of figures which the inexorable physicists can afford.

The origin of species by descent with modification is as yet only an hypothesis. During the whole period of recorded human observation, not one single instance of the change of one species into another has been detected; and, singular to say, in successive geological formations, although new species are constantly appearing, and there is abundant evidence of progressive change, no single case has yet been observed of one species passing through a series of inappreciable modifications into another.

To a number of species agreeing in most points of importance, and having kindred characters, and these characters appealing broadly to the senses, the term *genus*—meaning a kind—is applied. From the arrangement of species of animals in genera has sprung the modern system of zoological nomenclature, first adopted by the celebrated Linnæus. This system has received the name of the *binomial system*, from the fact that each animal receives two names, one belonging to itself alone, and the other which it possesses in common with the other species of the genus under which it is placed. Thus, the genus *Equus* contains the Ass, Horse, and Zebra as species. To all, the generic name *Equus* is applied; but a second or specific name is added to each, to distinguish it from all other species of the genus: thus, the Horse is called *Equus caballus*; the

Zebra, *Equus zebra;* and the Ass, *Equus asinus.* A number of genera with more common characters are usually grouped as an *order:* for example, the Ruminant animals, as cattle, deer, &c. form an order. Sometimes, however, a group of genera, with certain characters in common, is called a *family;* for example, the crow, jay, magpie, chough, &c. form the family *Corvidæ.* In these instances, a group of families forms an order. To a combination of orders, the term *class* is applied—for example, birds, fish, reptiles. Then we come to characters still more general, according to which the entire animal kingdom has been subdivided into six *sub-kingdoms.* These have also been called *morphological types,* and are, as it were, the great ground-plans upon which the Divine Architect has constructed all animals. Thus, we have Sub-kingdoms, Classes, Orders, Families, Genera, Species, and Varieties, each term in succession being applicable in a more and more particular way than its predecessor.

The six sub-kingdoms or morphological types of the animal kingdom are:

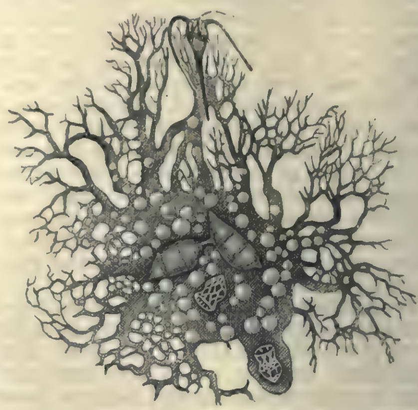
I. PROTOZOA—for example, amœba, sponges, infusoria.
II. CŒLENTERATA—for example, sea-anemones, sea-firs, corals.
III. ECHINODERMATA—for example, sea-urchins, star-fish.
IV. ANNULOSA, or Ringed Animals—for example, insects, spiders, worms.
V. MOLLUSCA, or Pulpy Animals—for example, sea-mats, oysters, cuttle-fish.
VI. VERTEBRATA, or Back-boned Animals—for example, fishes, birds, reptiles, and man.

I. SUB-KINGDOM PROTOZOA.

The Protozoa (Gr. *protos,* first, *zōon,* animal—the beginnings of life) are usually minute, and many of them can be seen only by the aid of the microscope; but sometimes they are of considerable size, for example, the sponges. They are formed of a jelly-like substance called 'sarcode,' or 'protoplasm,' which exhibits little or no trace of structure, resembling closely raw white of egg, more or less firm. In most is found a small solid body, the 'nucleus,' which, from recent observations, appears to be an ovary; and near this, one or two still more minute particles, the 'nucleoli,' which seem to be cells containing fertilising filaments. In many, contractile vesicles have been observed, spaces filled with a clear fluid which is driven by a contraction of the wall of the cavity through invisible channels in the body substance. Most are nourished by absorption through the general surface. They do not possess a nervous system or organs of sense, neither is there any distinct digestive system. In nearly all, a mouth is absent, but it is present in one group. They are nearly all aquatic.

CLASS I.—THE MONERA.

The Monera are the simplest of living beings. They consist of structureless, homogeneous, semi-fluid protoplasm, sometimes so soft and transparent that one can detect it only by its not mixing with the outer water. In this group there is no marked difference in consistence between the inner substance and the outer layer; there is neither mouth, contractile vesicle, nor nucleus. So far as we as yet know, the Monera in no case multiply by sexual reproduction. A portion separates as a bud, or an



Protomyxa aurantiaca (after Haeckel).

individual or a separated part contracts into a round ball, and becomes covered by a transparent layer; the central mass then breaks up into a multitude of grains. Finally, the outer covering bursts, and each of the grains becomes a separate 'moner' of the same species. Notwithstanding their extreme simplicity, the Monera present specific and even generic distinctions. They differ in colour: *Protomyxa aurantiaca,* described by Professor Ernst Haeckel, is bright orange. They differ likewise in habit. *Myxodictyum sociale* of the same author lives in a colony, each of the little round moners being attached to a number of others by spreading sarcode threads.

A large part of the bed of the North Atlantic at great depths is covered with a calcareous sediment composed almost entirely of the broken shells of Foraminifera, the group of Protozoa to be next mentioned. This lime-mud is usually slightly tenacious, as if a little size were mixed with it. On putting it under the microscope, this glairy matter separates into irregular strings, which shew movement. This would seem to be a form of the Monera, even more simple than those which have a definite shape. To this 'Urschleim' of the Atlantic chalk mud, Professor Huxley has given the name of *bathybius.*

CLASS II.—RHIZOPODA.

Gromia is the type. The sarcode body is inclosed in an egg-shaped membranous shell or 'test,' which has a single opening at one end, whence issue long prolongations of its body. These are termed *pseudo-podia* (false feet). They have no limiting wall, but seem just to flow along in the water, and when two come in contact, they flow together. It has no mouth, but obtains its food by throwing out its pseudo-podia, which, when they encounter any substance, such as a minute diatom, gradually close round it, and then pull it into the interior of the shell, where it is digested by the sarcode; and then the indigestible portions are expelled through the opening in the shell.

The *Amœba*, or Proteus animalcule, so called from the facility with which it can change its shape, possesses a nucleus and contractile vesicle, and its pseudo-podia are blunt and club-shaped, but they do not flow together.

Foraminifera :
Gromia.

The *Foraminifera* have a calcareous 'test,' perforated by numerous small apertures, through which pseudo-podia are emitted, or a test made up of sand grains cemented together, and leaving openings for the 'false feet.' Some are simple, as *Lagena*, but most are composite, produced by continuous gemmation or budding, each to the body by which it bud remaining attached was put forth. Some shells have only a single aperture placed at one end, through which the pseudo-podia are protruded. According to the plan of this budding, so will be the form of the composite body produced. In some, the parts are arranged in a straight row; in others, a single row is rolled into a spiral; and in some the parts are in the same plane, or they may form a spire, with a more or less conical form, the first chamber being at the apex. All the chambers communicate together by openings between adjacent chambers. They are marine, and exist in enormous quantities in the bed of the Atlantic, forming the chief part of the 'ooze,' which is composed almost entirely of a species of *Globigerina* (*G. bulloides*).

Foraminifera :
1. Lagena striata ; 2. Textilaria ; 3. Operculina.

The *Polycistinæ* have a silicious instead of a calcareous shell, which is often most beautifully sculptured. They are all minute, and are frequently found in infinite multitudes, forming a coloured cloud on the surface of the sea.

Podocyrtis.

CLASS III.—GREGARINIDÆ

are parasitic in the intestines of some insects, and in the earth-worm. They are probably more allied to some low forms of Entozoa than to the Protozoa.

CLASS IV.—PORIFERA OR SPONGIDEA.

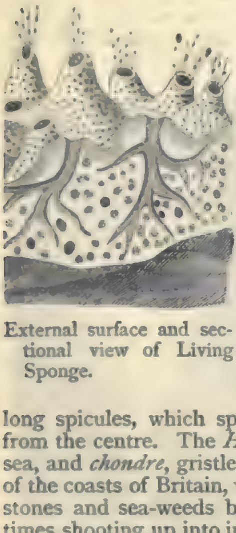
In the sponges, the Protozoa attain their largest dimensions, and their greatest prominence in the economy of the present time. The body consists of sarcode, which is supported by an internal skeleton or framework composed of carbonate of lime, of silica, or of horn, or of a combination of one of the former two with the latter. In the bath sponge, which is the best known example, the skeleton consists of a network of flexible horny fibres alone. When the sponge is taken living from the sea, it is completely filled and covered with the jelly-like living matter. A thin gelatinous membrane, perforated with very small holes, covers the surface, and every here and there rises into a papilla with a large hole at the top. These larger openings are called *oscula*, and they open into a set of channels which divide and branch till they penetrate through the entire substance of the sponge. The pores in the outer wall likewise communicate with the ultimate meshwork of the sponge, and are thus in communication with the channels and the oscula. The channels are lined with cilia—delicate hairs, which, by a perpetual lashing movement, drive the water along the channels ; or they have somewhere in their course chambers lined with cilia. The nutrition and respiration of the sponge are thus conducted : water, with organic food in solution or suspension, and containing air, enters the pores, passes through the tissue of the sponge, and is exhausted by the absorbing sarcode surface. The effete water is then collected into the channels, and urged forward by the cilia till it pours out at the oscula in a stream. True sexual reproduction has not yet been established for sponges : they multiply by the separation of small, oval, ciliated buds, called *gemmules*, which escape along with the water from the oscula.

Hyalonema.

The principal orders of the Porifera are the Calcispongiæ, the Hexactinellidæ, the Ceratospongiæ, the Corticatæ, and the Halichondriæ.

In the *Calcispongiæ* (*calx*, lime, and *spoggos*, a sponge), the sarcode is supported by granular horny matter, mixed with three-rayed needles or spicules of carbonate of lime. These sponges are found frequently

round the coast of Britain, hanging from the under-side of rocks between tide-marks. They are all marine. The second group, the *Hexactinellidæ*, so called from their spicules, which are always silicious, having usually six rays, seem to be confined to the deep sea, and are very abundant there. In this family we have some of the most singular and the most beautiful of natural objects. Venus' flower-basket (*Euplectella aspergillum*), from the seas of the Philippine Islands, is like a graceful horn-of-plenty wrought in an infinitely delicate tissue of spun-glass. *Hyalonema*, the Glass-rope Sponge of Japan, produces, growing downwards from the centre of a small conical sponge, a great wisp of glassy spicules, as thick as knitting-needles, and a couple of feet long, which penetrate the mud, and hold the sponge in its place, like a root. The upper part of this 'glass-rope' is almost always covered with a crust formed of a spreading zoophyte. This is a case of 'commensalism' (Lat. *con*, together; *mensa*, a table), an economical arrangement which is not at all uncommon in nature. Two animals live together habitually, one taking advantage of the excess of food procured by the other by means of currents produced by its cilia or some other like means, and doubtless contributing in some way to the comfort or support of its 'chum.' The bath sponge is the type of the *Ceratospongiæ* (Gr. *keras*, horn), distinguished by their soft flexible skeleton of horn. The sponge of commerce is brought up by divers from water of moderate depth, the finest coming from the coasts of Syria and the Greek Archipelago, the greater number from the Bahamas. The *Corticatæ* (Lat. *cortex*, bark) include the globular sponges, frequent in deep water, with a thick outer bark bristling with long spicules, which spring in sheaves radiating from the centre. The *Halichondriæ* (Gr. *hals*, the sea, and *chondre*, gristle) are the common sponges of the coasts of Britain, very abundantly incrusting stones and sea-weeds below tide-mark, and sometimes shooting up into independent branching tufts or tubes. They are quite frush, and unfit for any use. Their skeleton is composed of a combination of horny granules or fibres, with silicious spicules of diverse and often very elegant forms. Nearly all the Porifera are marine. One genus, Spongilla, or fresh-water sponge, is common in the fresh waters of Britain.



External surface and sectional view of Living Sponge.

CLASS V.—INFUSORIA.

The Infusoria are chiefly microscopic, and are found in all stagnant waters, or in any infusion which has been exposed to the air for some time—hence the name. They do not emit pseudo-podia. They possess a mouth, which leads into a sort of gullet, excavated in the soft gelatinous substance of the body; but this gullet is not continued into a defined stomach or alimentary canal, the organic matter introduced by the mouth passing into, and mixing with the sarcodic substance of the animal. The mouth is generally surrounded by cilia (vibratile hair-like appendages), by which currents are formed in the water, and food brought into it. In the body are a number of contractile vesicles, which pulsate at regular intervals, and may represent a rudimentary heart. *Bursaria* swims freely about by means of the cilia placed all over its surface. The Bell Animalcule, or *Vorticella*, is attached, and remains fixed like a plant. The body is bell-shaped, the opening of the bell being surrounded with a ring of cilia, which, by their vibratile movements, bring food within reach. It is situated on a long stalk, which is capable of spiral contraction. This takes place on the slightest movement or alarm.

Group of Vorticellidæ.

Bacteria, Spontaneous Generation.—If a little weak wine, or a thin syrup of sugar, or an infusion of tea or of meat, be left exposed to the air, it very soon begins to ferment or to putrefy. In doing so, it becomes muddy; and if a drop of the muddy liquid be placed under a microscope, it is found to contain myriads of excessively small living and moving beings, most of which must be referred to the Protozoa, though some are the germs of different kinds of mould (fungi). Two kinds are almost universal in such solutions—minute, transparent, oval bodies, slightly enlarged at each end, called *bacteria;* and very small rods, generally of two joints, called *vibriones.* No structure can be made out in either of these, but they are recognisable and distinguishable from other things, and they have a peculiar vibratile motion. A question has arisen, whether these creatures, which appear everywhere, are all produced from germs of already existing creatures of the same kind, or whether they may originate in the liquid by the uniting of the substances required to form them, which are all contained in the liquid, the product then becoming alive. This latter process has been called 'spontaneous' or 'equivocal' generation. Does life ever originate in such a way? The following considerations seem to render it improbable.

If a ray of sunlight pass through a chink, and traverse a dark room, its path is made evident as a long gray line of motes dancing in the vibrating air. These motes settle down as dust; and if a little of this be magnified, it is found to be mainly broken particles of wool and grains of starch; but it contains germs as well; for if a little dust be shaken into an infusion, we have a crop both of animals and plants at once. Here, then, is a source of germs which is universal. M. Pasteur, a French chemist, has shewn that if a flask be filled with a solution in which, if it were left open, bacteria would abound immediately; and if it be entirely freed by heat from living germs and air containing such, and the neck of

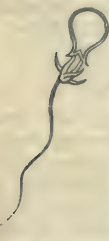
the flask be then closed with a plug of cotton-wool, the liquid may remain for months quite clear.

It is very difficult so to treat a vegetable or animal infusion, and to prevent even one of these infinitely minute and universally distributed particles getting into it during the process. The consequence is, that in many flasks, notwithstanding all precautions, bacteria do appear. One negative in such an investigation is, however, worth a thousand positive observations, and it would seem that the number of negative results is in proportion to the pains taken, and to the skill of the experimenter. All present evidence goes to shew that under no circumstances with which we are acquainted, does any living being arise, except as the progeny of a pre-existing living being of the same kind.

II. SUB-KINGDOM CŒLENTERATA.

The *Cœlenterata* (Gr. *koilos*, hollow, *enteron*, an intestine) have their parts arranged round a central axis in a radiate manner, like the segments of an orange, and they are capable of being split into right and left similar halves. They are thus said to have radial and bilateral *symmetry*. Further, each segment of the body can be divided into two symmetrical halves. They all have a distinct digestive cavity, which always communicates with the outer world by a mouth. In some, the digestive cavity is identical with the body cavity, the stomach being merely hollowed out in the gelatinous body substance; and in others it is distinct, the wall of the stomach hanging as a free sac within the body cavity; but in this latter case there are always free channels of communication between the digestive sac and the general cavity of the body. In the great majority, no circulatory or nervous system is developed.

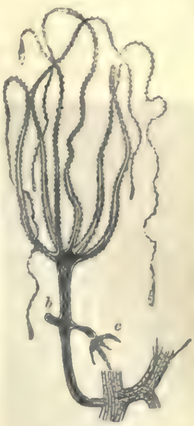
The body-wall is composed of two layers (*ecto-derm*, outer skin, and *endo-derm*, inner skin), which contain a number of peculiar bodies termed 'thread-cells.' These thread-cells consist of an oval bag filled with fluid, within which is coiled a long and extremely slender filament provided with three recurved darts or barbs. On the application of the slightest force to the tensely filled bag, this filament, often several times longer than the bag, is projected outwards, and transfixes and paralyses the prey, while the fluid seems at the same time to exercise a benumbing influence upon it. Distinct reproductive organs are present in all. The *Cœlenterata* are divided into two classes.



One of the larger thread - cells of the Hydra, with its three recurved barbs.

CLASS I.—HYDROZOA.

The digestive cavity is not separated from the body cavity, but is identical with it, and the reproductive organs are on the external surface of the body. *Hydra* is the type. It is usually seen attached to some aquatic plant or twig in our ponds and ditches. It is cylindrical in form and gelatinous in consistence, and usually about half an inch in length. It has at one end an expanded disc, by which it attaches itself to any object; at the other is the mouth, which is surrounded by a circle of arms or tentacles, which move about in all directions in the water. The body is composed of the two layers, armed with *thread-cells*, which are specially abundant in the ectoderm and in the tentacles. Small larvæ and worms are its favourite food. To entrap these, it spreads out its tentacles, moving them gently in the water, to increase their chances. The prey is paralysed by means of the thread-cells, and is pushed through the mouth into the internal cavity, where it undergoes digestion, the indigestible portions being finally expelled through the mouth. It is not permanently fixed, but can detach itself, and move about in the water.



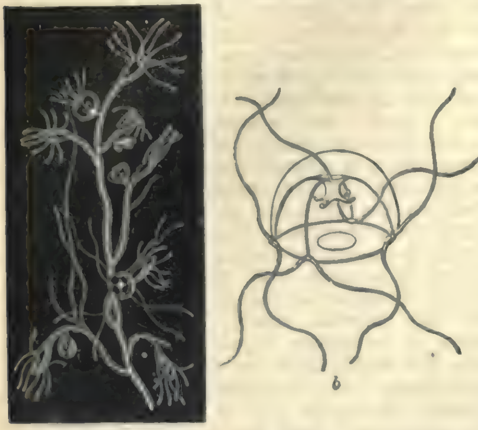
Hydra fusca:
With a young bud at *b*, and more advanced bud at *c*.

Trembley of Geneva shewed that Hydra is exceedingly tenacious of life, and endowed with extraordinary reparative powers. It may be turned inside out and still live, or be cut into pieces, each of which may become a perfect hydra. It increases towards the end of the year by ova; and during the summer months, by buds or *gemmæ*, which sprout from the sides of the parent. At first, the stomachs of the bud and parent are continuous; but they become separated by a constriction, tentacles are formed at the free end, and it then separates as a perfect hydra.

ORDER 1.—*Hydridæ* includes only the genus Hydra. Imagine a hydra going on budding, and the buds remaining attached to the parent—a tree-like arrangement would thus be produced.

ORDERS 2 and 3.—This is almost constantly the case in the second and third orders, *Corynidæ* and *Sertularidæ* (Sea-firs), and the animal is thus composite. It is usually permanently fixed, and is inclosed in a firm but flexible tube, which extends only up to the base of the buds or *polypites* in the *Corynidæ;* but in the *Sertularidæ* forms a little cup for each polypite, into which it can retract itself when alarmed. They are often found on the sea-shore, attached to old shells. The reproductive process in the *Corynidæ* and *Sertularidæ* is certainly very peculiar. At certain seasons, some of the buds become modified in form and structure, so that they assume an appearance not unlike a *Medusa*. To these buds the term *zooid* is applied. After a time, these zooids or Medusa-like buds become detached from the parent stem, and swim about for some period, when there are developed in them the organs of reproduction. So closely do these zooids resemble the true *Medusidæ*, that they were for a long time confounded with them. The ova and spermatozoa of these zooids now unite, and give rise to bodies having the appearance of a flattened disc covered with cilia, by means of which they swim freely about. This disc-like body becomes attached, part of it forming the root by which it is attached, while from its centre there

grows a single polypite, which by budding grows into a form exactly resembling the branched tree-like zoophyte, which gave origin to the Medusa-like bud. This is an example of what Steenstrup called 'alternation of generations,' although it is



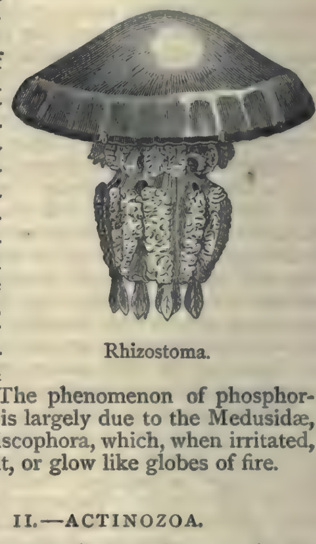
a, Hydromedusarium of ***Bougainvillia superciliaris***; *b*, Young Bougainvillia, or Medusoid bud, liberated from the Hydromedusarium.

not so in reality, there being only one truly generative act—namely, when the ova and spermatozoa of the Medusa-like bud or zooid unite to produce the disc-shaped ciliated body.

ORDER 4.—The *Siphonophora*, represented by *Physalia* (Portuguese man-of-war), *Vellella*, and by a multitude of wonderfully beautiful oceanic-surface forms, such as *Agalma* and *Diphyes*, which frequently swarm in the warmer seas, many of them forming branching feathery organisms several yards in length, and consisting of an infinite number of glassy swimming-belts, feeding polypites, reproductive polypites, and filaments covered with thread-cells, many of their parts relieved and brightened by coloured spots, crimson, blue, or purple. Some have a *float* or inflated bag, which enables them to float on the surface of the ocean. Depending from the under-surface of the animal are a number of thread-like appendages, and a soft flexible stem, to the sides of which are attached numerous buds or polypites. These also reproduce themselves by Medusa-like buds, like the *Sertularia*.

ORDER 5.—The true *Medusidæ* have a swimming-bell, like an umbrella, composed of a jelly-like material. A single polypite is suspended from the centre of the concavity of the bell; and, running inwards from its margin is a veil, perforated in the centre by an aperture, through which water is admitted into the interior of the bell, and is again expelled by its rhythmical contractions, so that the animal moves in a direction opposite to that in which the water is expelled. Four canals, radiating from the centre, run in its walls, and are joined at the circumference by a circular canal. Suspended from the margin of the bell is a number of tentacles, and on it are several coloured spots, which are supposed to represent rudimentary eyes. These Medusæ produce animals exactly resembling themselves.

ORDER 6.—*Discophora*. In the interior of old shells may be found an animal closely resembling Hydra, but sexless. It is called *Hydra tuba*. At certain seasons, a number of transverse markings may be seen upon a cone-like appendage growing from the free end of the hydra, which gradually deepen into annular constrictions, so that it looks like a pile of saucers. Each segment is thus a transverse segment of the cone-like body projecting from the free end of the hydra tuba. Each develops tentacles, and becoming detached, grows into a *hooded-eyed* Medusa. This, when perfectly developed, consists of an umbrella or swimming-bell, with one or more polypites suspended from its concavity. It has eight radiating canals, whose branches anastomose with each other; but it has no veil. It has a number of tentacles suspended from the margin of the umbrella, and upon it are coloured eye-spots, and small cavities containing a fluid with crystals of carbonate of lime. These last are supposed to represent organs of hearing. Both of these are covered over by a fold of membrane like a hood, and hence the name 'hooded-eyed' Medusæ. They are often of enormous size, and are commonly called *jelly-fish* or *sea-blubbers*. They are represented by such forms as *Rhizostoma* and *Pelagia*. These produce ova, which again, in turn, give rise to hydra tuba, affording another example of the so-called 'alternation of generations.' The phenomenon of phosphorescence of the sea is largely due to the Medusidæ, and some of the Discophora, which, when irritated, emit sparks of light, or glow like globes of fire.



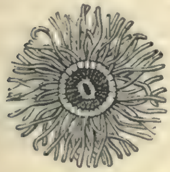
Rhizostoma.

CLASS II.—ACTINOZOA.

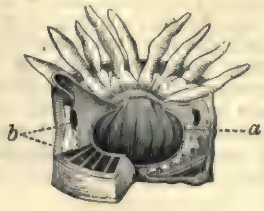
The digestive sac is distinct from, and suspended in, the body cavity, communicating freely with it by an opening below. The space intervening between the stomach and the body-wall is called the 'peri-visceral space,' and is divided into a series of chambers by vertical partitions, to the faces of which the reproductive organs are attached.

Actinia is the type (*aktis*, a ray). The body is short, and of fleshy consistence, attached at one end to a rock, and having at the other the mouth, surrounded by several rows of tentacles, which, from their arrangement and colour, like that of a full-blown many-petalled flower, have obtained for this animal its common name of sea-anemone. The mouth leads into a stomach, opening at its lower end into the peri-visceral cavity, which is divided by vertical partitions, having the reproductive organs attached to them. They feed upon shell-fish and other marine animals, which they draw into the mouth by the tentacles, disgorging shortly afterwards the shells and other indigestible parts. They are very sensitive to light, and expand or

close their tentacles according to the fineness of the day. When the feelers are drawn in, the apertures from which they proceed close like the



Actinia seen from above.



Section of Actinia : *a*, cavity of stomach ; *b*, surrounding chambers.

mouth of a purse, and the animal appears like a simple fleshy tubercle adhering to the rocks.

ORDER 1. *Zoantharia.*—The *Zoantharia* have the tentacles numerous and simple, while the radiating partitions are in multiples of *five* or *six*. They are represented by *Actinia* or Sea-anemone, many species of which occur along our shores. Some forms, however, are supported by a structure called a *coral*, which is composed of calcareous matter, or of horny matter, or partly of both. In one group this coral consists of a solid rod or axis, quite smooth on the surface, and presenting no appearance of cups, and merely acting as a support, over which the soft tissues of the animals are stretched. To a coral quite smooth and devoid of cups, the term *sclero-basic* is applied (Gr. *scleros*, hard, and *basis*, pedestal). The Black Coral (*Antipathes*), which is so much prized, has a sclero-basic coral, composed of horny and calcareous matter, forming a smooth, solid, branching structure, over which the tissues of the animal are stretched. In another group, the tissues of the animal are more or less completely calcified, by the deposition of particles of carbonate of lime in their structure. Such a coral is called a *sclero-dermic coral* (*scleros*, hard, and *derma*, skin), and it can at once be distinguished from the former by the presence of the calcified cups for the polyps. Like the animal which produces it, a sclero-dermic coral may be simple or compound. Thus *Carophyllia* is a simple coral, and consists of a calcified cup or *corallite*. The calcified boundary wall of this conical simple corallite is called the *theca*, the lower part of which is divided by a series of radiating calcified vertical partitions (*septa*) into chambers or *loculi*, while the upper part is vacant. Many of these septa run from the interior of the theca, and meet in the centre, forming a *columella* or axial support.

Caryophyllia borealis.

In a compound coral the various cups are united by calcareous matter, the whole exactly resembling in form the animal which secreted it. As examples of compound sclero-dermic corals may be cited the Brain Corals (*Meandrina*), and Star Corals (*Asteriadæ*). Amongst simple sclero-dermic corals, the following are found off the coast of Britain in deep water—*Lophohelia prolifera*, *Amphihelia ramea*, *Allopera oculina*, and *Caryophyllia borealis*.

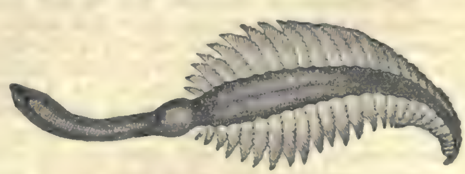
Extensive reefs and many islands in the Pacific Ocean, Indian Sea, and throughout Polynesia, are composed of coral, the product of these minute polypes. Darwin has classified coral reefs into (*a*) atolls, (*b*) barrier reefs, and (*c*) fringing reefs.

Fringing reefs skirt continents or surround islands. The channel between them and the land is shallow, and outside the reef there is no great depth of water.

Barrier reefs may encircle islands or skirt continents. The channel between the land and the reef is navigable, and outside, the soundings indicate enormous depths. The reef on the north-east of Australia is 1250 miles long, and from 10 to 90 in breadth, and rises from its seaward edge in some places free 1800 feet.

Atolls are circular coral reefs inclosing an expanse of water, which is called a 'lagoon.' The circle has breaks in it here and there, and is generally highest towards the windward side, against which the waves are continually dashing with great violence. The coral-producing polypes cannot exist in fresh water, hence the breaks in the circle where a stream had poured its waters into the ocean; neither can they exist at a depth of over 80 fathoms, or withstand the heat of the sun's rays. A mean winter temperature of not less than 66° is necessary for their existence. When a reef, by the gradual elevation of the land upon which it is placed, has reached the surface of the water, sand, shells, fragments of coral broken off by the waves, and other substances begin to accumulate, and cocoa-nut trees often grow while the waves still wash their roots. Further accumulations from the ocean, with decayed leaves, stems, &c. gradually convert the reef into fertile land. Mr Darwin shewed that a fringing might be converted into a barrier reef by the gradual sinking of the land on which the reef is built, the coral polypes gradually building upward; and by a further subsidence, a barrier reef might be converted into an atoll. This accounts for the great depth of some of the coral reefs that exist in the Pacific Ocean.

ORDER 2. *Alcyonaria*—characterised by having the tentacles fringed, and the parts in multiples of *four*—includes *Alcyonium*, or 'dead-man's fingers,'



Pennatula.

so called from its flabby appearance when seen in the fisherman's net. It is a composite animal, and is studded all over with little pits, from which polypes protrude. Its body contains a few spicules, and is traversed by a system of canals, which

connect the various polypes together. *Pennatula*, the Sea-pen, has one end of the axis, which is supported by a sclero-basic coral, fixed in the sand in the sea-bottom. From this axis, lateral branches are given off, upon which are placed the polypes. Its colour is reddish yellow, and when irritated, it shews phosphorescence. In *Gorgonia* (Sea-shrub), the coral is branched, horny, and sclero-basic. The Red Coral of commerce (*Corallium rubrum*), whose sclero-basic coral is so much admired for its fine colour and for ornamental purposes, has a smooth and branched tree-like form, about one foot in height, and is about the thickness of the little finger. It is chiefly obtained from the Mediterranean, and is largely exported to India.

ORDER 3. *Ctenophora*—are free-swimming ocean forms, which never develop a coral. They are gelatinous-like bodies, spherical in form, very delicate, and transparent. Eight bands covered with cilia run from pole to pole. By the motion of these cilia, the animal moves along. A trace of a nervous system has been discovered in some forms, *Beroe pileus*, which is like a globe of jelly, about half an inch in diameter, forms part of the food of the whale, and is often seen in the English Channel.

III. SUB-KINGDOM ECHINODERMATA.

The *Echinodermata* (*echinos*, urchin, and *derma*, skin), or Spiny-skinned Animals, are so called because they have a crustaceous or coriaceous covering generally armed with tubercles or spines. They have their parts arranged radially, but they also exhibit bilateral symmetry. The alimentary canal is completely shut off from the body cavity. The integument covering the animal is more or less completely calcified by the deposition of calcareous particles. In these animals there exists a peculiar system of tubes, called the *ambulacral system* (*ambulo*, I walk), because they are used for the purpose of progression. The nervous system consists of a gangliated nervous cord surrounding the commencement of the gullet, and sending branches which radiate outwards parallel with the ambulacral tubes. A blood-vascular or circulatory system is also present. In their mode of reproduction, the members of this group exhibit some very peculiar phenomena. The embryo is at first free, swimming, and ciliated, and is provided with distinct digestive organs, which do *not* become converted into the corresponding structures of the adult. This embryonic form has been called a *pseud-embryo* (false-embryo), bearing no resemblance to its parent; so much so, that the embryo of *Echinus* was at one time described as a distinct animal under the name of *Pluteus*. Only a part of this embryo is converted into the adult Echinoderm, the remainder entirely disappearing. The adult form is, as it were, a sprout from a particular part of this pseud-embryo. This sprout goes on developing a distinct mouth, digestive and other organs, until it exactly resembles the adult form which gave rise to the Pluteus.

It contains several orders, two of which, the *Blastoidea* and *Cystoidea*, are entirely extinct. Representatives of these two orders, such as *Pentremites* of the coal, and *Echinosphærites* of the Silurian rocks, flourished during the Palæozoic age.

ORDER 1. The *Crinoidea*, or sea-lilies, are fixed during the whole or part of their existence to the sea-bottom by a jointed and flexible stalk. They consist of a series of plates articulated together, forming a central cup or disc. From the edge of this cup there spring five arms, which bifurcate, and thus form ten beautifully fringed arms. Running along the inside of the arms is a furrow, covered in by the skin of the disc, and from which are protruded the ambulacral feet. Amongst the permanently fixed and best-known forms is the *Pentacrinus Caput-medusæ*, or Medusæ-head Star of the West Indies. More recently, several

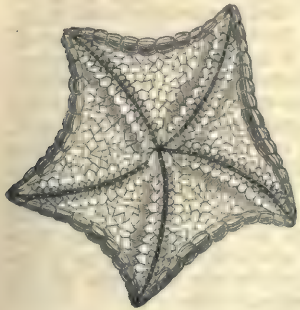
Pentacrinus Caput-medusæ.

new genera have been discovered, since deep-sea exploration and dredging have been suggested and carried out, such as *Rhizocrinus*, which was found off the coast of Norway. In *Comatula*, or the Feather-star, the adult form is free, whilst the young, which was formerly described as a distinct animal, is fixed. The *Crinoidea*, however, were much more abundant during the Carboniferous period, where the mountain limestone is largely composed of the stalks of the forms that flourished there. The individual joints of the stem, when separated, are known as St Cuthbert's beads. In the Muschelkalk, one of the secondary Triassic rocks of Germany, a very pretty form, the *Encrinus liliformis*, or stone-lily, is specially abundant, and is very well known.

ORDER 2. The *Ophiuridea*, represented by the 'Sand-stars' (*Ophiura*) and 'Brittle-stars' (*Ophiocoma*), are star-fishes having five slender arms radiating from a small central disk, on the lower surface of which the mouth is placed. The arms do not contain any prolongation of the viscera, but consist of a central series of ossicles united by powerful muscles, and of an external mailing of several series of plates of the perison. The ambulacral vessel runs along the lower surface of the arm, and gives off at each joint a pair of long conical tubular appendages, without suckers, which are used for locomotion and respiration. There is no excretory opening, the indigested matter being thrown out from the mouth.

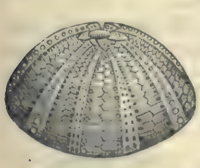
ORDER 2. *Asteroidea*.—The common *Asterias*, or Star-fish, which may be taken as the type of

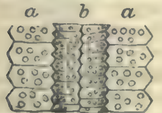
this order, is covered with a tough leathery skin beset with prickles. The animal has the form of a star with five or more rays radiating from a central disc. In the middle of the under surface of the disc is situated the mouth, opening into an intestine, which sends prolongations into each ray. In some forms there is no anus present, so that the indigestible portions of the food have to be ejected through the mouth, as in the common sea-anemone. If the prickly skin be removed, it is seen that it is supported by a series of plates, beautifully jointed together. On the under surface of each ray, the plates exhibit a series of perforations, through which, in the living state, the ambulacral feet can be protruded. They are found in almost all tropical and European seas, and some species are found as far north as Greenland.



Asterias tessellata (*Asteriadæ*).

ORDER 4. *Echinoidea.*—The members of this order are commonly known as Sea-urchins or Sea-eggs. The body is somewhat globose in form, and composed of a series of plates jointed together. In the Echinus, we observe two orifices situated at the two poles of this globe; the larger of these orifices, directed downwards, is the mouth; at the smaller one, placed superiorly, the intestine terminates. The mouth is furnished with a curious apparatus of teeth, known as 'Aristotle's Lantern,' worked by a powerful set of muscles attached to the edge of the shell near the mouth. By the action of the teeth the food is ground down before it passes into the intestine, which takes a couple of turns round the shell before its termination. Round the second orifice of the shell are disposed the ovaria, which are very largely distended with eggs at some seasons, and are eaten under the name of *roe of the sea-egg*. On looking at the *Echinoidea* in the living state, we see that most of them are covered with spines of considerable size. Moreover, these spines are movable at the base, which is hollowed out into a little cup, which fits on a rounded projection from the shell, thus forming a complete ball-and-socket joint. These spines are connected to the shell, and are moved by the skin which covers the latter. On looking at the shell of an Echinus, it is seen to be composed of twenty rows of plates, generally hexagonal in form, accurately fitted to each other, running from pole to pole. They are so arranged that there are ten alternating zones, each zone being composed of two rows of similar plates. There are five double rows of large plates, which are imperforate, and studded with tubercles. These are the *inter-ambulacral* areas. The other five double rows (*ambulacral areas*) alternate regularly with these, and are composed of small plates, which are perforated by numerous apertures for the protrusion of the *ambulacral feet.*





Shell of Echinus:
a, inter-ambulacral plates;
b, ambulacral plates.

These feet are distended by water admitted from without through a specially modified plate, called the madreporiform tubercle, which admits it into the sand-canal, a straight tube filled with peculiarly shaped spicules, which finally opens into a ring-like vessel surrounding the œsophagus, and sending off tubes in a radiate manner, from which the ambulacral feet spring. When water is admitted into these feet, they become distended, and are protruded through the ambulacral apertures. These feet are provided with a small sucker, by which they can adhere to the rocks, thus enabling the animal to move along. Attached to and communicating with the ring-like vessel surrounding the œsophagus, are two little sacs or bags, called *Polian vesicles*, which act as reservoirs for the water, so that the ambulacral feet can be protruded at will. The spines are most numerous in the inter-ambulacral areas. In order to provide for the growth of the shell, there is interposed between adjoining plates a thin membrane, by the calcification of which the plates increase in size at their edges. These animals are found on sandy shores, and on the bottom of the sea, creeping along with their feet. Their food is of a mixed character, consisting of crustacea and sea-weed. In some forms, as *Spatangus* (Heart Urchin), the shell is ovoid or heart-shaped, and the mouth is eccentric. In these cases, the dental apparatus is generally imperfectly developed.

ORDER 5. The *Holothuridea*, the last and most highly organised Echinoderms, are destitute of spines or prickles, and have the body shaped like a cucumber, and inclosed in a highly elastic skin. They are commonly known by the name of *sea-cucumbers.* Some of the species are edible, and, when dried, are the *trepang* of commerce. By the Malays, they are diligently sought after for the supply of the Chinese market.

IV. SUB-KINGDOM ANNULOSA.

The *Annulosa*, or Ringed Animals, have their segments arranged, one behind the other, from before backwards. They exhibit bilateral symmetry, each segment being also symmetrical. The alimentary canal, which is present in all except a few internal parasites, is distinctly shut off from the body cavity. In most, a blood-vascular system is present, and is always placed dorsally. In the higher orders, the nervous system consists of a double symmetrical cord, placed along the ventral surface of the animal, and having upon it small swellings composed of nervous matter, and termed *ganglia*, two ganglia corresponding to each segment. These ganglia give off branches to their respective segments. Anteriorly, the gullet is surrounded by these nervous cords, so that it passes through a ring of nervous matter.

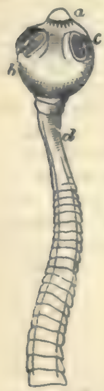
The *Annulosa* are divided into two principal divisions: I. Vermes, and II. Arthropoda.

DIVISION I.—VERMES

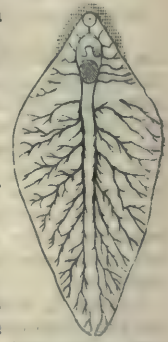
(Worms), in which the division of the body into longitudinally arranged segments is not apparent, or but imperfectly marked; and there is an absence of appendages jointed or articulated to the body.

CLASS (A). *Platyelmia*, or Flat-worms, are usually flattened and ovoid in form, and the segmentation of the body is not distinct. The nervous system consists of a pair of ganglia, situated at the anterior extremity of the body, from which filaments arise and pass backwards. Some live in the interior of other animals, and are parasitic; while others are covered with cilia, and swim freely in the water.

ORDER 1. *Cestoidea*—including the family of the *Tæniadæ*, or Tape-worms, which are parasitic in the intestinal canal of warm-blooded vertebrata. The mature worm is ribbon-like, and consists of many joints or segments, which resemble each other. The anterior segment, or *head*, has a circle of hooks and suckers by which it is enabled to fix itself to the intestinal canal of its 'host.' The various segments are produced by a process of budding from the head posteriorly, so that the oldest and most mature are farthest removed from it, each new bud being formed between the head and the last-formed segment. As neither mouth nor digestive system is present, the animal is nourished by absorption through the soft skin of the body. Running down along each side is a vessel, which communicates with its fellow by a branch at the posterior part of each segment. This is described as a water-vascular system, but in none of the Vermes is it ever used for purposes of progression. Each segment, except the head, is provided with male and female sexual organs. The female organ consists of a branched tree-like tube, occupying nearly the whole of each segment, which opens along with the male duct at the apex of a little elevation placed on the margin or surface of the segment. The development of these animals presents some most remarkable phenomena. Sexually mature segments can only be formed in the intestinal canal of a warm-blooded vertebrate; but the development of an embryo cannot go on unless the ova are introduced into the intestinal canal of some animal other than the one in which the mature segments were produced; so that the segments with ova have to be expelled from the bowel. The joints, after expulsion from the bowel, decompose, and liberate the ova, which, when swallowed by another warm-blooded vertebrate, give rise to an embryo which is provided with spines suited for boring. With these it perforates the wall of the stomach, and reaches some solid organ, such as the liver or brain, where it develops for itself a bag or cyst, and is said to become *encysted*. In this condition it is composed of a 'head' furnished with hooklets, and a vesicle filled with fluid at its posterior extremity; but it has no generative organs. These are the so-called *cystic worms*, whose presence in the brain of sheep gives rise to the disease called 'the staggers.' Unless the organ, such as the liver or brain, containing these cystic worms is swallowed by some other warm-blooded vertebrate, they undergo no further development. When swallowed, their vesicle disappears, and buds are given off from their posterior extremity, which develop organs of reproduction, and constitute the segments of the adult worm. The ordinary tape-worm met with in the intestinal canal of man in this country is *Tænia solium*, which sometimes measures several yards in length. The cystic form of this species is called *Cysticercus cellulosæ*. It is found in the muscles of the pig, constituting what is known as *measly* pork. If a portion of this is eaten by man, the cystic form develops itself in his intestinal canal into a tapeworm. Another tape-worm common in man is the *Tænia medio-canellata*, which is derived from the 'measles' of the ox.



Tape-worm: Head, neck, and upper joints of *Tænia solium* magnified; *a*, the circle of hooks; *b* and *c*, two of the sucking discs; *d*, the neck.



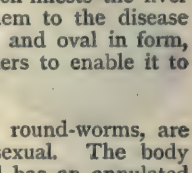
Fluke-worm (*Distoma hepaticum*).

ORDER 2. *Trematoda*—are parasitic, and include the *Distoma hepaticum*, or 'fluke,' which infests the liver of sheep, and gives rise in them to the disease called 'rot.' The body is flat and oval in form, being furnished with two suckers to enable it to adhere to its host.

CLASS (B). *Nematelmia*, or round-worms, are nearly all parasitic and unisexual. The body is rounded and elongated, and has an annulated appearance.

ORDER 3. *Gordiacea*, or hair-worms, distinguished by their great length, sometimes make their appearance in enormous numbers in particular places, and give rise to the phenomenon of 'worm-showers.'

ORDER 4. *Nematoda* are free or parasitic. Type *Ascaris lumbricoides*, or round-worms of the human subject, is elongated and cylindrical in form, and has a wrinkled appearance. An alimentary canal and distinct anus are present. The sexes are distinct. The nervous system is in the form of a ring encircling the gullet, giving branches forwards and backwards. The Thread-worms (*Oxyuris*), which are so troublesome to children, belong to this group. The Guinea-worm (*Filaria medinensis*) lives in the cellular tissue under the skin chiefly of the legs. It is often several feet long; and is common in tropical Africa.



Trichina spiralis spirally coiled within its cyst. (From Küchenmeister's *Parasites*.)

In the muscles of the human subject, coiled up

within a cyst, has been found the *Trichina spiralis.* This parasite has appeared most frequently in Germany, and its presence is ascribed to the use of pork, raw or imperfectly cooked, in which the Trichina exists, for it also inhabits the muscles of the hog as well as of the human being. When thus encysted, it never develops sexual organs, but must be again swallowed by a warm-blooded vertebrate before it can reproduce itself. Its presence in the muscles gives rise to the painful disease called Trichiniasis. The non-parasitic forms are represented by the *Anguillulidæ*, which are little eel-like worms. One species, *A. tritici*, causes the disease termed 'cockle' in wheat. Another, *A. aceti*, is met with in stale vinegar; whilst a third, *A. glutinis*, or 'paste-eel,' is met with in paste that is turning sour.

CLASS (C).—*Rotifera*, or wheel-animalcules, represented by such forms as *Hydatina* and *Floscularia*, are microscopic aquatic animals, having an elongated slightly segmented body, and carrying at its anterior end a ciliated disc, which, by creating a vortex, carries to their mouths any food which may be floating in their neighbourhood. They possess a mouth and intestinal canal; and a water-vascular system is present. They are very tenacious of life; so that, if they are dried until they are quite brittle, on the return of moisture, they unfold their wheel-like organs, and are as active as before.

CLASS (D).—In the *Annelida*, the segmentation of the body is generally distinctly recognisable, and all the segments usually resemble each other, except those at the two ends. If a segment carries lateral appendages, these are never articulated to the body. The digestive canal runs straight through the animal from the mouth to the anus. A system of canals exists, which contain a coloured fluid, usually red or green, which is supposed to represent the vascular system. The nervous system consists of a double gangliated cord placed ventrally, which encircles the gullet anteriorly.

This class includes two sections: 1. *Abranchiata*, including the Leeches and Earth-worms, in which there is no external respiratory organs or branchiæ. 2. *Branchiata* comprises the Tube-worms (*Tubicola*) and the Sand-worms (*Errantia*), in which branchiæ are present.

ORDER 1. *Discophora*—for example, the leeches, which possess an adherent sucker at their anterior and posterior extremities, which they use for locomotion. They have no lateral appendages. The body has well-marked annulations. They are aquatic, living chiefly in fresh water; but a few are marine. The mouth of the Medicinal Leech (*Sanguisuga officinalis*) is furnished with teeth arranged in a tri-radiate manner. Each tooth has a serrated edge, and when the teeth are worked backwards and forwards, they inflict the characteristic leech-bite when these animals are applied to the skin. Respiration is performed by the skin or by involutions of the integument. Leeches are hermaphrodite, but they are incapable of self-impregnation. They are very common in the south of France, Bohemia, Hungary, and Russia. The Horse-leech (*Hæmopis sanguisorba*) is common in Britain; it is larger than the medicinal leech, but its teeth are blunt, and it is useless for medical purposes. In Ceylon, the Land-leech is very troublesome to men and quadrupeds who have occasion to walk through the grass. They insinuate themselves under the finest stockings, and

Horse-leech (*Hæmopis sanguisorba*).

suck the blood of their victims; so that the coffee-planters are forced to wear *leech-gaiters* of closely woven cloth for protection.

ORDER 2. *Oligochæta*—comprise the Earth-worms (*Lumbricidæ*). Their organs of locomotion consist of a double row of bristles attached to the under surface of the body. They are all hermaphrodite. The Common Earth-worm (*Lumbricus terrestris*) is of great importance to the agriculturist, by continually bringing the deeper portions of the soil to the surface. Besides they are useful as food for birds and fishes, and their value as bait is well known to every angler.

ORDER 3. *Tubicola*—are all marine, and they invariably form for themselves a tube or case into which they can retract themselves. This tube may be composed of particles of sand, which the animal glues together with mucus, as in the genus *Terebella*, or it may be of a horny, or even of a calcareous nature, formed from matter excreted by the animal. There is no organic connection between the tube and its inhabitant, for the creature can be easily drawn out of it. The organs of respiration consist of a tuft of plume-like ciliated organs situated on the head. These are often beautifully coloured, from the coloured fluid, representing the blood, which circulates in them. The genus *Serpula*, which forms irregularly twisted

Serpula contortuplicata.

calcareous tubes attached to shells and stones, is very common along our coasts.

ORDER 4. *Errantia*—are free-swimming annelids, which do not develop a tube. The segmentation is distinctly pronounced, and the anterior extremity of the body is marked out as a head, which is usually provided with eyes. It

includes the *Arenicola piscatorum*, or Lob-worm, the *Nereis* (Sea-centipede), and the Sea-mouse (*Aphrodite*). The respiratory organs are in the form of tufts of branchiæ, which are placed along the back or sides of the creature. The back of the Sea-mouse is covered by a series of membranous plates, protecting the bristles of the feet, which exhibit beautiful iridescent metallic colours.

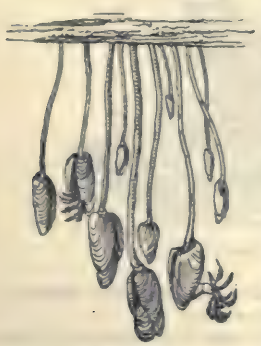
DIVISION II.—ARTHROPODA,

in which the division of the body into segments is well marked, and *jointed appendages articulated to the body are present*. Most of the segments and appendages are protected by an outer covering, often composed of chitine, which forms a sort of exo-skeleton. The appendages are hollow, and the muscles are prolonged into their interior. The nervous system exhibits the well-marked Annulose type. Respiration is performed differently in the different groups. The vascular system, when present, is always placed dorsally.

The *Arthropoda* (Gr. *arthros*, a joint, and *pous*, a foot) are divided into four great classes—namely, the *Crustacea*, the *Arachnida*, the *Myriapoda*, and the *Insecta*.

CLASS I. *Crustacea*.—In a typical crustacean, the body consists of twenty-one segments, seven of which belong to the *head*, seven to the *thorax*, and seven to the *abdomen*. But sometimes the head segments unite with those of the thorax, and form a *cephalo-thorax*. Some of the segments may be suppressed. Some or all of the segments are provided with a single pair of articulated appendages. The animals are fitted for life in water, and they therefore breathe by gills, or by the general surface of the body. The head carries two pairs of jointed antennæ or feelers. The appendages for locomotion are borne by the thoracic segments, and usually by those of the abdomen also. The body is protected by a calcareous or horny covering or 'crust.' They all undergo a series of metamorphoses or changes before they reach the mature condition.

ORDER I. *Ichthyophthira* and *Rhizocephala*, or the *Parasitica* of Lamarck—in their embryonic condition are furnished with eyes and antennæ, and swim freely about; but the adult is parasitic on the eyes and gills of fishes, to which it adheres by a suctorial mouth.



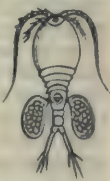
Barnacle.

ORDER 2. *Cirripedia* (Lat. *cirrus*, a tendril, and *pes*, a foot)—represented by the Acorn-shells and Barnacles. In the adult condition, they are permanently fixed, and are usually seen attached to rocks, pieces of floating timber, or the bottoms of ships. Several of the head segments are so modified as to form a multivalve shell, inclosing the animal, from which it can protrude itself. The thorax is provided with six pairs of ciliated limbs, which, being protruded through the opening in the shell, and creating currents in the water, bring food to the animal. The embryo is a free-swimming form, which is provided with one eye, has two pairs of antennæ, and six limbs, which it uses for swimming. In the barnacles (*Lepadidæ*), the animal is fixed by a long stalk or peduncle; while the acorn-shells (*Balani*) are sessile, having no stalk.

SUB-CLASS *Entomostraca*.—Those crustaceans which possess more or fewer than fourteen thoracico-abdominal segments are included under the sub-class *Entomostraca*, which includes five orders.

ORDER 3. *Ostracoda*—for example, the genus *Cypris*, which abounds in every pool of fresh water. It is a small animal, protected by a shell composed of two valves, which it can open and shut at will. It has two or three pairs of feet, and the branchiæ or gills are attached to the posterior jaws, which surround the mouth. In a fossil state, their shells are found abundantly in the Wealden rocks of England, in the Carboniferous Limestones, &c.

ORDER 4. *Copepoda*—for example, *Cyclops*, one of the 'Water-fleas,' which is common in all our ponds and ditches. It is of small size, and the head and thorax are protected above by a structure called a *carapace*. It has a single large eye, placed anteriorly, and two pairs of antennæ. Five pairs of feet are present, and are used for swimming.



Cyclops vulgaris, magnified.

ORDER 5. *Cladocera*—represented by *Daphnia pulex*, another of the Water-fleas. The head is distinct, and has a single eye, and the remainder of the body is inclosed in a shell.

ORDER 6. *Phyllopoda* (*phyllon*, a leaf, and *pous*, a foot)—includes the genus *Apus* and the Fairy Shrimp, in which the body is protected by a carapace. They have always more than sixteen feet, which carry the gills; and the eyes are well developed.

An order, the *Trilobita*, now entirely extinct, was probably allied to the *Phyllopoda*. The body was covered by a chitinous shield, consisting of a cephalic shield, a variable number of body-segments, and a tail with the joints more or less anchylosed, the whole shewing a division into three longitudinal lobes, hence the name. The eyes were sessile and compound, and the number of facets in the lens of one species numbered 6000. They were entirely confined to the Palæozoic rocks, and over 200 species have been described from the Silurian rocks alone.

Asaphus tuberculatus.

Limulus Polyphemus.

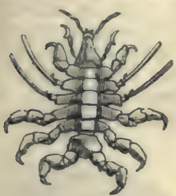
ORDER 7. *Xiphosura* (*xiphos*, a sword, and *oura*, a tail)—represented at the present day by

the King Crabs or Molucca Crabs (*Limulus*), which sometimes measure two feet in length. The dorsal surface of the cephalo-thorax is covered by a large convex shield, upon which are placed the eyes. The abdomen is also protected by a second shield, which terminates in a long sword-like process. The mouth, placed on the under surface of the head, is surrounded by six pairs of appendages, whose bases are suited for masticating food, their extremities being clawed. Attached to the abdomen are six pairs of appendages, which carry the gills.

SUB-CLASS *Malacostraca* includes those crustaceans which have a *definite* number of body-segments. It includes

DIVISION (A).—EDRIOPHTHALMATA,

in which the eyes are not situated on stalks, and the body is unprotected by a shield. It comprises three orders.



Cyamus Ceti.

ORDER 8. *Læmodipoda* (*laimos*, the throat, *pous*, a foot).—The head is confluent with the first thoracic segment. These segments support the four anterior feet, so that they seem to be under the throat—hence the name. The abdomen is rudimentary. The most common is the *Cyamus Ceti* (or Whale-louse), which is a small animal parasitic on the body of the whale.

ORDER 9. *Amphipoda* (*amphis*, on both sides, and *pous*, a foot).—The respiratory organs are attached to the thorax; the abdomen is well developed, and composed of seven segments. The first thoracic segment is distinct from the head, and the thorax carries seven pairs of limbs, some of which are directed forwards, some backwards. The species best known in Britain is the *Talitrus locusta* (Sand-hopper), which burrows in the sand, and seldom enters the water.

ORDER 10. *Isopoda* (*isos*, equal, and *pous*, a foot).—The head is distinct. The feet are alike, and adapted for locomotion and grasping. The most familiar is the *Oniscus* (Wood-louse).

DIVISION (B).—PODOPHTHALMIA.

The eyes are supported on movable stalks, and the cephalo-thorax is protected by a carapace. It includes two orders.

ORDER 11. *Stomapoda* (*stoma*, a mouth, and *pous*, a foot).—They are all marine. The Locust-shrimp (*Squilla*), which is common in the Mediterranean, is a well-known form, and is about seven inches long. The gills are naked, and adhere to five pairs of feet, which are abdominal in position, and leaf-like in form. Some of the anterior appendages are transformed into powerful, prehensile feet, but they are never used for nipping, while the posterior feet are used for swimming.

ORDER 12. *Decapoda* (*deka*, ten, *pous*, a foot).—It includes the stalked-eyed crustaceans, whose cephalo-thorax is protected by a strong calcareous carapace, which exhibits no trace of segmentary division. The gills lie in a cavity on each side of the cephalo-thorax. The thoracic legs are ten in number, hence the name. It includes a great number of species, most of which are useful for food, and they are by far the most highly organised of all the Crustaceans. According to the development of the abdomen, three sub-orders are formed.

Sub-order 1. *Macrura* (*makros*, long, *oura*, a tail), or Long-tailed Decapods—including the Lobster, Prawn, Cray-fish, and Shrimp. The abdomen is well developed, and ends in a powerful fan-shaped swimming organ. The head carries the compound eyes, placed on long movable stalks. Two pairs of antennæ are also present. The mouth is on the under surface of the head, and some of the appendages are so modified as to form powerful claws or nipping organs. The abdominal segments carry swimming organs. The heart is well developed, and is situated dorsally. The nervous system is well pronounced, and is situated ventrally.

Sub-order 2. *Anomura* (*anomos*, irregular, and *oura*, a tail).—The abdomen is not so long as in the Macrura, nor so short as in the next order. To this order belongs the Hermit Crab (*Pagurus*), whose abdomen is quite soft. They are remarkable for living in the deserted shells of mollusca, exchanging a less for a larger as they increase in size. It fixes itself in the shell by a sucker and rudimentary feet. Well-developed feet are present, the anterior pair being usually transformed into formidable nippers. They feed upon dead fish. When alarmed, they retire within the shell, and close the aperture with their claws.

Hermit Crab in shell.

Sub-order 3. *Brachyura* (*brachys*, short, *oura*, a tail), or Short-tailed Decapods—have the tail short, and folded under the large cephalo-thorax. The Large Edible Crab (*Cancer pagurus*) is the type. The legs are of moderate length, but the claws are large. At low tide in summer, it is found in holes of rocks. The Small Edible Crab (*Carcinus mænas*) is another well-known British species. The Land-crabs (*Gecarcinus*)—called also violet crabs and white crabs, from their colour—are natives of the West India Islands and South America. They have an arrangement of leaflets for retaining moisture for their gills. They live in mountainous places, far from the sea, which they visit once a year to deposit their eggs. During the day, they retire into their burrows, which they make in the earth, roaming about at night in search of food. The Common Crab, on coming out of the egg, has a long tail, with several curious spine-like processes attached to it, and was formerly described as a distinct animal under the name of *Zoea*. It undergoes curious metamorphoses before it reaches the adult condition.

CLASS 2. *Arachnida*—are annulose animals, whose respiration is aërial. The head is confluent with the chest, thus forming acephalo-thorax, and the abdomen never carries jointed appendages. Eight legs are present, but the antennæ as such are absent. It includes the familiar group of Spiders and their allies.

SUB-DIVISION (A). *Trachearia* (*trachea*, the windpipe)—includes such spiders as breathe by tracheæ. These tracheæ are tubes which ramify through the tissues of the body, and open on the surface by distinct apertures called *stigmata*. The tubes are kept pervious by a spiral elastic filament, which is coiled up within them. The *Trachearia* have never more than four eyes.

ORDER I. *Podostomata*.—They are all marine, and are commonly known as 'Sea-spiders.' Some of them, as *Nymphæ*, are found amongst the stones and weeds on the sea-shore, while others, such as *Pycruogonum* are parasitic upon fish and other marine animals.

ORDER 2. *Acarina*, or *Monomerosomata* (*monos*, one, *meros*, a part, and *soma*, the body)—including the Mites and Ticks. The body consists of a roundish mass, exhibiting no trace of segmentation. They breathe by tracheæ. The family of the *Linguatulina* is remarkable in that, in their adult condition, the characters of the order are not easily traced, but the young, when still in the egg, are furnished with four pairs of jointed legs. The *Linguatulina* are found in the lungs of some of the mammalia. The family of the *Macrobiotidæ* are microscopic, and are known by the name of Sloth or Bear Animalcules. Their favourite habitat is under the gutters of houses. They resemble the Rotiferæ in so far as, though dried for a considerable time, they return to life the moment they are moistened. But the most familiar of all is the family of the *Acarida*, including the Cheese-mite, which has four pairs of legs, and uses them for walking. The *Sarcoptes scabiei* produces, by burrowing under the skin, the disease called 'itch.' The *Hydrachnidæ*, or water-mites, have their legs fringed, and swim about in water. The Ticks (*Ixodes*) have a 'rostrum,' which enables them to penetrate and attach themselves to the skin of their host, generally one of the beetles.

Acarus (Mite).

ORDER 3. *Adelarthrosomata*.—The abdomen is united to the cephalo-thorax, but it is always more or less distinctly segmented. The mouth is armed with jaws, and the tracheæ open by two or four openings on the under surface of the body. To this order belong the family of the *Phalangidæ*, or Harvest-spiders, characterised by the enormous length of their legs, which resemble stilts. The family of the *Cheliferidæ* includes the Book-scorpion, whose palpi are long, and terminated by long nippers like those of the scorpion. Their favourite habitat is amongst old books.

SUB-DIVISION (B). *Pulmonaria*.—These breathe by pulmonary sacs, which are involutions of the integument, opening on the surface of the body by stigmata, which lead into a blind chamber. They have six or more simple eyes. The *Pulmonaria* comprise two orders.

ORDER I. *Pedipalpi*—in which the abdomen is distinctly segmented, and attached to the cephalo-thorax. This order includes the family of the *Scorpionidæ* — which are amongst the largest and best known of the Arachnida. They have an elongated abdomen, armed at its extremity with a short curved claw. It is with this organ that the Scorpion inflicts its sting, which is doubtless very disagreeable, and often attended with troublesome symptoms, though its danger, to man at least, seems to have been overrated. The maxillary palpi are very large, and form prehensile organs like the claws of a lobster. With these they seize their prey, strike it with the sting, and then devour it. They have four pairs of stigmata opening on the under side of the abdomen. It is in the tropics that the Scorpions attain their largest development.

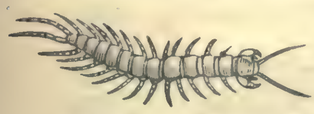
ORDER 2. *Dimerosomata* (Gr. *di*, two, *meros*, a part, and *soma*, a body) includes the true Spiders. The head and thorax are united into a single mass, and the abdomen is soft and unsegmented, being separated from the cephalo-thorax by a slight constriction. The head carries six or eight simple eyes. The mandibles are large, and perforated by the duct of a gland, which secretes a poisonous fluid. The palpi are never chelate or clawed. The pulmonary sacs are two or four in number, and open on the under surface of the abdomen. Tracheæ may also be present. But by far the most remarkable organs are the *spinnerets*, by means of which these animals spin their curious and beautiful webs for intercepting the prey upon which they expect to feed, or for lining their abodes. The spinnerets are teat-like organs, four or six in number; they are perforated at the apex by minute openings placed on the under surface of the abdomen. The substance composing the web is secreted by glands placed close to the spinnerets. It is viscid at first, and passes through the spinnerets, which give it its proper thread-like shape, becoming hard on exposure to the air. The *Argyroneta aquatica*, or Diving-spider, weaves for itself a bell-shaped cell, at the bottom of the water, to which it retires to devour its prey. It carries down air by entangling it amongst the hairs which cover its body. All spiders are predaceous, but some do not construct a web for the capture of their prey, such as the Tarantula (*Lycosa tarantula*) of Southern Europe, which springs suddenly upon its unwary victim. The *Mygale*, the most powerful of the spider order, when at rest, covers a space of six or seven inches in diameter. Other species are called Mining-spiders, because they construct their habitations in the ground, lining them with their silk-like secretion. The *Aranea domestica* (Common House-spider) is well known. The maxillary palpi of the male spider are specially constructed for bringing the male into contact

Spider, with thread-making organ magnified.

with the female element in the process of reproduction. Spiders are oviparous, but undergo no metamorphoses.

CLASS 3. *Myriapoda* have the head distinct, bearing a pair of antennæ, and usually a number of simple eyes. The thorax is united with the abdomen, the whole being divided into a large number of similar segments, each furnished with one or two legs on each side. They respire by tracheæ.

ORDER 1. *Chilopoda*, in which the number of joints composing the antennæ is never less than fourteen. *Lithobius forcipatus*, a British species, is about two inches in length, and quite harmless; but some of the *Scolopendra*, well known as Centipedes, found in hot climates, are powerful and predaceous, and sometimes measure one foot in length.



Lithobius forcipatus.

ORDER 2. *Chilognatha*, in which the antennæ are composed of only seven joints. It includes the vegetable-eating Millepedes (*Iulus*), characterised by the great number of the legs. The familiar Gally-worm (*Polydesmus*) is another example.

CLASS 4. *Insecta*—are articulate animals, in which the body is divided into three distinct regions—the *head*, *thorax*, and *abdomen*. The head carries the antennæ or feelers; the legs, six in number, being borne by the thorax; while the abdomen is destitute of jointed appendages. They breathe by tracheæ, and are generally furnished with wings attached to the thorax.

Considering the vast number and variety of insects that are found everywhere upon the earth, with their diversity of habits and structure, it must suffice here to point out the main characters of the class, merely mentioning some of the most important families. Indeed, the subject is so vast, that it is studied as a distinct branch of Zoology, under the term *Entomology*.

The body is never composed of more than twenty segments, which have usually a horny or chitinous investment, forming an exo-skeleton, to which the muscles are attached. The segments are united to each other by a membranous skin, thus giving flexibility to the whole. The segments of the head are united into a single piece, which bears the antennæ, the eyes, and organs of the mouth. The mouth is variously modified, according as it is suited for biting, for suction, or for both combined. In Masticating or Biting insects, such as Beetles, the mouth consists of six separate organs (see fig.). (1) An upper lip (labrum, *l1*) attached to the under surface of the head; (2) A pair of horny biting jaws (mandibles, *mm*); (3) A pair of chewing jaws (maxillæ, *mx*), bearing one or more pairs of 'maxillary palpi' (*mp*); and a lower lip (labium, *l2*) also bearing a pair of palpi (*lp*). The typical *suctorial mouth*, as seen in the Butterflies, consists of a long trunk, which, when at rest, is coiled up in a spiral form beneath the head. It represents the maxillæ, which, coming together, form a tube, through which the juices of the flowers are sucked up. The maxillary palpi are very small, and the labrum and mandibles are rudimentary. The labium, though very minute, bears two large palpi, forming the hairy cushions between which the trunk is coiled up when at rest. In the Bee, the parts are modified partly for biting, and partly for suction. The labium and maxillæ are elongated, the latter constituting a sheath which incloses the elongated tongue, thus forming a tubular organ, quite incapable of being coiled up, and through which fluid nutriment is sucked. The mandibles and labium retain their ordinary form. In Bugs and their allies, the labium forms an elongated tubular sheath, inclosing four bristle-shaped organs, which are the modified mandibles and maxillæ. The labium of the House-fly is lengthened and grooved on its upper surface. This groove receives the modified mandibles and maxillæ in the form of bristles and lancets, which are used for penetrating the skin and sucking the blood of other animals.

Mouth of a Beetle.

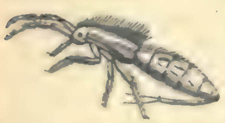
The thorax is composed of three segments, which are named from before backwards, *pro-thorax*, *meso-thorax*, and *meta-thorax*. Each of these bears a pair of jointed legs. The latter two segments also usually carry a pair of wings each. The legs are composed of several joints, named the coxa, trochanter, femur, and trasus. The wings are variously modified in the different orders, and consist of a double membrane, which is supported by hollow tubes or 'nervures,' which ramify in every direction, and contain processes of the tracheæ, and passages for the circulation. The abdomen is composed typically of nine segments, though these never carry legs. Some appendages connected with the generative function, or for leaping, for offence or defence, may, however, be connected with it. The *digestive system* in insects consists of a mouth leading into a gullet, which opens into a 'crop.' From this, in Masticating Insects, it leads into a 'gizzard,' furnished with horny plates. This gizzard leads into the true stomach, continued into the intestine, which terminates in a 'cloaca,' common to it and the generative organs. Salivary and other glands are present, but no absorbent system. The heart is placed dorsally, and consists of several sacs, which open into each other from behind forwards. The circulating fluid enters at the posterior extremity of the so-called 'dorsal-vessel,' and is propelled forwards by it, escaping anteriorly, and passing amongst the tissues, and, as it were, bathing them, for no true veins or arteries have been detected in the bodies of insects. In its course it is aërated by being exposed to the air contained in the tracheæ, which ramify throughout the body. The *nervous system* exhibits the typical annulose plan, and is placed ventrally. The eyes are usually compound—that is, they consist of multitudes of simple eyes, each of which receives a nervous twig. The eye of the house-fly has four thousand of these simple eyes. Insects are distinguished beyond all other animals by their powers of locomotion, and the perfection of their instinctive actions. The antennæ seem to be organs of touch. Insects are unisexual,

and most are oviparous. Many insects undergo changes of form (*metamorphosis*) in their development from the immature to the adult condition. Those which do not undergo this change are called *Ametabolic Insects* (Gr. *a*, without, *metabole*, change). The young of these insects resemble their parents in all respects except in size; moreover, they are destitute of wings. Those which only undergo a half-metamorphosis are called *Hemimetabolic Insects*. They undergo three stages. The young is termed *larva;* in the second stage it is *pupa;* and in the third, the perfect insect or *imago*. The larva differs from the imago in its smaller size, and in the absence of wings, while the pupa differs from it only in the wings being rudimentary. This metamorphosis is said to be *incomplete*. Those which undergo a *complete* metamorphosis are called *Holometabolic Insects*. The larva is worm-like, feeding voraciously, and growing rapidly. It is then called caterpillar or grub. After frequently changing its skin, it passes into the pupa or chrysalis state, when it becomes incased by a coriaceous covering, and seems all but devoid of life. Other larvæ spin for themselves a protective covering, which surrounds the chrysalis, and is termed the 'cocoon' (the *Silkworm*), while others reside in tubes constructed by themselves (the *Caddis-worm*). Finally, it emerges from this condition as the imago, or perfect insect, with fully developed wings, ready for flight.

SUB-CLASS I. *Ametabola*.—The young pass through no metamorphosis; imago destitute of wings; eyes, if present, are simple. It includes three orders.

ORDER 1. *Anoplura*—are typified by the Common Louse (*Pediculus*), a creature justly regarded with loathing, because it never exists unless in connection with dirty habits. The head bears two simple eyes and a suctorial mouth. They are all parasitic on mammiferous animals—man, the dog, and sheep having each an appropriate parasite of this order.

ORDER 2. *Mallophaga*—are specially common on birds, hence called *Bird-lice*. Their mouth is suited for biting, and they live on the more delicate portions of the feathers.



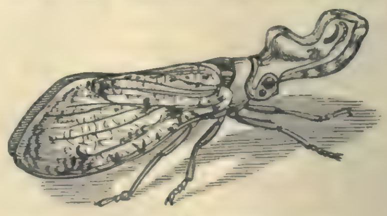
Podura villosa.

ORDER 3. *Thysanura*—includes the *Poduræ*, or Spring-tails, which possess a forked tail, curved under the animal, by suddenly extending which, they are enabled to spring to a considerable distance.

SUB-CLASS II. *Hemimetabola*—in which the metamorphosis is incomplete. This sub-class includes three orders.

ORDER 4. *Hemiptera* (*hemi*, half, *pteron*, wing). —Mouth suctorial, the labial palpi forming a sheath for the style-like maxillæ and mandibles, and thus protecting them. With these bristles, the insect pierces the plants or animals upon the juices of which it feeds. The head bears a pair of compound eyes, and usually also several simple eyes. Most of them possess four wings. This order is subdivided into

SUB-ORDER (A). *Homoptera* (*homos*, like, and *pteron*, a wing)—in which the anterior pair of wings are of similar consistence throughout, often somewhat parchmenty, and the mouth looks backwards, so that the rostrum springs from the back of the head. These are represented by the *Coccidæ* (Blight Insects)—for example, the *Coccus cacti* (Cochineal Insect), esteemed for the splendid colour it furnishes. It takes seventy thousand of these insects to make a pound of cochineal. An East Indian species (*Coccus lacca*) yields *shell-lac* and *lac-dye*. In these cases, it is only the female insect that yields the colouring matter. The *Aphides* (Plant-lice) inhabit trees or plants, to which they prove highly destructive, feeding, as they do, upon the juices they contain. They exhibit some very peculiar phenomena in their



Fulgora laternaria.

manner of reproduction. The *Fulgora laternaria* (Lantern-fly of Guiana), in which the forehead is much prolonged, is said to emit light in the dark. The *Aphrophora spumaria*, or Frog-hopper, a British species, also belongs to this group. Its larva envelops itself in a frothy secretion, which has received the name of 'cuckoo-spit.' The *Cicada* was celebrated by the Greek poets for its fine song, peculiar to the male, and produced by the vibration of a drum-like organ situated at the side of the abdomen.

SUB-ORDER (B). *Heteroptera*, or Bugs (*heteros*, different, *pteron*, a wing)—in which the wings are chitinous towards the base, and membranous towards the point, the beak springing from the front of the head. The Boat-flies or Water-bugs (*Notonecta*) haunt the surface of still waters. They use their hind oar-like feet for swimming, and with their anterior pair they seize their prey. The *Nepidæ* (Water-scorpions) are fierce insects, and lurk in ponds, living solely on insects. The *Cimicidæ* (Bugs) are unhappily familiar to us, by their intrusion into our bed-chambers. When irritated, they emit an offensive odour.

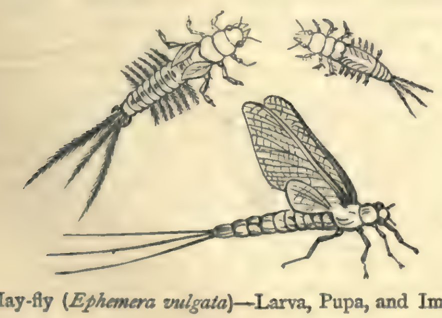
ORDER 5. *Orthoptera* (*orthos*, straight, *pteron*, a wing). The mouth is admirably suited for biting; wings four, the anterior pair of a leathery texture, and forming a protection for the posterior, which are larger, and folded in a fan-like form. This order contains two sections. The first of these sections, the *Saltatoria*, are all herbivorous insects, and have the hind-legs elongated, and fitted for leaping. It includes the family of the *Locustina* (Locusts), so common in warm climates. 'Wherever they alight, all signs of vegetation disappear, and cultivated grounds are left a desert.' The most common species is the *Locusta migratoria*, which is so formidable an enemy to agriculture in Southern Europe, and even reaches our own island. The *Gryllina* (Grasshoppers) have very long antennæ, and the largest British species is the *Gryllus viridissimus*, measuring about two inches in length. They are so pugnacious that if two are put into a box, they almost invariably fight, and the victor dines off the legs of the vanquished. The other British species are all of

small size. These are the little chirpers which we hear on heaths and sunny banks. The *Achetidæ*

Female Grasshopper (*Gryllus viridissimus*).

(Cricket family) are a very noisy race; for the chirping of the House-cricket (*Acheta domestica*), produced by the rubbing of the elytra-cases against each other, can be heard at a considerable distance. The Field-cricket (*A. campestris*) and Mole-cricket (*Gryllotalpa vulgaris*) also belong to this family. The section *Cursoria* have the legs long, and suited for running. The *Mantina* have the fore-legs converted into powerful raptorial organs. They are carnivorous, and very pugnacious. The Chinese amuse themselves with their combats, keeping them for this purpose in cages. The *Blattina* (Cockroaches) are nocturnal insects, which infest kitchens and bakehouses. The Common Cockroach (*Blatta orientalis*) is too well known to require description. The *Forficulidæ* (Ear-wigs) are likewise placed in this section.

ORDER 6. *Neuroptera* (Nerve-wing)—have four membranous wings, which are reticulated or interlaced with a delicate network of fine nervures. Metamorphosis in some is complete, though in most it is incomplete. The *Libellulidæ* (Dragonflies) are slender in form, and beautiful and varied in their colouring, though very voracious in their habits. They have four large, nearly equal reticulated wings, and a powerful masticatory apparatus. Their larvæ and pupæ inhabit the water. The *Ephemeridæ* (May-flies), also called Day-flies, from the short duration of their life in the perfect state, are found, during autumn and summer, in every



May-fly (*Ephemera vulgata*)—Larva, Pupa, and Imago.

brook and pond. The *Termitidæ* (White Ants) are social insects, living in vast communities, and chiefly confined to warm climates. They construct most beautiful habitations either on the ground or on trees, and assist in the removal of dead and decomposing organic matter. The *Myrmeleontidæ* or Ant-lions, whose larvæ are so destructive to ants, live, in the perfect state, upon the nectar of flowers. The larvæ entrap their prey by excavating conical pits in sandy places, at the bottom of which they conceal themselves entirely, with the exception of the head and powerful jaws. When an unfortunate ant or other insect falls into this pit-fall, it is soon devoured by the voracious myrmelio.

SUB-CLASS III. *Metabola*—in which the metamorphosis is 'complete.' It includes six orders.

ORDER 7. *Aphaniptera*—includes the Common Flea (*Pulex irritans*). The wings are rudimentary, and represented by four scales. The mouth is suctorial, and its power to penetrate the human skin, for gastronomic purposes, is too well known.

ORDER 8. *Diptera*—have only a single pair of wings developed—namely, the anterior; the posterior pair being rudimentary, and represented by organs called 'halteres' or 'balancers.' The mouth is suctorial. The *Hippoboscidæ* (Horse-flies or Forest-flies) are parasitic upon other animals. *Hippobosca equina* infests the horse, and *Melophagus ovinus* is the Sheep-tick. Amongst the *Muscidæ*, or Flies, the most familiar species is the *Musca domestica* (House-fly), whose larvæ are bred in manure, and undergo their change in a few days. Their purpose is to consume substances which would taint the atmosphere. They possess the power of flying backward. The *Tabanidæ* or Gad-flies have a suctorial mouth, provided with six lancets, with which they pierce the skin of their victim. The Cleg (*Tabanus pluvialis*) is familiar to most of us. Many of the *Tipulidæ* (Water-spinners), in their larval condition, are very destructive to the roots of grass and to wheat-crops. The *Culicidæ*

Gnat, magnified:

1, insect depositing eggs; 2, insect escaping from pupa case; 3, larva of gnat; 4, floating raft of eggs.

(Gnats) are specially blood-thirsty, and the disagreeable effects of their bite are frequently enough experienced. Their larvæ are aquatic. The Mosquitoes of warm climates interfere so much with our ease and comfort as to become one of the worst of pests. The Midge, so well known for its aerial dances, is the smallest species of the family.

ORDER 9. *Lepidoptera* (Gr. scaly-winged), Moths and Butterflies.—The structure of the mouth has been described already. The wings, four in number, are covered by minute scales, which are implanted on the membrane of the wing like the tiles on a roof. The beautiful metallic colouring which occurs in many species of this order is not due to the presence of pigment, but is owing to these minute scales having

upon them numerous delicate striæ, which break up the rays of light, and so cause the iridescent appearance. The *Lepidoptera* feed upon fluid nutriment. The larvæ are known as Caterpillars, which have a masticatory mouth; and when they attain their full size, they spin around their bodies a case or cocoon of silk, in which to spend their life as a pupa or chrysalis. From one species we derive the silk which is woven into one of the most elegant kinds of cloth. The glutinous matter of which the threads are composed is secreted by glands analogous to the salivary glands. It is forced through a small opening at the end of the lip, and hardens as it is exposed to the air. Some species, however, form no cocoon,

Argynnis Paphia.

but hang in the pupa state from some lofty place. At the proper time, the perfect insect bursts from its case, to spend a brief, gay existence in the air, to lay its eggs, and then perish.

Family *Papilionidæ* (Butterflies) are also called *Diurna*, because they fly about during the day, and are distinguished by the extraordinary beauty and variety of the colours which adorn their wings. Their antennæ are almost always terminated by a knob. Over 2000 species exist in Great Britain alone; but it is in tropical climates where these most beautiful of all insects attain their greatest size, and exhibit the greatest variety of absolutely dazzling hues.

Family *Sphingidæ* (Hawk Moths), or *Crepuscularia*, so called from their general habit of flying abroad at twilight. Their colour is duller than the butterflies, and when flying, they make a humming noise. The Death's-head Moth (*Acherontia atropos*) has a skull-shaped patch of colour on the back of the thorax, and its sudden appearrance has been regarded as an evil omen.

Family *Noctuina*, or Moths Proper, fly only by night, and are of a dull style of colouring. This family includes the Silkworm (*Bombyx mori*), a native of China. It was imported into Europe in the reign of the Emperor Justinian, in 550 A.D. The caterpillar of the silkworm, when it has attained its full size—three inches long—and before it passes into the chrysalis stage, spins for itself an oval ball or cocoon composed of a long slender filament of yellow silk. After emancipating itself from its silken prison, it seeks its mate. In two to three days afterwards, the female having deposited her eggs, from 300 to 400 in number, both insects terminate their existence.

ORDER 10. *Hymenoptera* (or Membrane-winged)—in which the wings are four in number, of a membranous texture, with few nervures, the anterior being larger than the posterior pair; they are sometimes absent. Mandibles are always present, and the arrangement of maxillæ and labium into a suctorial organ has been described already. The females are furnished at the extremity of the abdomen with an ovipositor, and in some species (Bees, Wasps) this organ is modified, so as to constitute a most formidable offensive weapon. Many possess instinct of a very high degree, and some live in social communities, as the Bees and Ants. This order includes the following families:

Tenthredinidæ (Saw-flies). The females have an ovipositor which combines the properties of a saw and a file. With this, they bore a series of holes in trees, depositing in each an egg, with a drop of frothy liquid, which seals up the hole. The larvæ have from ten to sixteen feet, and so are easily distinguished from the caterpillars of the *Lepidoptera*, which they resemble.

Ichneumonidæ (Ichneumons). These are parasitic, and insert their sting into and deposit their eggs in the larvæ of other insects, where the young, when hatched, find sufficient nourishment. The grub ultimately falls a victim to its ravages; though they carefully avoid injuring the vital parts of the larva on which they prey. Scarcely an insect exists which in the larval stage is exempt from attacks from one or other species of this family, so numerous are they.

Cynipsidæ (Gall-flies). These insects deposit their ova in living trees, and by their presence give rise to the formation of excrescences, called *galls*, such as those on the leaves of the oak-tree. The larvæ feed on the interior of their habitations, where they remain for five or six months. Some undergo their metamorphoses within the galls, but others escape through small apertures to undergo that change. Galls are imported from the Levant, and are used in the manufacture of writing-ink and dye-stuffs.

Formicidæ (Ants), so celebrated for their industry, live in societies, often of great extent, consisting of three distinct kinds of individuals—males, females, and neuters. The males are winged during the whole of their existence, the females during only part of their mature state. At a certain period in summer, the males and females appear in large quantities, quit the nest, and copulate in the air, when the males speedily die. The females then lose their wings, fall to the ground, and are picked up and carried to the nest by the neuters, when they become the queens of future societies. The neuters form the great bulk of the community, and upon them depends the entire labour of the community. They are really females in which the sexual organs are undeveloped from the difference of food in the larval stage. They construct the nest, and attend upon and feed the young larvæ. Like the females, they possess a sting. The larvæ of ants, unlike those of bees, are never inclosed in cells. The food of most species of ants consists chiefly of aphides or plant-lice. Some species in India and in the south of Europe hoard grain and other seeds. The nests of ants consist of numerous chambers communicating by winding and tortuous passages, and they are sometimes excavated in the ground, at other times in the trunks

Neuter Ant (Worker).

of old trees. Some ants, as *Formica rufescens*, have the very peculiar instinct of capturing the pupæ of other ants and making slaves of them. Ants have another very strange habit—namely, that of *milking* the aphides or plant-lice. These aphides excrete a saccharine substance, or honey-dew, of which the ants are extremely fond. To obtain this, the ant pats the abdomen of the aphis with its antennæ, and when the drop has been obtained, it passes on to another aphis.

Vespidæ (Wasps) generally form large communities, composed of males, females, and neuters. A colony is commenced in spring by young females which have lain dormant during the winter, when they set about building a nest, in which they lay eggs, and attend to the larvæ. The first brood consists of workers, upon whom ultimately depends the work of the community. The nest is made of a paper-like pulp, made by masticating and moistening the wood or bark of a tree.

Of the *Apidæ*, or Bees, some are solitary, while others live in detached communities, under the apparent rule of an individual. Amongst *Social Bees*, such as the *Humble* and *Hive Bees*, only one in each hive is a true female, distinguished by her size, and called the *queen*. About six hundred are males, usually called *drones*, and the remainder, about fifteen thousand, are *neuters*, destined for labour. The queen, in the larval state, is furnished with a cell of royal dimensions, and is supplied with the most nutritious and delicate kind of food. In due time, she comes forth in all the dignity of majestic size and full colouring. The neuters are placed in six-sided cells, so proportioned as to limit their growth, and prevent their full development. They are fed on simple fare. The males exist only between April and August, when they are destroyed by the workers. The cells are six-sided, and are so constructed as to yield at the same time the least expenditure of material with the greatest strength ; the instinct of an insect thus coming to the very same result as the highest human intelligence. In some cells, honey is stored up, and in others the eggs are laid. The eggs from which perfect females or queens are to be produced are laid in cells much larger than the rest, and of different forms. The drones are killed at the end of summer, but the queen and the workers remain ; and when the hive is over-peopled, colonies are sent forth with young queens in search of another habitation.

The *Solitary Bees* present great variety of habit, some, such as the Carpenter Bees (*Xylocopa*), making their nests in old wood ; the Mason Bees (*Osmia*) construct their nests by gluing together grains of sand ; while the Cuckoo Bees (*Nomadæ*) build no nest at all, but deposit their eggs in the nest of other species.

ORDER 11. *Strepsiptera*—are parasitic in the interior of Bees and Wasps. The females have no wings, but the males have a pair—the posterior—of large membranous wings, folded longitudinally. Neither the jaws nor the anterior pair of wings are developed.

ORDER 12. The *Coleoptera* (*koleo*, a sheath, and *pteron*, a wing), or Beetles, have the anterior pair of wings horny or chitinous, and forming a protective covering (elytra) for the posterior pair. The mouth is masticatory, and possesses both mandibles and maxillæ. The metamorphosis is complete, and the pupa is inactive. They are the most numerous and best known of all the orders of insects.

The primary division of Beetles is founded upon the number of joints in the divisions of their feet or *tarsi*.

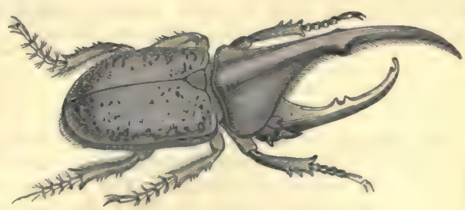
Section Trimera, or beetles which have only three joints in their tarsi. The Two-spotted Lady-bird (*Coccinella bi-punctata*), so called from having two spots on its elytra, is an example. Its larvæ feed upon aphides, so that these insects ought to be encouraged, and they are of great use to land-owners by devouring the aphides which swarm on hops.

Section Tetramera contains such beetles as have four joints in each foot. They all feed upon vegetable substances. It includes the Weevils (*Curculionidæ*), which have the anterior part of the head extended into a kind of muzzle. They are dangerous enemies to our vegetable stores. The *Xylophagi*, or Wood-eaters, are small in size, but exceedingly numerous, and do almost incredible mischief to mankind. The *Longicornes*, distinguished by the length of their antennæ, in their larval state bore deep tunnels into trees.

Section Heteromera, which have five articulations in the first four tarsi, and only four in the hindmost pair. They are terrestrial in their habits, live chiefly in dark places, and feed upon vegetable substances. The Churchyard Beetle (*Blaps mortisaga*), found in dark and dirty places about houses, is a well-known example. The larva of *Tenebrio molitor* is known as the Meal-worm. The *Trachelidæ* have the head supported on a pedicle or neck. Example—*Lytta vesicatoria* (Blister-fly) is very common in Spain, and hence the common name, Spanish-fly. The beetles are shaken from the trees, and collected in sheets spread upon the ground, and are killed by exposure to the fumes of vinegar.

Section Pentamera.—The majority of insects in this section have five joints in the tarsi. It includes several families—for example :

The vast family of the *Lamellicornes* have the antennæ club-shaped, composed of thin plates arranged like the leaves of a book, which they can open or shut at pleasure. They are entirely vegetable feeders, and vary much in form, colour, and size. The *Cetonia aurata* (Rose-beetle) may be taken as the type. It includes also the sacred Egyptian Beetle (*Ateuchus sacer*), which was consecrated to the sun, and therefore regarded as an emblem of fertility ; the Stag-beetle (*Lucanus cervus*) ; and the Cockchafer (*Melolantha vulgaris*). The *Dynastes Hercules*, a native of Brazil,



Dynastes Hercules.

sometimes attains a length of five inches. It has a horn projecting from the head, which is opposed by a corresponding protuberance from the thorax.

The family of *Palpicornes* have the antennæ long, club-shaped, and leaf-like. Their feet are suited for swimming. The genus *Hydrophilus* is common in Britain, being found in ponds and ditches.

The family *Clavicornes* have the antennæ thick, and terminated by a solid mass. In their habits, they are partly aquatic and partly terrestrial. The *Necrophorus*, or Burying-beetle, is a remarkable genus, so called from burying small quadrupeds, such as mice and moles. They deposit their eggs in the carcass, upon which the young feed during their larval stage.

The *Serricornes* have the antennæ serrated or saw-shaped, and the elytra completely covering the body. The Wire-worm, which devours the roots of corn, often to a disastrous extent, is the larva of *Elator obscurus.* The genus *Lampyris*, or Glow-worm, is remarkable for the light it emits at night. The females especially possess this property. The body is soft, and the light resides in the last two or three sections of the abdomen. The 'Death-watch' (*Anobium*) makes a ticking noise with its jaws while perforating wood; and as this is usual in a sick-chamber, and is consequently apt to be heard before one dies, the noise so made is held by the ignorant mind to be a warning of death, hence its common name.

Firefly (*Lampyris Italica*).

The *Brachelytra* are so called from having short crustaceous wing-coverings, and are represented by the single genus *Staphylinus*, which is frequently seen running about garden walks.

The *Dytiscidæ* are aquatic in their habits. Their feet are fringed with broad stiff hairs. They have to come to the surface of the water to breathe, as their respiratory organs are the same as other insects.

Carnivora.—These beetles have been placed by entomologists at the head of this order, on account of the structure and development of the organs which fit them for a mode of life pre-eminently carnivorous. The mandibles are armed with strong and powerful teeth. They are remarkable for the beauty of their colours, and hence the name of Tiger-beetles. They prey, even in their larval state, upon other insects. The Common Beetle (*Cicindela campestris*) is about half an inch in length, of a green colour, with whitish spots on the elytra, and may be seen running about in sandy fields, exposed to the hottest sunshine.

V. SUB-KINGDOM MOLLUSCA.

The *Mollusca* (Lat. *mollis*, soft) are soft-bodied animals, exhibiting bilateral symmetry, usually protected by an outer skeleton. The alimentary canal is completely shut off from the general body-cavity. A nervous system is always present, and consists of a single ganglion, or of scattered pairs of ganglia.

The *Mollusca* may be divided into two chief divisions:

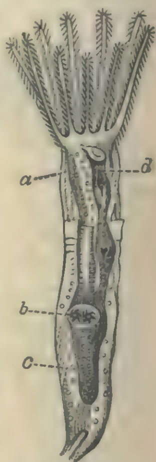
I. *Molluscoida*, in which the nervous system consists of a single ganglion, or of a principal pair with accessory ganglia. Heart very imperfect, consisting of a simple open tube, or entirely absent.

II. *Mollusca* (Proper), in which the nervous system consists of three principal pairs of ganglia. Heart always well developed, and consisting of at least two chambers.

I. The *Molluscoida* include the following three classes:

CLASS I.—POLYZOA.

The *Polyzoa* or *Bryozoa.*—'Animals always forming composite colonies, each zoöid of which consists of an alimentary canal suspended in a double-walled sac, from which it can be partly protruded by a process of evagination, and into which it may again be retracted by invagination. The mouth is surrounded by a circle of hollow ciliated tentacles.' *Plumatella repens*, a fresh-water species, may be taken as the type. It is a composite animal; each individual consists of a sac with a double wall. Within this is suspended the alimentary canal. The hollow ciliated tentacles surrounding the mouth are concerned partly in respiration, and partly in creating currents in the water, and so bringing food to the animal. The intestine can be protruded from, or retracted within the sac by means of muscles. The intestine is curved, so that the anus opens near the mouth. No heart or blood-vessels are present. The fluid within the perivisceral cavity, which is supposed to represent the blood, is clear and colourless, and is kept in continual motion by the cilia lining the inner surface of the body-wall. The nervous system consists of a single ganglion, placed between the gullet and the anus. They (*Bryozoa*) are all hermaphrodite, and reproduction takes place by budding and by eggs.



Bowerbankia: *a*, œsophagus; *b*, gizzard; *c*, stomach; *d*, orifice of intestine.

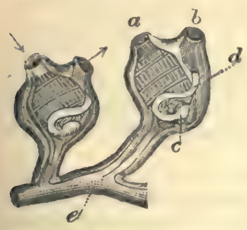
The Sea-mat (*Flustra*), so common on our shores, is a well-known example. It is flat and leaf-like in its form, and on the whole it presents an appearance like brown sea-weed, for which it is often mistaken. But, on examining its surface carefully, it is seen to be studded over with little openings, through which the little animals can protrude their tentacles.

CLASS II.—TUNICATA OR ASCIDOIDA.

The *Tunicata* are defined as having the 'alimentary canal suspended in a double-walled sac, but not capable of protrusion and retraction. Mouth opening into the base of a respiratory sac, whose walls are more or less completely lined by a network of blood-vessels.'

They are all marine. Take one of the solitary forms, *Ascidia*, as the type. It is globular in form, and consists of a double-walled sac, the outer layer of which contains cellulose, and is of a tough leathery consistence. It is perforated by two apertures placed close to each other, one the oral, the other the anal opening, so that the whole

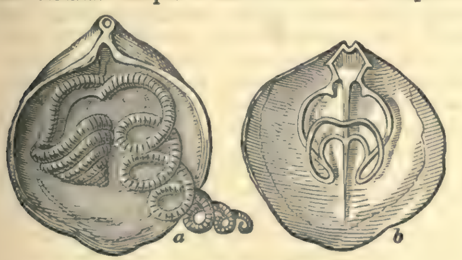
animal resembles a double-necked bottle, hence the name of Ascidian (*ascus*, a bag). The inner bag is perforated like the outer. The mouth leads into the large *respiratory* or *pharyngeal sac*, which is continued at its lower end into the œsophagus. This respiratory sac is perforated by a number of apertures, and is richly supplied with blood-vessels, for it is here that the blood is aerated. The intestine is twisted on itself, and does not open on the surface directly, but through the medium of a cloacal chamber. The circulatory apparatus differs remarkably from that of all other animals. It consists of a simple open tube without valves, which pulsates rhythmically. The blood is driven first through one end, and then through the other, so that the course of the blood is periodically reversed. The nervous system consists of a single ganglion placed on one side of the mouth. The Ascidians are all hermaphrodite. Some forms are composite, as *Botryllus*, which is also fixed. Others, such as *Salpa*, are free, and float on the surface of the sea, their tunic being so delicate and transparent that they would scarcely be observed if it were not for their iridescent appearance. The *Tunicata* have attracted a considerable amount of attention lately, from the fact that, while in their embryo state, their nervous system presents appearances somewhat resembling those found in the little fish the Lancelet or *Amphioxus*, the lowest of vertebrated animals.



Section of Social Ascidian: *a*, mouth; *b*, vent; *c*, stomach; *d*, intestinal canal; *e*, common tubular stem.

CLASS III.—BRACHIOPODA.

The *Brachiopoda* (arm-footed), are so called because of their possessing two long ciliated arms, supposed to be for creating currents, thus bringing food to the mouth, which is placed at the bases of the arms. The animal is inclosed in a bivalve shell, lined by a mantle. The two valves of the shell are united by a hinge, and kept in position by means of muscles. The valves are generally of unequal size, the larger one being in some cases provided with a beak, which is perforated by an aperture, and hence the common name of *Lamp-shells*, from their supposed resemblance to the old Roman lamps. The valves with respect to the body are placed ventrally and dorsally. The *Brachiopoda* are all marine, and all the known living forms are fixed. The shell is lined by, and is a secretion from the mantle, a strong muscular tunic which invests the soft parts of the animal. The long arms are in some genera supported by a calcareous framework called a *carriage-spring apparatus*. The arms probably perform the function of respiration, and the nervous system consists of a single ganglion, placed between the mouth and the anus. It includes the genera *Lingula*, *Terebratula*, *Crania*, &c. The *Brachiopoda* were very abundant in some rocks, particularly in the Silurian formations, where they appear to have attained their maximum of development. The genus *Lingula* is found in the lowest fossiliferous rocks, and what is very remarkable, this genus still exists at the present day.

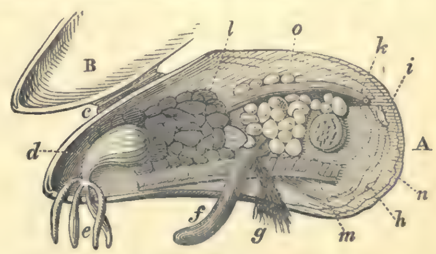


Terebratula:
a, valve with the spiral arms; *b*, valve with arms removed.

II. The *Mollusca* proper, which include the following four classes:

CLASS IV.—LAMELLIBRANCHIATA.

The *Lamellibranchiata* (plate-shaped gills)—including the so-called 'Shell-fish,' as Oysters, Mussels, Cockles, &c. They have no head, are inclosed in a bivalve shell, and have two lamelliform or plate-like gills on each side of the body, and neatly arranged within the margin of the shell. The body is inclosed in a mantle, from which the shell is secreted. The mantle is more or less completely attached to the shell. This is indicated in the interior of the shell by a line called the *pallial line*. In some bivalves, the edges of the mantle are united, so that a closed respiratory chamber is the result, to which water is admitted by means of a 'siphon,' which is just the mantle lobes united and perforated by two tubes, through one of which the water enters, and is expelled through the other. This siphon can in most cases be retracted within the shell. In the shell of those bivalves which do not possess a siphon, the pallial line is simple, and is not indented; but in those which have a siphon, the pallial line forms a deflection inwards, like a little bay, to which the muscles that retract the siphon are attached. The valves of the shell, unlike those in the *Brachiopoda*, are equal and alike, and, with respect to the body of the animal, are placed laterally, that is, right and left. Further, the valves are closed by muscles called *adductors*, but are opened by an elastic ligament, and a cushion of cartilage, which is placed between the beaks of the valves, so that, when the creature approximates the valves, the elastic ligaments, being placed behind the beaks of the valves, are put on the strain, while the cartilage is compressed, so



Interior of Mussel:
A, right valve; B, left valve; *c*, hinge; *d*, stomach; *e*, tentacula; *f*, foot; *g*, byssus; *h*, branchial orifice; *i*, vent; *k*, termination of intestine; *l*, liver; *m*, gills; *n*, adductor muscle; *o*, ovarium.

that, when the animal wants to separate the valves, it has only to relax the muscles, and the shells fly apart, in virtue of the elasticity of the elastic ligaments and the cartilage. In the Brachiopoda, the valves are both closed and opened by means of muscular action. The heart is always well developed, and consists of at least two chambers, and the blood is aerated in the plate-like ciliated gills. The nervous system consists of three well-defined ganglia. In many of the *Lamellibranchiata*, there is present a muscular organ called the *foot*, which is used in progression. This class comprises two sections, namely:

Section (A). *Asiphonida*—in which no respiratory siphon is present, the pallial line is not indented, and the lobes of the mantle are free, and not united. This section includes the Oyster family (*Ostreadæ*), represented by the *Ostrea edulis*, the Common Edible Oyster, which is deficient in a foot, and is fixed to the sea-bottom by the shell alone. It has its headquarters in Britain, and is considered full-grown for the market in from four to seven years. The Common Pecten, the type of another family, is so called from the resemblance of its shell to a comb, has a well-developed foot, and a number of brightly coloured spots placed along the edge of the mantle, which are supposed to represent eyes.

The *Mytilidæ*, represented by the Common Mussel (*Mytilus edulis*), so abundant on our shores, has a quantity of hair-like filaments (*byssus*) developed in connection with the foot, by which it attaches itself to solid objects. Of the family *Unionidæ*, the *Unio*, or Fresh-water Mussel, is noted for producing small pearls. They all inhabit fresh water, and the shell is covered by a very thick epidermis. The *Unio pictorum* is so called from its shell having been used by painters to hold colours.

Section (B). The *Siphonida*—possess a siphon, and the mantle lobes are more or less united. In some, the siphons are short, and the pallial line simple, as in the Cockle family (*Cardiadæ*), in which the foot is well developed, and fitted for burrowing in the sand of the sea-shore. The Common Cockle (*Cardini edule*), which is eaten in some localities, can spring to a considerable height by means of its bent foot. In others, the siphons are long, and the pallial line is indented, as in the Myas, which burrow and form a habitat for themselves. The Solen, or Razor-shell, sinks in the sand with great rapidity. The Pholas has a shell composed of arragonite, and can perforate timber and solid rocks, thus producing great destruction by attacking ships and wooden piles in water. Another celebrated species is the *Teredo navalis*, or ship-worm, a worm-like animal, furnished with two small shells at its anterior extremity, often attaining the length of one or two feet, and doing immense damage by boring into timber.

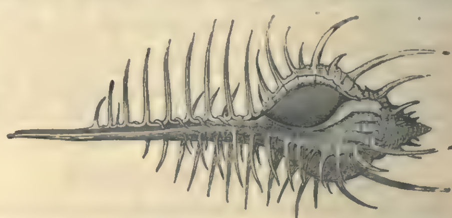
CLASS V.—GASTEROPODA.

Animals with the head well developed, and never inclosed in a bivalve shell. Locomotion effected by a horizontally flattened ventral disc ('foot'), or by a vertically flattened ventral fin-like organ. This class includes the *univalved* shells, such as the Snail and Whelk. In the mouth, there is a peculiar strap-shaped masticatory apparatus called an *odontophore*. The mantle is continuous round the body. The heart consists of an auricle and a ventricle. In one group, respiration is effected by an apparatus for breathing the air in water (*Branchifera*); in the other, the respiration is aerial (*Pulmonifera*). The sexes are mostly distinct. The young *always* possess an embryonic shell. The shell is composed either of a single piece (*univalve*), or of many pieces (*multivalve*). This class comprises:

Section (A). *Branchifera*—in which the respiration is aquatic. This section includes three orders, characterised according to the position of the branchiæ.

ORDER I. The *Prosobranchiata* have the mantle so arranged as to form a vaulted chamber over the back of the head, in which the respiratory organs, or branchiæ, are usually lodged. These gills are situated in front of (*proson*) the heart. This order is divided into two sections:

1. The *Siphonostomata*, in which the aperture of the shell is notched or produced into a canal. They are all marine, and carnivorous in their habits—for example, the Whelk family (*Buccinidæ*), represented by the Common Whelk (*Buccinum undatum*), in which the shell is of a spiral form. The *Volutidæ* contain many beautifully marked shells, and are chiefly confined to warm latitudes. The Cowry family (*Cypræidæ*), so remarkable for their beauty, are largely used as mantel-piece ornaments. In certain parts of Africa, the shell of *Cypræa moneta*, or Money Cowry, is used by the natives as money. The *Muricidæ* (*murex*, purple)

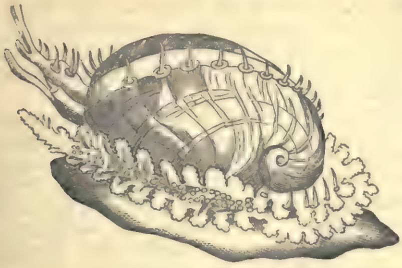


Murex tenuispina.

have a univalve spiral shell, with a small oval aperture ending in a straight ascending canal. The *Strombidæ*, or Wing-shells, have the aperture of the shell much dilated, and the lips expanding and extended into a groove leaning to the left.

2. The *Holostomata* have the aperture of the shell entire. They are chiefly plant-eaters, and are either marine or inhabitants of fresh water. It includes a great many families—for example, the *Patellidæ*, or Limpet family. In the Common Limpet (*Patella vulgaris*), locomotion is at a low ebb, for they seldom move far from the place where they are produced. The *Haliotidæ* (Ear-shells) are used in making those mother-of-pearl ornaments which constitute so much of the beauty of works in papier-mâché. The Marine Snail family (*Turbinidæ*) have the shell of a regular turbinated form. They are found in great abundance in the Indian seas, and are used as food, many being of large size. The Common Periwinkle (*Littorina littorea*) is nearly allied to this family. In the *Dentalidæ*, the shell is tubular, slightly curved, open at both ends, and shaped like an elephant's tusk, hence their name of Tooth-shells. The Chiton family (*Chitonidæ*) have multivalve shells, the mantle being covered by

eight testaceous symmetrical plates placed transversely. These animals live on rocks and stones



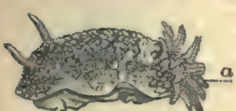
Haliotis tuberculata.

on the sea-coast, and are distributed nearly over the whole globe.

ORDER 2. In the *Ophisthobranchiata* (Gr. *ophisthen*, behind, and *bragchi*, a gill), the shell is rudimentary, and the branchiæ are more or less completely exposed on the back and sides towards the posterior extremity of the body. They are commonly called 'Sea-slugs,' and are divided into two sections:

Section (*a*). *Tectibranchiata* comprehends those species in which the gills are protected by the shell or mantle. They are all marine, living chiefly on the shore or on floating sea-weed. In the family of the *Bullidæ* (Bubble-shells), the shell is large and convolute, and in some cases is large enough to receive the greater part of the animal. The *Aplysiadæ* are slug-like in form, and have the mantle very large, and reflected upwards, so as to cover in the gills. They possess a merely rudimentary shell, and owing to their tentacles being turned backwards, like ears, they are popularly known as 'Sea-hares.'

Section (*b*). *Nudibranchiata*, in which the shell is absent, and the branchiæ are exposed on some part of the back in the form of a rosette. It includes all the naked marine Gasteropods, as *Doris* (Sea-lemon), *Triton*, and *Tethys*. They are elegant and beautiful little creatures, like slugs, and are generally ornamented with beautiful colours. They are found creeping on sea-weeds or attached to stones at low-water.



Doris: *a*, gills.

ORDER 3. The *Heteropoda* have the foot compressed into a thin vertically flattened ventral fin, by means of which locomotion is effected. They are free-swimming and pelagic. This order comprises two families, *Firolidæ* and *Atlantidæ*. In the *Firolidæ*, the shell is absent, or exists in a rudimentary form, and protects the circulatory and respiratory organs, including the genera *Carinaria* and *Firola*. In the *Atlantidæ*, such as Atlanta and Bellerophon, the shell is large, and capable of containing the whole animal.

Section (B). The *Pulmonifera* are characterised by having their respiratory organs so arranged as to breathe air directly. The mantle is inflected so as to form a pulmonary chamber, into which air is admitted from without, and where it comes in contact with the plenus of vessels with which the wall of the chamber is supplied. They are hermaphrodite. Most of them are land animals: although a few are aquatic, living chiefly in fresh waters and brackish pools, they are forced to come to the surface to breathe. This section includes two orders.

ORDER 4. *Inoperculata.*—The animals in this order are not provided with an operculum for closing the shell. The family of the *Helicidæ* (Land-snails) are among the most familiarly known of all animals. The shell is large, and capable of containing the entire animal. They feed exclusively on vegetables, and the destructiveness of the Garden-snail (*Helix hortensis*) is well known. In tropical climates, the genus *Bulimus* sometimes attains to a great size. The tropical *Achatina* is distinguished by the beautiful colours of its shell. The family of the *Limacidæ* (Slugs) are naked snails, and are very destructive to vegetables. The head bears

Mature Snail.

four tentacula, and at the end of the longer pair the eyes are situated. These tentacula (usually called the 'horns') can be drawn in by a process resembling the inversion of the finger of a glove. The family of the *Lymnæidæ* (Pool-snails) reside in stagnant waters, feeding upon plants and seeds. The shell is thin, well developed, with the aperture simple, and the lip sharp. The *Lymnæa* is connected with the development of the immature cercaria into distoma. In the genus *Planorbis* (Marsh-snails), the coils of the shell are all upon the same plane.

ORDER 5.—In the *Operculata*, the shell is provided with an *operculum*, which is a horny or calcareous disc attached to the foot, and is drawn into the mouth of the shell by the contraction of the animal. It includes the genus *Cyclostoma*, a snail-like animal provided with a thin spiral shell, with the margins usually reflexed all round.

CLASS VI.—PTEROPODA.

The *Pteropoda* (wing-footed) are free-swimming oceanic forms, provided with two wing-like appendages on each side of the anterior extremity of the body. They are small animals, and exist in all seas, but are found in enormous multitudes in the Arctic and Antarctic Oceans. One of them, the *Clio Borealis*, forms the chief food of the whale, which swallows thousands at a mouthful. They are eminently carnivorous, feeding upon minute crustaceans and other small animals.

Example of the Pteropoda (*Cleodora pyramidata*).

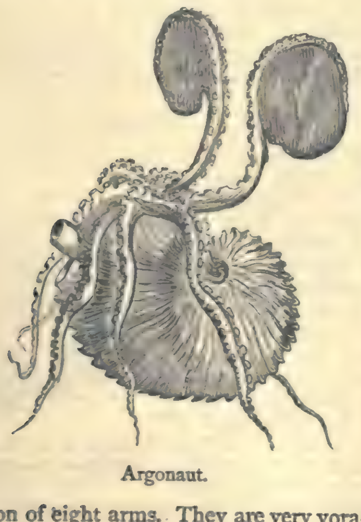
CLASS VII.—CEPHALOPODA.

The *Cephalopoda* are so named from having their limbs arranged in immediate connection with their head. These limbs are eight or ten in number, and perform all the functions of feet, arms, and feelers. The body is inclosed within a muscular mantle-sac. Through the anterior tubular orifice ('funnel'), the effete matter of respiration is expelled. They are the most highly organised of invertebrate animals, presenting rudiments of an internal skeleton. The eyes are well developed, and, in most of the existing species, organs of hearing are present. The head is large and conspicuous. They possess distinct hearts for the systemic and pulmonary circulations, and highly complicated nervous, digestive, secretory, and respiratory organs, which are in the form of two or four plume-like gills, situated within the mantle. They are all marine and carnivorous.

ORDER 1.—The *Dibranchiata* are specially suited for swimming rapidly through the water. These animals have two gills and three distinct hearts; an ink-sac for secreting and emitting an inky fluid; and the arms never above ten in number, and supporting suckers. The funnel is a complete tube, and the shell is internal, or, if external, it is not chambered. The Cuttle-fish are the most typical members of this order. They swim backwards by means of the jet of water expelled through the funnel, and by means of their arms and suckers they creep on the bottom of the sea, and retain a forcible hold of their prey. This order is divided into two sections, characterised by the number of their arms.

Cuttle-fish.

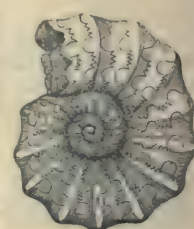
Section 1. *Octopodidæa* are distinguished by the possession of eight arms. They are very voracious animals, and to this family belongs the Poulpe (*Octopus*) of the Mediterranean, whose shell is placed internally. It is eaten as a regular article of diet in the south of Europe. In the Paper Nautilus (*Argonauta*), the female alone is protected by a very delicate and beautiful external non-chambered shell. The male argonaut is only about one inch in length.



Argonaut.

Section 2. The *Decapoda* have ten arms, two of which are longer than the others (tentacles), of a rounded form, and club-shaped at the extremity. The suckers are placed on stalks, and the body has a fin-like organ on each side; further, the shell is always internal. It includes the *Calamaria*, or Squids—for example, *Loligo*, the shell of which is horny, and is called the 'cuttle-fish pen.' The common British species (*L. vulgaris*) is used as bait by the fishermen, and is often cast upon the shores in great quantity after high winds. In *Sepia*, the shell is calcareous, and is called 'cuttle-bone,' and was formerly used in medicine. This section also includes the extinct *Belemnites*, or Jove's Thunderbolt.

ORDER 2. The *Tetrabranchiata*—have four gills, and are protected by an external chambered shell with simple partitions or septa, perforated by a tube or *siphuncle*. The last chamber of the shell is the largest, and contains the body of the animal. There is no ink-sac. The arms are numerous, and devoid of suckers. It consists of only one living family, the *Nautilidæ*, of which the Pearly Nautilus (*Nautilus pompilius*), which inhabits the tropical seas, is the type. The shell of *N. pompilius* is partitioned off by septa into chambers which gradually increase in size towards the mouth of the shell, where the largest chamber is left for the habitation of the animal, while the other chambers are filled with air. The septa are perforated in the centre by apertures, through which there passes a *vincula siphuncle*, communicating with the chamber where the heart is placed. This order was abundantly represented in past time by such genera as *Ammonites*, *Orthoceras*, and *Ceratites*, which are now entirely extinct.



Ceratites nodosus.

In the *Dibranchiata*, the mode of reproduction is peculiar. The sexes are distinct. One of the arms of the male enlarges, becomes cystic, and spermatozoa are developed in its interior. Thus changed, it is said to be *hectocotylised*. It is then detached, and swims about, ultimately bursting, and depositing the spermatic fluid within the pallial chamber of the female.

VI. SUB-KINGDOM VERTEBRATA.

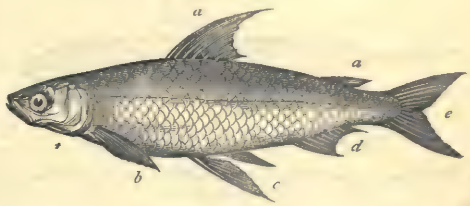
The last and highest division of the Animal Kingdom is composed of animals which have their segments arranged along a longitudinal axis, and exhibit bilateral symmetry. The fundamental character of vertebrates is the possession of an *internal* central axial structure called the *spine* or *vertebral column;* hence the name of the sub-kingdom. This structure may be bony or cartilaginous, or both, and it shuts off the nervous

system from the general body cavity. In a typical vertebrate, such as man, it consists of a series of bones or *vertebræ*, which are articulated together in such a manner as to permit of a greater or less degree of flexibility, and giving attachment to appendages, of which some support and protect important viscera, while others assist in the motion of the animal. Each vertebra has more or less the form of a ring, and when the various vertebræ are articulated together, the whole is termed the *vertebral column*, or backbone. The ring-like apertures in each vertebræ, when thus joined together, form a tube, in which the *spinal cord* is lodged, and from which the nerves which supply the body are given off. The vertebral column is placed dorsally, and serves not only as a surface of attachment for muscles, and a central axis, but also as a protection for the main masses of the nervous system, which are thus also placed dorsally, and are separated by a partition from the general body cavity. The anterior extremity of the spinal column is expanded in a box or case, the *skull* (technically called the *cranium*), in which the *brain* is lodged. The brain is continuous with the spinal cord through an opening in the base of the skull, called the *foramen magnum*. The theory that the skull is composed of a series of vertebræ, whose arches are expanded, and unite to inclose and protect the brain, originated with Goethe, in 1791, on his picking up an old and broken sheep's skull amidst the sandy dunes of the Jewish cemetery in Venice. Lorenz Oken came independently to the same conclusion, and in 1807 published his vertebral theory of the skull. According to Professor Owen, the skull is a continuation of the back-bone, and consists of four vertebræ or segments, corresponding to the four consecutive enlargements of the nervous system which we call the brain. These segments, reckoning them from behind forwards, are termed the occipital, the parietal, the frontal, and the nasal segment. In the embryo of all vertebrates, a structure called the *notochord* (*notos*, back, and *chorde*, string), or *chorda dorsalis*, is invariably present. It generally disappears in the adult, but it is persistent in some fishes. It is a cellular, rod-like structure, situated immediately under the spinal cord, and out of which the vertebral column and some other structures are developed. The general bony fabric of which the vertebral column is the main or central part, is *internal*, an arrangement contrary to that in the lower provinces of creation, where the hard and sustaining parts are *external*. The limbs never exceed four in number, and are turned ventrally, serving for progression, and occasionally for prehension or seizing, but subject to many variations, according to the element in which the animal lives, and the nature of its necessities. By reason of their superior nervous system, vertebrated animals stand decidedly above other provinces in intelligence. With the single exception of the Lancelet, all the vertebrata have red blood, which is due to presence in the blood of an innumerable multitude of minute red, round or oval bodies, called *blood-corpuscles*, about $\frac{1}{3500}$ of an inch in diameter, the fluid in which they float being itself colourless.

This sub-kingdom is divided into the five great classes—Fishes (*Pisces*), Amphibians (*Amphibia*), Reptiles (*Reptilia*), Birds (*Aves*), and Mammals (*Mammalia*). By Professor Huxley, the fishes and amphibia are grouped together under one section, and called *Ichthyopsida*, because at some period or other they breathe by gills. The reptiles and birds he puts into another section, under the name *Sauropsida*, characterised by their never possessing gills, by the skull being articulated to the vertebral column by a single occipital condyle, by the articulation of the lower jaw to the skull through the intervention of a distinct bone (the *os quadratum*), and by the ramus of the lower jaw being composed of several pieces. He retains the name *Mammalia* for the mammals, for the characters of which see Mammalia.

CLASS I.—FISHES.

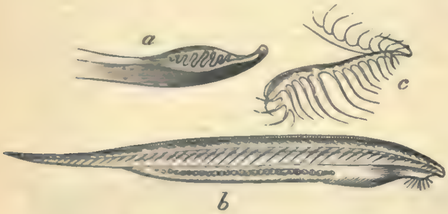
In this class, the animals are wholly aquatic, and breathe by means of gills or *branchiæ*. The heart consists of a single auricle and ventricle. The auricle receives the blood from the system, and propels it into the ventricle, by which it is sent on to the gills, where it is aerated by being exposed to the air contained in the water, and is then distributed throughout the body. The blood is cold—that is, it never rises in temperature above the temperature of the surrounding medium. The four limbs of a typical vertebrate assume in fishes the form of *fins*, and are generally, although not always, all present, the first pair being the *pectoral*, the second pair the *ventral* fins. When the ventrals are placed far forwards, underneath or in front of the pectorals, they are called *jugular* fins. There are other fins, however, which are not placed in pairs, towards the sides, but vertically in the middle line; one or more (*dorsal*) on the back; one or more (*anal*) on the ventral aspect, behind the anus; and one (*caudal*) at the extremity of the tail. These last are called the *unpaired fins*, in contradistinction to the former or *paired fins*. The chief propelling power resides in the *vertically* flattened caudal fin or tail, which is used by the fish in the same way as a single oar is employed in sculling along a boat. The pectoral and ventral fins serve chiefly for balancing the body, while the dorsals and anals, like the keel of a ship, keep it in its proper position. The surface of the body is usually covered with scales. In many species, the gills are covered by a corneous plate, styled the operculum. In those fishes which have a well-formed vertebral column, the individual vertebræ are hollowed on each side, with a bag of lubricating fluid between them, an arrangement which gives great suppleness and agility of movement. They are nearly all oviparous, and some are amazingly productive. The



Fish:
a, dorsal fins; *b*, pectoral fin of one side; *c*, ventral fins; *d*, anal fin; *e*, caudal fin, or tail; *f*, operculum.

female deposits her eggs or spawn, leaving to the male the duty of afterwards fertilising them. The teeth of fishes are chiefly designed to serve as means of seizing prey. They are not only placed on the jaws, but also on the tongue, palate, and other parts of the passage leading to the stomach. The lungs of other vertebrates are represented in fishes by the *swimming-bladder*, which is of service in floating the animal.

ORDER I. The *Pharyngobranchii*—includes only a single genus, the *Amphioxus lanceolatus*, or Lancelet, which differs remarkably from other fishes. It has neither skull nor brain; the lower jaw and limbs are absent. The spinal column exists in its embryonal form. The heart is represented by pulsatile swellings upon the great vessels. The mouth is in the form of a longitudinal fissure, surrounded by filaments, and leads into a pharynx perforated by clefts, which are ciliated, and perform the function of respiration. This singular little fish, which measures about one



Lancelet (*Amphioxus lanceolatus*):

a, mouth, seen from below; *b*, general figure; *c*, hyoid bone, with filaments attached.

inch in length, is found burrowing in the sand on the shores of the Mediterranean. The body is lanceolate; and running along the dorsal surface in the median line is an imperfect crust or fin, which expands at the tail into a lancet-shaped caudal fin.

ORDER 2. The *Marsipobranchii*—have the body cylindrical in form, and destitute of limbs. The skull and spinal column are cartilaginous, and the lower jaw is absent. The mouth is round, and supported by a cartilaginous ring, and adapted for adhering to prey. The skin is soft, with scarcely a vestige of scales. The gills are sac-like, communicating internally with the pharynx, and externally by one or more openings situated on the side of the body near the head. It comprises the Lampreys (*Petromyzon*), characterised by having roundish gill orifices on each side of the neck, and by the possession of a tooth within the cartilaginous ring, with which they tear their

Common Lamprey (*Petromyzon marinus*).

prey. There is a marine species two or three feet long, and other smaller ones which inhabit rivers. The *Myxine* (Hag-fish) is blind, and is found parasitic in the interior of other fish, usually the cod, into which it penetrates by means of its singular curved tooth. In this genus, the nasal sac opens posteriorly into the pharynx.

ORDER 3. The *Teleostei*, or 'osseous' fishes have a well-ossified skeleton, and the skull is composed of numerous bones. A lower jaw is present. The gills, which are supported upon bony arches, are tufted and comb-like in shape, and lodged in two branchial chambers, each of which communicates internally with the pharynx, and from which the water passes away by a single aperture (gill-slit), which is covered with a bony operculum. The *bulbus arteriosus*, which is situated immediately in front of the ventricle, is not contractile, and there is never more than a single row of valves separating it from the ventricle. The fins, when present, are supported by rays. The nasal sacs do not communicate posteriorly with the pharynx.

Sub-order (A). The *Malacopteri*—have *soft* or many jointed fins—that is, fins which are supported by bones, which split up longitudinally as they diverge from a common point of insertion. Further, these bones are divided transversely into shorter pieces. A swimming-bladder is always present, and communicates with the gullet. This sub-order is divided into two groups: I. *Apoda*, from which the ventral fins are absent, comprising the well-known *Murænidæ*, or Eel tribe. They are all lengthened in form, have the spine very flexible, the skin soft and thick, and the scales almost invisible. Many of them inhabit rivers, while others are marine, as the Conger, which is from four to six feet long, and destitute of both pectoral and ventral fins. The Common Eel (*Anguilla*) can live for some time out of the water. This is due to the smallness of the gill apertures, which keep the breathing organ moist.

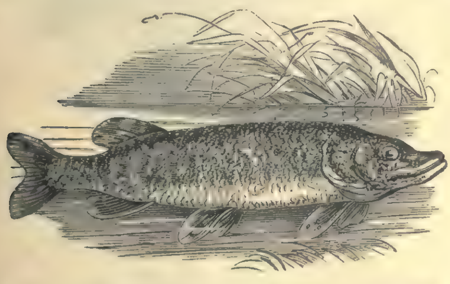
Electrical Eel (*Gymnotus electricus*).

The most remarkable form is the *Gymnotus*, or Electrical Eel. It is a native of the South American rivers. It attains the length of five feet, and can communicate a shock powerful enough to stun men and horses. The electrical apparatus is largely supplied with nerves, and extends throughout the greater part of its body. By giving these shocks, the animal is greatly exhausted, and requires rest and nourishment before it can renew them. In this genus, the anus is placed in front of the gill openings. The second group—namely, the *Abdominalia*—have

the ventral fins attached to the abdomen behind the pectorals. It includes the greater number of the fresh-water fishes. There are five families.

The *Cyprinidæ* (Carp tribe) are all fresh-water fishes. The mouth is shallow, the jaws feeble, and the pharynx strongly toothed. They feed chiefly on seeds and decomposing vegetable matter. One of the finest European species is the Carp (*Cyprinus carpio*), which is imported into England, and thrives well in ponds and lakes. The Barbel and the Cobitis or Loche are allied species well known to anglers. The Gold-fish of China (*C. auratus*), now naturalised in this country, also belong to this family. The *Anableps*, from the rivers of Guiana, has the cornea and iris divided by transverse bands, so as to give the fish the appearance of having four eyes.

The *Esocidæ* (Pike tribe), the most voracious of the fresh-water fishes, are characterised by the absence of fatty matter in the dorsal fin, and by the position of this opposite to the anal fin. The Pike (*Esox lucius*) sometimes weighs forty pounds, and is very destructive to the smaller fishes in the ponds and rivers which it inhabits. The Gar-fish, or Sea-pike, which frequents the British

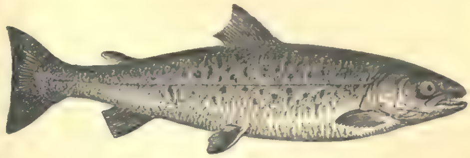


Pike, or Jack (*Esox lucius*).

shores, sometimes attains the length of eight feet. The Mackerel-pike, or Saury, a British species, is gregarious in its habits, and is preyed upon by porpoises and tunnies.

The *Siluridæ* (Sheat-fishes) have no true scales, the skin being either naked or covered with bony plates. They inhabit the rivers of warm climates. The genus *Silurus* have a strong spine in front of the dorsal fin, which can be laid flat or raised perpendicularly, so as to form a formidable weapon. The *Malapterurus electricus* of the Nile and rivers of Central Africa, which attains the length of twelve inches, has electric properties similar to those of the torpedo and gymnotus.

The *Salmonidæ* (Salmons and Trouts) are very extensively, indeed almost universally, diffused over the globe ; some of them being confined to fresh water, and others passing a part of their lives in the sea, but resorting to rivers to deposit their eggs. They are distinguished by the fatty deposition in the dorsal fin. All of this family are clouded with dusky patches when young, and many remain permanently spotted. The flesh of most of them is esteemed as food. The Salmon inhabits the seas of comparatively cold regions, ascending the rivers for the purpose of spawning, at seasons varying with the climate. They swim against powerful streams, and leap up cascades of considerable elevation, and find their way to the brooks and small lakes of lofty mountains. After this operation is accomplished, they return to the sea, followed by the young fish. The best known British species are the Common Salmon (*S. salar*),



Salmon (*Salmo salar*).

the Salmon Trout (*S. trutta*), and the Gray or Bull Trout (*S. eriox*). The Trout appears to vary much in size and colour according to the climate and other conditions of its residence, so that it is difficult to distinguish species from mere varieties. The Common Trout (*Salmo fario*), whose growth is wonderfully rapid, is too well known to require description. The Smelt (*Osmerus*) and Grayling (*Thymallus*) of British rivers, and the Capelin, which is used on the shores of Newfoundland for bait, also belong to this family.

The *Clupeidæ* (Herring tribe) is one of the most important families in the whole class, for the amount of food it supplies to man. The fishes belonging to it resemble the Salmonidæ in many characters, but differ in having no fatty matter in the dorsal fin. They chiefly inhabit the seas of the temperate zone. The Herring (*Clupea harengus*) usually lives in open ocean, but periodically visits the nearest coast in immense shoals to deposit its spawn. There are many species, differing but little from the herring. Thus, the Pilchard is caught on the Cornwall coast, the Sardine on the west coast of France and in the Mediterranean, where the Anchovy, well known for its rich and peculiar flavour, also abounds. The Sprat, Whitebait, and Shad belong to the same family.

Sub-order (B). The *Anacanthini*—have the fins entirely 'soft.' The ventral fins, if present, are brought forward beneath, or even in advance of the pectorals. If the swim-bladder is present, it never communicates with the gullet by a duct. Two groups are included under this sub-order :

1st Group, the *Apoda*, which are destitute of ventral fins. The Sand-eels (*Ammodytes*) belong to this group. They bury themselves in the sand during the ebb of the tide, and are used as bait by the fishermen.

In the *2d Group*, the *Sub-branchiata*, the ventral fins are present. It comprises two families—

Family *Gadidæ* (the Cod tribe) are easily known by the softness of all their fins, and by having the ventrals inserted under the throat, and pointed. To this family belong the Haddock, Whiting, Ling, Pollack, and the Cod itself. Besides being used as food, the oil obtained from their livers is very serviceable in the arts and in medicine.

The second family is that of *Pleuronectidæ* (the Flat-fish or Flounder tribe). The body is compressed from side to side, and margined almost throughout by long dorsal and anal fins. The two flat surfaces—one of which, in the ordinary position of the fish during life, is above, and the other below—are in reality the two *sides* of the fish, differing in several important respects. The bones of the head are singularly twisted, so that both the eyes are placed on one side of the

body, and this, which is always the upper, is dark in its colour, whilst the opposite side is always white. The two sides of the mouth are not equal, and the pectoral fins rarely so. On the other hand, the dorsal fin, which runs along one of the lateral edges, corresponds with the anal, which occupies the other, and with which the ventrals are sometimes united. They frequent the bottom of the sea, and swim along by an undulating motion of the whole body, while the colour of their upper surface usually corresponds closely with that of the ground on which they lie, and thus they escape the observation of their enemies, and are unnoticed by the small fishes on which they prey. The Flounder, Turbot, Brill, Plaice, Halibut, and Sole are the chief species on our

Sole (*Solea vulgaris*).

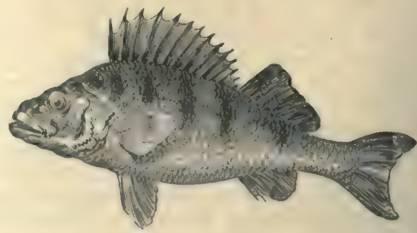
own coasts; they are agreeable and wholesome as food.

Sub-order (C). The *Acanthopteri* (Spiny-finned Fishes)—in which one or more of the first rays in the fins are supported by a 'spiny,' or injointed bony ray. There is no duct to the swim-bladder. The ventral fins are situated on the breast or throat in the neighbourhood of the pectorals. The scales are generally ctenoid or comb-like. This sub-order includes a great number of families:

The *Labridæ* (Wrasse or Rock-fish tribe) are known by the thickness and fleshiness of their lips, whence their name. Those of the genus *Labrus* are called 'old wives;' and this family contains a large number of species, which are principally inhabitants of tropical seas, and they are of but slight direct importance to man. Some of the tropical forms are remarkable for the beauty of their colours.

The *Fistularidæ* (Pipe-mouthed Fishes) are recognised by their very prolonged muzzle. They are chiefly found in warm latitudes, but Sea-snipe (*Centriscus scolopax*) is occasionally found on the Cornish coast as a straggler from the Mediterranean.

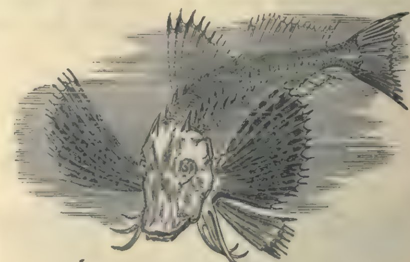
The *Percidæ* (Perch tribe) are numerous in the waters of warm climates, some species inhabiting the rivers, and others the sea. Their bodies are oblong, and covered with hard scales; and the gill-covers are toothed at the margin. The teeth are minute and set together in numerous rows. The ventral fins are generally placed under the pectorals. This family includes the Common Perch (*Perca fluviatilis*), which is found in almost every piece of clear fresh water, and a large number of marine fishes used as food on different shores. Some of the most remarkable are the *Trachinus*, or Weaver, which has a very prolonged and sharp dorsal spine, capable of inflicting a severe injury; the *Polynemus*, or Mango-fish of the Ganges, which has the pectoral fins on each side prolonged into threads thrice as long as the body; the *Uranoscopus* (Star-gazer), so called from the position of the eyes on the top of the



Perch (*Perca fluviatilis*).

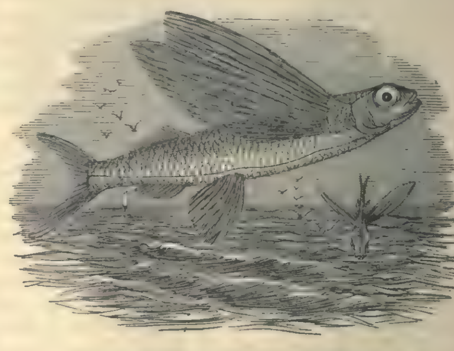
nearly cubical head; the *Mullus surmulletus* (Red Mullet) of British seas, and many others.

The *Triglidæ* (Gurnard tribe) bear a resemblance to the perches, but have the head armed with spines or hard scaly plates. The Gurnards,



Gurnard (*Trigla pini*).

the Sticklebacks, and the *Sebastes*, or Norway Haddock, the spines of which are used by the Greenlanders as needles, belong to this family. The most interesting of all is the *Dactylopterus*, or Flying-fish. This has a kind of supplementary pectoral fin on each side, formed of a membrane stretched over finger-like processes, which in the gurnards are unconnected. By the impulse of these on the surface of the water, the flying-fish can rise several



Flying-fish (*Exocœtus volitans*).

feet into the air, and suspend themselves above the surface for a few seconds, often skimming lightly over it for a considerable distance.

In the *Sparidæ* (Sea-bream tribe), the genus

Sparus has the jaws covered with round flat teeth, like pavement, for grinding down the stony corals, and the hard shells of mollusca on which they principally feed.

The *Chætodontidæ* have the body compressed, and the soft and spinous parts of their dorsal fins covered with scales, so as not to be distinguished from the rest of their body. The *Chætodon rostratus*, a native of India, which has a very prolonged snout, has the faculty of shooting insects with drops of water projected from the mouth, and it then seizes them as they fall.

The next family, *Scomberidæ* (the Mackerel tribe), is one of very great importance to man. It comprises a large number of genera, a vast collection of species, and numberless individuals. The aspect of the Common Mackerel, with its spindle-shaped, beautifully coloured, smooth, and small-scaled body, is well known. It very rapidly dies out of water, and soon becomes tainted. The Tunny (*Thynnus vulgaris*), which frequents the Mediterranean, is a much larger fish, sometimes attaining the length of twenty feet. The *Xiphias*, or Sword-fish, which abounds in the Mediterranean, and often attains the length of fifteen feet, also belongs to the family. It can drive its long-pointed beak into the timbers of a ship. The

Dory (*Zeus faber*).

Dory—remarkable for the filamentous prolongations from its dorsal fins—is much prized by epicures. And lastly, may be mentioned the *Coryphæna*, commonly known as the Dolphin. This is a large and splendidly coloured fish. It has long been celebrated for its change of colour when dying. It swims with great rapidity, and is very voracious, committing great havoc among the flying-fish.

The small family of the *Tænidæ* (Ribbon-shaped Fishes) are remarkable for the lateral flattening of their body. The *Lepidopus argyreus* (the Scabbard-fish) belongs to the family.

The *Mugilidæ* are lengthened and often nearly cylindrical fishes, with a somewhat projecting snout, and a very small mouth placed beneath it. They are gregarious in their habits, frequenting the mouths of rivers in large troops, and constantly leaping out of the water. There are several species found in European seas, but the one best known on the British coast is the *Mugil chelo*, or Thick-lipped Gray Mullet.

The family of the *Anabatidæ*—of which the Climbing Perch of India (*Anabas scandens*) is an example—are remarkable for having the superior pharyngeal bones divided into irregular leaves, placed in the base of the skull, and containing cells among them, in which a supply of water for moistening the gills may be carried, thus enabling the animal to continue respiration out of its proper element. By means of this apparatus, these fishes are enabled to quit the pool or rivulet which constitutes their usual element, and move to a considerable distance overland. They are able not only to traverse plain grounds, but can even climb trees in search of their prey.

The members of the family *Gobiodæ* (or Goby tribe) are known by the thinness and flexibility of their dorsal spines. Many of them are remarkable for producing their young alive. This is the case with the Blenny, of which several species frequent the British shores, living in small troops among the rocks. They are remarkably tenacious of life, and are capable of being kept a good many days in moist grass or moss, but they are of little value as an article of food. One of the most interesting species of this family is the *Anarrhicas lupus*, or Sea-wolf. It inhabits the northern seas, and is often met with on our shores, attaining the length of six or seven feet. It is very formidable in aspect, is remarkably strong, very active, and equally ready to defend itself or attack an enemy. In the *Echeneis remora*, or Sucking-fish, the upper surface of the head is furnished with a series of thin cartilaginous plates, by means of which the animal can attach itself to any kind of surface. It seems to prefer bodies in motion, and is not unfrequently found adhering to large fish, and to the bottoms of vessels, whose course it was once absurdly believed capable of arresting. It is abundant in the Mediterranean. The true Gobies have the ventral fins placed far forwards and united at their bases; they are chiefly remarkable for the *nest* which they construct among the sea-weed for the protection of their young.

The last family, the *Lophiidæ*, have the wrist bones much elongated, upon which the pectoral fins are supported, thus forming a kind of arm. This conformation gives these fish a very strange appearance. One of the most curious is the *Lophius piscatorius* (Angler or Fishing-frog) of the British seas. It derives its name in part from its wide gaping mouth, which is placed transversely, and furnished with many sharp-curved teeth, and

Angler (*Lophius piscatorius*).

in part from the peculiar manner in which it angles for its prey. There are some curious appendages to its head, which terminate in long, round, and rather brilliant filaments. The animal, which sometimes measures four feet in length, lurks in the mud, and puts these appendages in vibration; they are mistaken for worms by small fishes, which they attract, and these are gulped down the capacious maw of the lophius. To such an extent is this voracity carried, that the angler

is often an article of value for the fish which it has in its stomach, although its own flesh is but little worth.

Sub-order (D). The *Plectognathi*—approach the Cartiligines in many points of organisation; principally, however, in the slow ossification of the skeleton, and the imperfect structure of the mouth. They derive their name from the union of the upper jaw to the skull; so that its motion is obtained, not from a distinct joint, but by the mere flexibility of the half-ossified cartilages. The gill-lid is concealed under the thick skin, with only a small opening; the ribs are scarcely developed; and there are no true ventral fins. This order contains two families:

The family of the *Sclerodermata* contain fishes which are remarkable for their hard and granulated skins. They have the head prolonged into a muzzle: at the extremity of this is the mouth, which is armed with a series of distinct teeth. The *Ostracion* (Trunk-fish), which is found in the Indian and American seas, has the whole of the body except the tail covered with an inflexible suit of bony armour, composed of bony plates. The *Balistes* (File-fishes) have the dermal skeleton in the form of small grains, leaving the skin a certain amount of flexibility. They are principally inhabitants of warm seas.

The *Gymnodonta* (Naked-toothed fishes) are distinguished by having the jaws covered with an ivory-like substance arranged in small plates, which are reproduced as soon as destroyed by use. They live on crustacea and sea-weed. The most remarkable species of this family are the Spinous Globe-fishes, *Diodon* and *Tetraodon*, which have the power of blowing themselves up like balloons, by filling with air a large sac which nearly surrounds the abdomen. They are defended by spines over their whole surface, which are erected as they are inflated. The *Sun-fish* has a body of somewhat similar form, but incapable of inflation; from the shortness of its tail, it looks like the anterior half of a fish cut in two in the middle. There are only two British species of sun-fish (*Orthagoriscus*), and some specimens have been known to weigh 300 pounds.

Sub-order (E). The *Lophobranchii*—are a small

Hippocampus brevirostres.

group, which have the gills arranged in tufts in pairs upon the branchial arches. The swim-bladder is destitute of an air-duct. The body is covered, not with small scales, but with shields or plates, which often give it an angular form. In general, they are of small size, and almost without flesh. The *Syngnathus* (Pipe-fish) possesses a long tubular snout. It is peculiar for the protection it affords to its young. The eggs are conveyed into a sort of pouch under the body of the male, and are hatched there, the young fry afterwards finding their way out. Some of these are found in the British seas; as are also the *Hippocampi*, commonly called 'sea-horses,' from the resemblance of the upper part of the body to the head and neck of a horse in miniature. The tail is prehensile, and they climb or hold on to the stalks of marine plants by its means.

ORDER 4. The *Ganoidei*—are a group of which there are few living representatives at the present day, but they attained an enormous development during the Palæozoic period, when they were represented by such genera as Pterichthys, Coccosteus, Pteraspis, and Cephalaspis, from the Old Red Sandstone. In this group of fishes, the endo-skeleton is very imperfectly ossified; in fact, in many of the fossil forms the skeleton was entirely cartilaginous. The exo-skeleton consists of plates or scales, which are composed of an upper layer resembling enamel, and termed *ganoine*, and an under layer of true bone. These plates in some genera are of a rhomboidal form, and delicately sculptured, and being placed edge to edge, afford an efficient yet flexible investment for the soft parts within. The ventral fins are usually present, but they are placed far back near the anus. In some recent forms, such as the Polypterus, and in many extinct forms, the paired fins have their fin-rays arranged round a central lobe. Those fishes with fins so constructed are 'fringe-finned,' and belong to the division *Crossopterygidæ* of Huxley. The tail is generally unequally lobed, when it is said to be 'heterocercal.' The gills have the same structure as in the *Teleostei*. The swim-bladder possesses an air-duct which communicates with the pharynx. The *bulbus arteriosus* is rhythmically contractile, and is separated from the ventricle by several rows of valves. The intestine is furnished with a folding of its mucous membrane, so as to form a spiral valve.

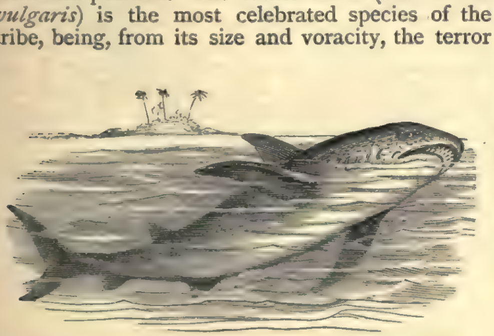
The *Lepidosteus* (Bony Pike) of the rivers and lakes of North America, and the *Polypterus* of the Nile, are recent examples. The former has the jaws prolonged into a long narrow snout, and the tail heterocercal; the body is protected by transversely arranged rows of ganoid plates. The latter has its dorsal fin broken up into a series of small fins, each of which has a strong spine in front, and a soft fin attached to it posteriorly. The *Sturionidæ*, or Sturgeons, also belong to this order. In them the notochord is persistent, and the tail is heterocercal. They are found in the Black and Caspian Seas, and ascend the rivers for the purpose of spawning. They are extremely valuable to man, their roe furnishing the caviare so much esteemed in Russia, and the air-bladder furnishing isinglass. The Common Sturgeon (*Accipenser sturio*) of the British coasts is about six feet long; but the Beluga (*A. huso*) of the Caspian Sea measures fifteen feet in length. The *Spatularia* (Paddle-fish) of North America is a nearly allied form.

ORDER 5. The *Elasmobranchii*, including the Sharks and Rays, correspond pretty closely with the Cartilaginous Fishes of Cuvier. The skull is a simple cartilaginous box, without sutures. The vertebral column is more or less cartilaginous, and the exo-skeleton is 'placoid' in its character—that is, consists of bony grains or tubercles scattered throughout the integument. The gills are peculiar, in that the branchial laminæ are fixed like the leaves of a book to partitions which divide the gill-chamber into a series of pouch-like spaces, which communicate internally with the pharynx, and externally by one or more apertures placed on the side of the neck, there being no operculum or branchiostegal rays. The structure of the intestine and of the heart is the same as in the *Ganoidei*.

Sub-order (A). The *Holocephali*—including the *Chimæra monstrosa*, which often accompanies herring shoals, hence called the 'King of the Herrings.' It has the mouth terminal in position, and only a single gill aperture on each side of the neck, covered by an imperfect operculum.

Sub-order (B). The *Plagiostomi*, which have the mouth transverse, and placed on the under surface of the head. There are several apertures representing gill-slits on each side of the neck. It includes the Port Jackson Shark (*Cestracion Philippi*) of the Australian seas, with its curious pavement-like teeth, adapted for crushing the crustacea and mollusca upon which it feeds. The *Selachii*, including the true Sharks and Dog-fishes, also belong to this group. They are distinguished from other fishes by many peculiarities: in several species, the young are produced alive, the eggs being hatched within the body of the parent; and in others, the eggs are inclosed in a horny casing, which has often long tendril-like appendages, that coil around and attach the mass to other bodies. This is the case with the eggs of the common Dog-fish and Skate of our coast, the receptacles being vulgarly known as 'sea-purses.'

The sharks are distinguished by their lengthened spindle-shaped bodies, by the gill-slits being placed laterally on each side of the neck, and by the fact that the pectoral fins have the ordinary form and position. The White Shark (*Carcharias vulgaris*) is the most celebrated species of the tribe, being, from its size and voracity, the terror



White Shark (*Carcharias vulgaris*).

of mariners in the seas it inhabits. It frequents warm latitudes, but has occasionally visited the British shores. It has been known to attain a length of thirty feet, and the opening of the jaws in the largest individuals is sufficient to admit with ease the body of a man. As the mouth is placed in the under surface of the head, the fish cannot bite while in the act of swimming forwards, so that a dexterous person has been known to defend himself from its attack. The teeth are triangular and lancet-shaped, with acute points and edges, and form several rows; they are not fixed in the jaw itself, but in a muscular membrane, by which they are erected and made to project when in use, lying flat in the intervals. As the foremost are torn away, they are replaced with others, which are brought up from the rows behind. The Blue Shark (*C. glaucus*), which frequents the Mediterranean, is not unfrequently a source of great trouble to the fishermen of our coasts, on account of the injury which it does to their nets. It sometimes attains the length of eight feet. The *Zygæna malleus*, or Hammer-headed Shark, is a remarkable genus, so named from the projection of the head at each side in the form of a double-headed hammer, with an eye in the middle of each extremity. The Fox-shark (*C. Vulpes*) is a British species. It is also called the Thrasher, from the use it makes of its tail, the upper lobe of which is elongated and very powerful.

The last group, the *Batides*, including the Rays, and Skates, and Thornbacks (*Raia clavata*), are remarkable for extreme horizontal flattening of the body, on the under surface of which, a little behind the mouth, the gill-slits are disposed in two rows. They abound rather in temperate than tropical seas. The eyes are placed on the back or upper surface. The most interesting of all is the Electric Ray or Torpedo of the Mediterranean. It possesses an electrical apparatus, by which it can give a smart shock to any animal it touches. The flesh of the ray is wholesome. The skin of some of them is employed in the arts for polishing, and from that of others shagreen is made. In the *Pristis*, or Saw-fish, the body is not flattened like the typical rays, but bears a resemblance in its form and general characters to the sharks. Its snout is extended like the blade of a sword, with strong and cutting tooth-like spikes on both sides. This fish sometimes measures from 12 to 15 feet, and will attack and inflict dreadful wounds even on large whales. Of the *Scylliidæ*, or Dog-fishes, three species are known on our coasts. They are distinguished from the true sharks by their oviparous reproduction. Their skin is used by cabinetmakers as a fine rasp, under the name of 'fish-skin.'

ORDER 6. *Dipnoi*—including only the singular Mud-fishes (*Lepidosiren*) of the Gambia and the Amazon. They are peculiar in that they exhibit

Lepidosiren (*Lepidosiren annectans*).

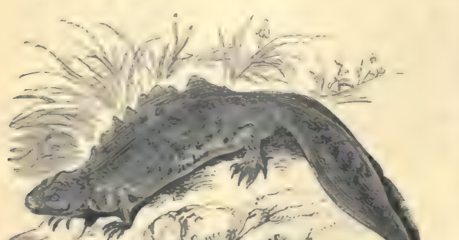
a distinct transition between the Fishes and the Amphibia. They inhabit marshy places, and are able in the dry season to bury themselves in the mud, there remaining dormant until the return of the rainy season.

CLASS II.—AMPHIBIA.

This class was included by Cuvier along with the Reptiles, but there is sufficient reason for separating them into a distinct group of equal importance. They may be regarded as intermediate in their structure and in their habits and mode of life, as well as in many of their forms, between Fishes and true Reptiles. To the former they are allied, in that at some period of their life they breathe by gills, but differ from them in always possessing lungs in the adult condition. Their limbs are never in the form of fins. The skull articulates with the vertebral column by two occipital condyles, and the heart consists of two auricles and a single ventricle. From the arterial and venous blood being mixed in the ventricle, the body is nourished by imperfectly oxygenated blood. They are, like Fishes and Reptiles, cold-blooded animals. They all undergo a metamorphosis after their expulsion from the egg. At first, they possess gills, and are water-breathing animals; but in the adult state they invariably possess lungs. In some genera, the gills disappear as the lungs are developed; but in other cases, both gills and lungs are permanently retained throughout life. As in Reptiles, the gut, and the ducts from the kidneys and generative organs, open into a common cloaca.

ORDER 1. *Ophiomorpha* (serpent-forms)—including one genus, the *Cæcilia*, Blind Newt, or Naked Serpent. It is snake-like in form, and destitute of limbs. The eyes are exceedingly small, and are nearly hidden under the skin. It is a native of South America, Guinea, and Ceylon.

ORDER 2. *Urodela*, or Tailed Amphibians.—The animals included under this group retain their tails in the adult condition, and their skin is soft, and destitute of scales. In one section (*Amphipneusta*), both gills and lungs are retained throughout life—for example, the Proteus of the caves of Illyria, and the Siren or Mud-eel of the rice-swamps of South Carolina. In the second section, the gills disappear at maturity, and the animals breathe by lungs alone. This section includes the Land and Water Salamanders. The Tritons, or Aquatic Salamanders,



Warty-newt (*Triton cristatus*).

commonly called Newts, have their tail vertically compressed, and are oviparous. They pass the greater part of their life in the water. They possess the remarkable power of reproducing limbs that have been cut off. The anterior limbs are developed first in the Salamanders, the reverse of what takes place amongst the frogs. Three species are indigenous to Great Britain. The Land Salamanders (*Salamandra*) are distinguished from the former by the cylindrical form of their tail, and by their producing their young alive. All these forms are easily distinguished from the Reptiles by always possessing gills at the earlier period of their life, and by the soft, smooth, naked skin.

ORDER 3. The *Anoura*, or Tail-less Amphibians, including the Frogs and Toads. The adult is destitute of both gills and tail, both of which structures exist in the larva. Four limbs are always present. The larvæ are known as 'tadpoles,' which have a round head, a fish-like tail, and breathe by gills. Ultimately, the tail disappears, limbs are budded forth (the posterior pair first), and the gills are replaced by lungs, so that the adult is an air-breathing animal.

Family *Ranidæ*, or Frogs (*rana*, a frog). They are so well known that a description of them seems unnecessary. They always possess teeth in the upper jaw. They are of a yellowish-brown colour, with black spots, and their power of leaping is well known. As there are no movable ribs to expand the thorax, the mode of breathing is peculiar. The animal closes its mouth, and fills it with air taken in through the nostrils; the nostrils are then closed, and by the compression of the muscles of the throat and cheeks, the air is propelled forcibly into the lungs. The animal would be choked if the mouth was held open. No doubt, the skin also aids in the process of respiration. Their feet are webbed, and suited for swimming. Of the European species, the Edible Frog (*R. esculenta*) is the one most approved of on the continent for culinary purposes. The *R. temporaria* is the only species indigenous to Britain. The Tree-frogs (*Hylæ*) of America have their feet provided with suckers, which enable them to climb trees in pursuit of their food—insects.

Family *Pipida*, distinguished by the absence of the tongue, including the ugly *Pipa Americana*, or Surinam Toad, which is eight inches long in the tadpole condition, while the perfect frog is only three in length. It is a native of Brazil and Surinam.

Family *Bufonidæ* (Toads) in which the jaws are destitute of teeth. They are of a dull, cadaverous appearance, and their bodies are covered with warts. They have a swelling above each eye, from which a fetid, milky secretion is expressed. Two species are found in Britain, the Common Toad (*Bufo vulgaris*), and the Natterjack (*B. calamita*). They seldom frequent the water but for the purpose of depositing their eggs. The tongue in these animals, as in the frogs, is fixed to the *front* of the mouth, and *free behind*.

CLASS III.—REPTILIA.

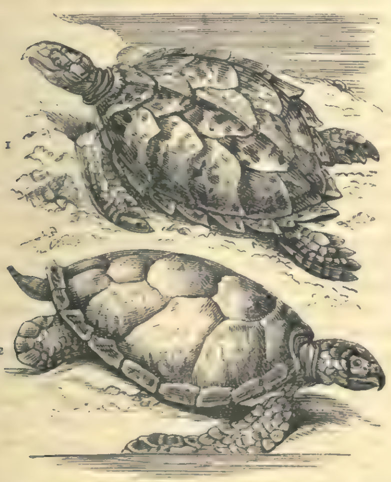
The Reptilia, or creeping animals (*repo*, I creep), though in outward form many of them resemble the Amphibia, yet in intimate structure they are more closely allied to birds. They are oviparous, and many of them are covered by hard scales, but never by feathers. They never breathe by gills, but always by lungs. The heart consists of two auricles and a ventricle, so that only a portion of the blood returned by the veins is propelled

through the lungs, the greater part passing again into the circulation without being aerated. Hence it is that the blood is cold, the digestive powers weak, and their vitality low, so that their functions may be suspended for a considerable time without apparent injury to the animal. The skull is articulated to the vertebral column by a *single* occipital condyle.

ORDER 1. *Chelonia.*—In typical species, the ribs are expanded so as to form but one bony plate, having no flesh outside, but being covered with horny plates, secreted from the skin like hair or nails; the breast-bone is similarly expanded into a plate, covering the whole of the lower surface, and joining the edges of the upper plate; so that the animal may be said to be sheltered in a box formed of its bones. Within this box, the upper plate of which is named the *carapace*, and the lower the *plastron*, the animal can even withdraw its head and feet, and thus set most enemies at defiance. There are no teeth, and the edges of the jaws are sheathed in horn, so as to form a kind of beak.

The family *Chelonidæ* (Turtles) are designed for sea-life, and their extremities take the form of paddles. They swim with great ease, and only come to land to deposit their eggs, which they do thrice a year, laying about 100 at a time. They feed chiefly on marine plants. They are sometimes five feet in length, and weigh 800 pounds. The *Chelone midas* (Edible or Green Turtle) of the tropical seas of America, is noted for the delicious food which it yields. Ascension Island is one of their favourite retreats.

The *Chelone imbricata* (Hawk's-bill Turtle) is a



1, Hawk's-bill Turtle (*Chelone imbricata*); 2, Green Turtle (*Chelone midas*).

smaller species, and is remarkable for the imbricate beautifully marked horny plates covering its carapace, which yields the *tortoise-shell* of commerce. These plates do not join at the edges like those of land-tortoises, but overlap each other like the scales of other reptiles. The finest tortoise-shell is brought from the Indian Archipelago.

The *Chelone* or *Sphargis caretta* (Leathery Turtle) has the carapace covered by a leathery skin in place of horny plates. This animal inhabits the Mediterranean as well as the Atlantic and Pacific Oceans.

The family of the *Emydæ* (Terrapenes) and the *Trionycidæ* (Mud Turtles) have the feet furnished with toes, and being partly webbed, they are useful for swimming. The Snapping Turtle (*Trionyx ferox*) of America is capable of biting through a stick half an inch in diameter. The *T. Niloticus* is highly serviceable in the Nile and other rivers in destroying young crocodiles and alligators. They are all inhabitants of fresh water.

The *Testudinidæ* (Land Tortoises) have the feet furnished with short nails, and adapted for walking on firm ground. Their armour is thicker and

Common Land Tortoise (*Testuda græca*).

stronger in proportion to their size than the aquatic species. They are vegetable feeders. The *T. græca* of Spain is often kept as a domestic pet.

ORDER 2. *Ophidia*—have an elongated cylindrical body, covered with scales, but destitute of limbs, though in some serpents rudimentary posterior limbs can be traced, but these are of no use for progression. The ribs are exceedingly numerous, and very movable, and their pointed extremities are attached by muscles to the abdominal scales, or 'scuta,' of the integument. By this arrangement, the animal moves along on the points of its ribs, the whole being facilitated by the very movable spinal column. The tongue is forked, and there is no eyelid, the eye being covered with a glassy capsule, within which the eye moves freely. All are furnished with teeth, which never occupy distinct sockets, but are united to the jaw, and are arranged either in two or three rows. The two halves of the lower jaw, which are composed of several pieces, are united in front by ligaments and muscles, which permits of their being separated to a considerable distance, so that, though the head is small, these animals are enabled to swallow their prey entire. They remain torpid during winter, and each season cast their skin.

Sub-order 1. *Viperina*, or Venomous Snakes—have a pair of perforated poison-fangs in the upper jaw, which can be erected or depressed at will. When the animal is irritated, they are unfolded, and struck into the victim, the poison being at the same time ejected by the action of the muscles of the jaws. The matter is poisonous only when introduced into the blood. The *Viperina* comprise the Rattlesnakes (*Crotalidæ*) of America, which are distinguished by a pit behind each nostril, and by the presence of the rattle. They are highly venomous, but they will not attack man unless when trodden on or provoked. The extremity of the tail in *Crotalus horridus* is furnished

with a series of horny epidermic rings, known as the 'rattle,' which produces a rattling noise when the animal moves, hence the name. Some

Common Viper, or Adder (*Pelias berus*).

measure five or six feet in length, and are as thick as a man's arm. Their food consists of birds and small animals. The *Viperine Snakes* are distinguished from the former by a broader head, by the absence of the rattle, as well as the cavities behind their nostrils. They are entirely confined to the Old World, in the warm countries of which they are very abundant. The Common Viper (*Pelias berus*) can inflict a dangerous bite, and is the only venomous reptile found in Britain.

Sub-order 2. The *Colubrina*—in which the maxillary bones are armed with solid conical teeth. If fangs are present, they are only grooved on one side. They are for the most part harmless, but some of them are extremely venomous. This sub-order may be divided into two sub-orders:

(*a.*) *Innocua*, or Harmless Snakes, in which there are only solid teeth on the maxillæ. The *Coluber natrix* (Ringed Snake) of Britain, and the *C. constricta* (Black Snake) of North America, are perfectly harmless. The former is tolerably abundant in Britain, and is a very pretty little creature, about three feet in length. It is of a pale olive colour, spotted in black on the sides, and immediately behind there is on each side a yellowish spot, which gives to the animal its common name of Ringed Snake.

The *Boa Constrictors* of tropical America have the under part of the body and tail covered with transverse shields. Many of the species exceed twenty feet in length, and they can swallow even sheep and oxen. This they effect by coiling themselves round the body of the victim, and crushing it till every bone is broken. They then moisten it with saliva, and proceed to swallow it. The *Pythons* are inhabitants of the Old World, and many of them, from their size and great muscular power, are amongst the most formidable of all Ophidia.

(*b.*) In the group *Venenosa*, which have grooved fangs placed in front of the upper jaw, and solid teeth behind them, are included some of the most venomous of all snakes. The most formidable of these is the Hooded Snake, Cobra di Capello (*Naja tripudians*) of India, the snake usually carried about by the Indian snake-charmers, the bite of which is fatal within an hour. The *Hydrophidæ* (Water-serpents) have a vertically compressed tail, and so can swim with great facility. They are very venomous, and are chiefly found in the rivers and seas of the East Indies.

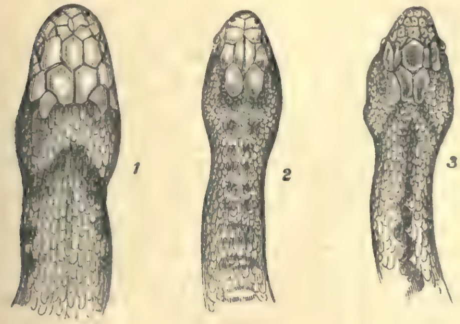
Cobra di Capello (*Naja tripudians*).

ORDER 3. The *Lacertilia*—comprising the Lizards, which have a lengthened body, terminating in a tail, and covered with small scales. Eyelids are present in all with the exception of the *Geckotidæ*. As a general rule, four limbs are present, although the Blind-worm or Slow-worm (*Anguis fragilis*), which belongs to the family of the *Scincidæ*, has no external appearance of limbs, although the bones of the pelvis and shoulder exist in a rudimentary condition under the skin. It is serpentiform, and quite harmless, and when alarmed, its muscles become so rigid that the tail can be broken off. In the course of a year, however, this member is replaced. It is found all over Europe, and feeds upon insects, slugs, &c. Nearly allied to the former are the *Amphisbænidæ* (Double-walkers). They can move forwards or backwards with equal facility. They are small harmless animals, found in the warmest parts of South America. These serpentiform *Lacertilia* are at once distinguished from the *Ophidia* by the structure of the lower jaw, the two halves of which are united in front by a suture so as to restrict the gape.

In order that any one may be able readily to make out the differences between the three snakes indigenous to Great Britain, and thus perhaps be saved from the danger that might accrue from handling or incautiously approaching a viper, mistaking it for the harmless ring-snake or coronella, we give an illustration and brief description of the heads of the three species.

1. The common ringed snake has a somewhat almond-shaped head, covered with broad plates or shields. It has invariably a yellow collar at the back of the head, the yellow colour being made more apparent by a jet-black collar behind it. This black collar does not in every case extend right across the neck, but varies in different specimens. The eye is rather prominent, of a hazel colour. The prevailing colour of the back and sides is dusky brown. The centre line of the back is marked with a double row of small black spots, which extend from the head to the tail, and from these rows, lines made up of similar dots stripe the sides.

2. The head of *Coronella lævis*, it will be at once evident, is exceedingly small, compared with



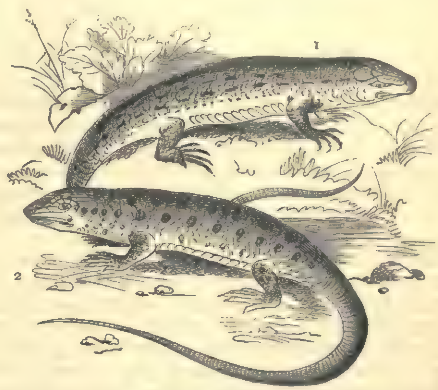
1, The Common Ringed Snake (*Coluber natrix*); 2, The Small-crowned Smooth Snake (*Coronella lævis*); 3, The Common Viper or Adder (*Pelias berus*).

the other two; moreover, it is rounder, and more like the head of a lizard, and carried in a more erect position than the head of the ring-snake. The plating on the top of the head is very like that of the ring-snake, but the lateral plates differ from those of the viper. One marked peculiarity in the head of *Coronella lævis* is that it is beautifully iridescent, and of bronze green colour. There is but a very imperfect V-mark—not at all distinct, like the brand on the viper, being broken or imperfect at the sharp terminal angles, while that on the viper is complete. The general colour of the skin is brown; and it is remarkable for its almost polished smoothness, which gives the reptile its name, *lævis*. Two rows of dark spots run along the sides of the back, which at once distinguish it from the viper, with its zigzag marking. The belly is a brightish orange colour.

3. The head of the viper, it will be observed, is not shaped like the head of the snake; it is perfectly flat. The viper has no collar encircling the neck, but instead the letter V distinctly marked on the back part of the head, as will be more plainly seen by reversing the illustration. It really would almost appear that nature had branded this, the only poisonous reptile inhabiting our land, so that people might the more easily recognise and avoid it, with V, the first letter in the name viper. Continuing from this V-marking, a diamond-shaped pattern of a dark colour extends along the whole line of the back. The general colour of the body is extremely variable, being influenced by local conditions.

With respect to its dangerous properties, Mr Bell remarks: 'In this country, I have never seen a case which terminated in death, nor have I been able to trace to an authentic source any of the numerous reports of such a termination. At the same time, the symptoms are frequently so threatening, that I cannot but conclude that in very hot weather, and when not only the reptile is in full activity and power, but the constitution of the victim in a state of great irritability and diminished power, a bite from the common viper would very probably prove fatal. The poisonous fluid is perfectly innocuous when swallowed. Dr Mead and others have made this experiment, and never experienced the slightest ill effects from it. It is, however, clear that there would be danger in swallowing it were any part of the mouth, the throat, or the œsophagus in a state of ulceration, or having an abraded surface.'

The family of the *Lacertidæ* (Lizards) have four limbs, terminated by five toes of unequal lengths. Their tongues are long, slender, and protrusile. Their bodies are covered with scales, and the head and abdomen with large regular plates or 'scuta.' They are terrestrial in their habits, as their rounded tail indicates. They vary from five to thirty inches in length. They feed upon frogs, insects, and small mammals. The Scaly Lizard (*Zootoca vivipara*), which is viviparous, whence its specific name, is found abundantly in this country on dry banks and sandy heaths, where it may be observed basking in the sunshine, watching for its insect prey. The *Lacerta agilis*



1, Viviparous Lizard (*Zootoca vivipara*); 2, Sand Lizard (*Lacerta agilis*).

(Sand Lizard) is found in England, and the *L. viridis* (Green Lizard) is common in Jersey.

The *Varanidæ* (Monitors) are closely allied to the former, but differ from them in having the head and abdomen covered with ordinary scales. They sometimes measure six feet in length—for example, the *Varanus Nilotus* of Egypt. They are also called Monitors, because they warn each other of the approach of an enemy by a shrill whistling sound. They are confined to the Old World.

Family *Iguanidæ* (Iguana, or Guana Lizards) are distinguished from the true lizards by a short and thick tongue, with the extremity very slightly cleft. It contains several genera. Iguanas, properly so called, are covered with small scales, and they have a dorsal crest and a compressed tail, and are confined to the New World. A large thin fold of skin, or dewlap, hangs from under the throat. Each jaw has a range of triangular teeth, with finely sharpened edges, and a double row also on the palate. They feed upon vegetable substances, and live chiefly upon trees. They sometimes measure four feet in length; and both their flesh and eggs are esteemed as delicacies. One of the most remarkable American species is the Basilisk (*Basiliscus Americanus*), which, although perfectly harmless, is one of the most forbidding of reptiles. It is distinguished by a mitre-shaped crest on the top of its head. The

Amblyrynchus cristatus of the Galapagos Isles, first described by Mr Darwin, is partially aquatic in its habits, spending the greater part of its time in the sea.

A gigantic fossil form, the Iguanodon, characteristic of the Wealden Period, had teeth closely resembling the Iguana of the present day. It attained the length of fifty feet. More remarkable than the iguanas is the Flying Lizard (*Draco volans*) of the East Indies. It is a small animal, possessing a membrane at its sides, stretched over the false ribs, by which it can float, though it has no true power of flight, as upon a parachute, from one tree to another.

Flying Lizard (*Draco volans*).

The *Geckotidæ*, or Nocturnal Lizards, have the toes terminating in little suckers, enabling the animal to creep up vertical walls, and along ceilings, like the flies upon which it feeds. They have a flattened body and a broad head, which, aided by their sombre colour, gives them a disagreeable appearance. They are timid and harmless, and are common in the warm climates of the Old and New World. Like the *Iguanidæ*, they constitute an exceedingly numerous family.

Family *Chamæleonidæ* (Chameleons), which includes the Common Chameleon (*C. Africanus*), are animals of small size, with a prehensile tail. They are readily distinguished from other lizards by having climbing feet, and by the fact that the eye is covered by a circular lid, which is perforated by a small opening opposite the pupil. They are natives of the Old World, and live in trees, which they seldom leave. Their prey, consisting of flies and insects, is taken by darting out the glutinous tongue, which is terminated by an adhesive disk. They are also remarkable for the power they possess of changing their colour.

Chameleon (*Camæleo Africanus*).

ORDER 4. *Crocodilia* (Crocodiles)—are inhabitants of the rivers and fresh waters of equatorial countries. They are formidable animals, and attain the length of twenty or thirty feet. The head is large, and each of the lengthened jaws is furnished with a single row of teeth, which are implanted in distinct sockets. The back and tail are covered with strong dermal plates, permitting of easy motion of the body and limbs. The back is impenetrable to a musket-ball. On land, the motion of the animal is slow, because the legs are short, and the feet are palmated; but in water it moves rapidly, using the tail as a powerful oar. The tail, with its serrated ridge of scales, is a formidable weapon of offence and defence. These animals usually feed upon decayed carcasses that may come in their way, and are thus of considerable service in the hot countries which they inhabit. The eggs, which are about the size of those of a goose, are deposited in the sand, and hatched by the sun. There is only a single genus in this order containing three species —1. The true *Crocodile*, which abounds in the Nile; 2. The *Alligator*, found in the rivers and swamps of North and South America; and 3. The *Gavial*, which inhabits India and the islands of the Eastern Archipelago.

Gavial (*Gavialis Gangeticus*).

Fossil Reptiles.—The *Ichthyosaurus*, from the Lias and Oolite strata, was a marine animal, sometimes twenty feet long, possessing the vertebræ of a fish, with paddle-feet, like those of a turtle, and a crocodile-like head, armed with sharp and formidable teeth. The *Plesiosaur* was a smaller animal, with a neck of extraordinary length, and a small head. But the most singular fossil saurian is the *Pterodactyle*, which had the last digit of the fore-limb extraordinarily lengthened. It was furnished with a pair of wings, like those of a bat, and thus is supposed to have been able to fly through the air in pursuit of its prey.

CLASS IV.—AVES, OR BIRDS.

These are oviparous vertebrates, with a complete double system of circulation, with its proper consequence of warm blood. The skull is articulated

to the vertebral column by a *single* occipital condyle. The young are hatched and nurtured by the parent. Their body is covered with *feathers*, instead of hair or wool; and, as a rule, the fore-limbs are in the form of wings adapted for flight, but they are never used for prehension. The lungs are fixed in the chest, and the air-tubes open on the surface of the lungs into *air-cells*, scattered throughout the body. By this organisation, they can increase or diminish their density, so as to range over the aerial regions with ease and celerity. The bones of birds are singularly light, and exhibit a greater degree of hardness than in any other vertebrate. The lightness is due to the marrow being replaced by air, and the hardness to the presence of a large proportion of phosphate of lime. The eye is generally so constructed that they can see objects far and near with almost equal clearness. Their posterior extremities serve as the sole support of the body on the ground. Most commonly the feet exhibit four toes, of which one is directed behind, and three in front. In the single posterior toe, the number of joints is two; in the external, five. The toes are terminated by claws, which are used for different purposes. Birds have no teeth, and therefore cannot masticate their food, which is either torn by the beak or swallowed whole, and is reduced to a soft state in the stomach. The plan of the digestive system most usual in this class is that which is exemplified in the common fowl. The stomach consists of three cavities: the first being formed by an expansion of the gullet, which produces a bag or chamber known as the *crop*. In this receptacle the food is stored up, and transferred by degrees to the second or membranous stomach, where it is softened by the action of the gastric juice. It is then conducted to the *gizzard*, or third cavity, in which the process of digestion is completed. This last stomach presents modifications varying with the nature of the food upon which the bird subsists. If it feeds on grain, the sides of this stomach are of considerable thickness, and are moved by powerful muscles, which act as a mill in grinding down the food; but in those species which subsist on animal substances, or soft herbage, the muscles are reduced to extreme delicacy. In many cases the process of digestion is promoted by the swallowing of small pebbles, which, being brought into contact with the food in the gizzard by the muscular action of the stomach, produce an effect similar to that of teeth, and in some measure serve the purpose of these agents.

The change of the plumage, termed *moulting*, generally takes place annually; while with some species a partial casting of the feathers occurs also at the breeding season. Many birds migrate from one latitude to another, chiefly for the sake of obtaining a better supply of food. The summer immigrants that visit our island, as the swallow, the rail, the cuckoo, are from tropical regions; while all winter visitants, as the Swan and Wild Goose, come from the north. Under the direction of their highly developed instinctive powers, the place for their nests appears to be selected, their material collected, the nests themselves built, the young reared in them, and their migrations performed.

Many birds are capable of domestication, and in this we see an obvious approach towards that higher form of attachment to man which is exhibited by many species among Mammalia. Birds are of great utility to man, not only as an article of food, but also by keeping in check noxious animals; and in consuming carrion and other refuse. A good classification of birds is still a desideratum. Various classifications have been proposed, but the one given here is that generally employed. In the meantime, it must be looked upon as merely provisional, since it is founded upon *habit*, and not upon anatomical characters or *structure*. All true classification must be founded upon structure.

Natatores.

ORDER I. *Natatores*, or Swimmers, are adapted to an aquatic life, and have the toes united by a membrane or web, the legs short, and placed behind the point of equilibrium. The body is closely covered with feathers, and coated with a thick down next the skin. In this order we find the nearest approach to reptiles which is to be found amongst birds.

The *Alcidæ* (Auk tribe) exhibit the most remarkable adaptation of the structure of the bird to an aquatic life, with which the entire order presents us. This is best seen in the Penguins (*Aptenodytes*), whose wings are very small, and covered with mere vestiges of feathers, resembling scales; so that they serve as admirable fins or paddles, but are totally useless for flight. The feet are placed very far back, so that, when upon land, the bird stands nearly erect. Having no power of flight, and not being able to run, the penguin may be overtaken with ease upon land; but once in the water, it distances its pursuers, swimming with the ease and rapidity of a fish. The Penguins are exclusively inhabitants of the southern seas; but the Puffins (*Fratercula arctica*)

Puffin (*Fratercula arctica*).

and Auks of the northern seas approach them in their peculiar characters. The former, which come to Britain, have short wings, capable of sustaining them for a little while. Of the latter, only one species has wings adapted for flight; all the other species are fitted for aquatic progression. The Great Auk (*A. impennis*) is now entirely extinct, having been destroyed by man himself. The Puffin obtains its food by diving into the water from a height, and often captures three or

four sprats at once. The Guillemots (*Uria*), which are found in all parts of the north of Europe and in the Arctic Seas, resemble the auks in the form of their bodies, and in their general habits. The Razor-bill (*Alca torda*) also belongs to this family.

In the family *Colymbidæ* (Divers), the wings are remarkably short, and the feet placed so far behind the point of equilibrium of the body, that they are ill adapted for walking. The Northern Diver (*Colymbus glacialis*) is a familiar example. It is generally an inhabitant of the most northern parts of the Old and New World; but on the approach of winter, it journeys southward, and is then occasionally found in Scotland. On the least alarm it dives under the water, rising perhaps a quarter of a mile from the spot where it disappeared. The Grebes (*Podiceps*) are more inland in their habits, living chiefly on the borders of lakes. The toes are separate, but each has a fin-like membrane along the side, presenting a considerable surface to the water. Of these, five species are found in our country, the most familiar being the Little Grebe (*P. minor*), and are largely killed for their feathers, which are used for making muffs, collars, &c. The Alcidæ and Colymbidæ are included by Owen under one family, which he calls the *Brevipennatæ*), in which the wings are short, and the legs are placed far back, so as to render progression on land very difficult.

The family of the *Laridæ* (Gulls) have well-developed, powerful wings, the three anterior toes united by a membrane, and the hinder one free. They feed on the carcasses that float in the sea, or are cast upon its shores. Genus *Larus* (Gulls proper): The Common Gull (*L. vulgaris*) is about one foot and a half in length, and three feet in the expanse of its wings; above, it is of a bluish-gray colour, and white beneath. On the approach of stormy weather, it leaves the shore, and sails round and round in circles at a great elevation. Genus *Sterna* (Terns), or Sea-swallows, are so called from the resemblance they bear to the Land-swallow in their pointed wings and forked tail. Their food consists of molluscs and fish. The tern is often seen chasing a small gull, in order to force it to disgorge the fish it may have taken. As soon as the fish has been dropped, the tern descends like an arrow, and generally succeeds in catching it before it reaches the water. The Common Tern (*S. hirundo*), which is about fourteen inches in length, visits our shores in April, leaving in September. Genus *Lestris* (Skuas) are more powerful birds than the terns. The Common Skua (*L. parasiticus*) is about two feet in length, and its general colour is a reddish-brown. Their peculiar habitat in this country is the Shetland Isles, where they breed in communities on unfrequented heaths. When the breeding is over, they retire to the sea, and feed upon fish-offal and animal matter.

The *Procellaridæ* (Petrels) differ from the Gulls in having no hinder toe, and having the upper mandible strongly hooked. The name Petrel (a diminutive of Peter) is given to these birds from their habit of walking on the waves. The common one (*P. pelagica*), called by mariners 'Mother Carey's Chickens,' is found in most seas. When it seeks shelter upon vessels, it is generally supposed as indicative of storms and shipwrecks. The largest member of the group is the gigantic Albatross (*Diomedea exulans*), which often measures fifteen feet across the wings. Its flight is very powerful, and it is often found at enormous distances from land in the northern and southern oceans. It is very voracious, and is said to destroy great numbers of flying-fish when they are forced to seek refuge in the air.

Owen included the two former groups under his family of *Longipennatæ*, which are characterised by their well-developed wings, by their pointed, sometimes hooked bill, and by their hinder toe never being united to the anterior toes by a membrane.

The *Pelicanidæ* (Pelicans) have the hinder toe directed inwards, and united to the innermost of the anterior toes by a membrane. The European Pelican is about as large as a swan, and altogether white. Attached to its long slender bill is

Pelican (*Pelecanus onocrotalus*).

a large neck-pouch, in which the fish are stored when captured. Nearly allied to the pelicans is the genus *Phalacrocorax* (Cormorants), in which the lower mandible is not furnished with a pouch, but the throat is capable of considerable dilatation. The Black Cormorant (*P. carbo*) is about the size of a goose, and is of a bronze-black colour. It is common on our shores, and is proverbial for its voracity. The Fishing Cormorant (*P. sinensis*) is an inhabitant of China, and is regularly trained and employed in fishing. Genus *Sula* (Gannet, or Solan Goose): These birds take their prey by hovering in the air at some little distance above the surface, and then dropping down upon any fish that they may see rising within their reach. They haunt the cliffs of solitary islands, for the purpose of bringing forth their young. The Bass Rock in the Firth of Forth, and Ailsa in the Firth of Clyde, are noted habitations of the Solan. It is eatable, but forms rather a coarse dish for most palates. The Frigate Bird (*Trachypetes aquilas*), which is distinguished by the immense length and power of its wing, and is often found far from land, and the Darter (*Plotus*), also belong to this group. The *Pelicanidæ* are called by Owen the *Totipalmatæ*, because they have the hinder toe directed inwards, and united to the innermost of the anterior toes by a membrane.

Family *Anatidæ* (Ducks) have the bill flattened in form, and covered with a soft membrane. The edges of the bill are furnished with a series of transverse plates, forming a kind of strainer for gathering food in a watery element. Of the genus *Cygnus* (Swan), the most remarkable wild species is the Hooper or Whistling Swan (*C. ferus*) of the Arctic Seas, which migrates southwards in flocks, under a leader, and ranged in the form of the letter

V, when their loud notes may occasionally be heard. The Tame Swan (*C. olor*) is a most elegant bird, and a beautiful ornament to our lakes and rivers. Swans are remarkable for their longevity. Genus *Anser* (Goose) presents several wild and migratory species. They all live on vegetable substances, and are useful as food. The *Canada Goose*, going northward every summer, is of great use to the Hudson's Bay residents, who kill and preserve great quantities for their winter provision. Our own tame goose is supposed to be derived from the Gray Lag Goose (*A. ferus*), once very abundant in the fenny districts of Lincoln. Genus *Anas* (Duck) includes many species, as the Velvet Duck, Eider Duck, Shoveller, and Shelldrake, all of them wild animals, frequenting pools and lakes remote from human haunts. The Mallard or Wild Duck (*A. Boschas*) is the parent of all the common ducks. The Common Duck, when searching for food amongst mud and turbid waters, is assisted by the sensitive skin of its bill, which enables it to feel for objects which it may devour. Another well-known species is the Eider Duck (*Somateria mollissima*) of the arctic portions

Common Eider Duck (*Somateria mollissima*).

of Europe and America, whose down is used for making quilts and similar articles.

The family of the *Phœnicopteridæ* (Flamingoes), from having the three anterior toes webbed, are entitled to be placed amongst the Natatores. They inhabit the marshes of hot climates. The Common Flamingo (*P. ruber*) is about four feet in height. It is purple red on the back, and has rose-coloured wings. The fleshy tongue was used by the Romans during the Empire as a great delicacy. The extreme length of their legs incapacitates them from sitting on their nests in the usual manner, so that they have to place themselves astride of them during the act of incubation.

Flamingo (*Phœnicopterus ruber*).

By Owen the last two families are called *Lamellirostres*, from the character of the bill, described under the *Anatidæ*.

Grallatores.

ORDER 2. *Grallatores* (Waders or Stilt-birds).—This order derives the name from their habits and conformation. Their bodies are raised upon long legs, like stilts. This elongation is mainly due to the elongation of the tarso-metatarsus. Their legs are unfeathered from the lower end of the tibia downward. They frequent the banks of rivers, lakes, marshes, and the shores of estuaries; and whilst resting with their feet on the land, derive their nourishment chiefly from the water; some feeding upon small fishes and reptiles, worms and aquatic mollusca; whilst others are more terrestrial in their habits and mode of feeding. The more aquatic species have a web to their toes. Their wings are long, and suited for flight. During flight, they stretch out their long legs behind, to counterbalance their long necks; and the tail is always extremely short, its function as a rudder being transferred to the legs. They mostly construct their nests on the ground, and the young are able to run about as soon as hatched, except in those species which live in pairs.

Family *Gruidæ* (Cranes) are elegant, large, and stately birds, with the bill strong and sharp-edged. The legs are long and slender. The Crane (*Grus cinerea*) is chiefly remarkable for its migrations, and it is described as a beautiful sight to see thousands of them passing over the Mediterranean in marshalled order, in groups of twenty to sixty, and each group headed by one of the larger birds. It is with reference to the migrations of these birds that Jeremiah (viii. 7) says: 'Yea, the stork in the heaven knoweth her appointed times.' Its length is nearly five feet, and its weight about ten pounds.

Family *Ardeidæ* (Herons): The Common Gray or Crested Heron (*Ardea cinerea*) is well

Common Heron (*Ardea cinerea*).

known in Britain. It passes the winter in the north of Africa, migrating thither in autumn,

and returning northward in spring. It is about three feet in length; its colour is of an ash gray, with a bluish tinge; and its head is ornamented with a crest. The Bittern, or Mire Drum (*Botaurus stellaris*), was once well known in Britain, but is becoming rare, as waste lands are reclaimed. It is the emblem of desolation, and as such is spoken of by the prophet in his denunciation against Babylon: 'I will also make it a possession for the bittern, and pools of water: and I will sweep it with the besom of destruction, saith the Lord of hosts.' The booming of the bittern is peculiarly dismal; and from this circumstance, and the lonely marshes it inhabited, it was the unconscious hero of many a ghost story in the superstitions that are past.

Of the Ibises (*Tantalinæ*), the most noted is the *Ibis religiosa*, which was held in great veneration in ancient Egypt, being often embalmed with their mummies, or figured on their monuments.

The *Ciconinæ* (Storks) have the bill strong and compressed. They are all large birds and feed upon reptiles and other small animals. They migrate in summer from Africa over a wide range of temperate latitudes. The Stork (*Ciconia alba*) stands about four feet high. In Holland, they prepare false chimneys on their houses, that the stork may build in them, each returning regularly to its own nest every year.

The Spoonbills (*Plataleadæ*) are large birds like the storks, but their bill is flattened in a broad spoon-like plate.

The family *Scolopacidæ* (Snipes) include the Snipe, Woodcock, &c. Their bill is long, slender, and cylindrical, and is used for searching in the mud for worms and insects. The Woodcock is well known in Britain, and is much esteemed for the exquisite flavour of its flesh. The Common Snipe (*Scolopax gallinago*) is one of the most common visitors of the British Isles. It chooses swampy parts of meadows; and insects, worms, &c. constitute its food. The Curlew (*Numenius arquata*), whose name is derived from its peculiar cry, also belongs to the family. The Sandpipers (*Tringidæ*), the Ruffs, and Avocat need no particular notice.

Curlew (*Numenius arquata*).

The Family *Rallidæ* (Rails), in which the bill is sharp, compressed, and wedge-shaped, includes several genera. *Gallinula* (Water-hen) is common throughout Europe. It frequents ponds and quiet water-courses. It is of a deep olive-brown colour above, and slaty gray below, with a frontal shield of bright red. The Coot (*Fulica atra*) is another well-known example of the Rails; the commonest species is the *Crex pratensis* (Land-rail, or Corn-crake), which is a regular summer visitor in the British Isles. It is of a reddish-brown colour, and conceals itself amongst grass and young corn, where it utters its peculiar cry. The Common Rail (*Rallus aquaticus*) remains in this country all the year round. In the Jacana, which inhabits Brazil, the feet are exceedingly long and slender, thus enabling it to run on the leaves of aquatic plants.

The *Charadriidæ*, or Plover tribe, are less aquatic than most of the other families. Their legs are short, and the hind toe is either absent, or so short as not to reach the ground. They congregate in flocks, on sandy and unsheltered shores, or on exposed commons, and run with great swiftness. The bill is of considerable strength, to enable them to penetrate the ground in search of worms. Several species of plovers exist in Britain, such as the *Charadrius pluvialis* or Golden Plover; the *C. morinellus*, or Dotterel; and the *C. hiaticula*, or Ring Plover. Some frequent the sea-coast, and others the upland moors. The Lapwings (*Vanellus cristatus*) are nearly allied to the plovers, and, like them, are migratory; they are peculiar to the Eastern hemisphere. They are very noisy birds, and defend themselves bravely against birds of prey. They derive their name from the stratagem by which they lure away intruders from their nests; they drop their wings in flight, appearing as if wounded, and thus induce their pursuers to follow them to a considerable distance. They are abundant in England, and are easily known by their wild and plaintive cry of 'peewit.'

The Oyster-catcher (*Hæmatopus ostralegus*) has a long, straight, wedge-shaped beak, which is strong enough to enable it to force open the bivalves upon which it feeds. The Turnstones (*Strepsilas*) derive their name from the habit they have of turning over the stones along the water's edge, in order to obtain the insects and small crustacea which are found beneath them.

Connecting the Grallatores with Rasores are the Bustards (*Otidæ*), in which the legs are long, and the toes are furnished with stout claws. Their wings are large, and their flight is easy. They are entirely confined to the Old World. The Great Bustard (*Otis tarda*), which is the largest of European birds, is one of the noblest of native British birds, and one of the finest kinds of game.

Order Cursores, or Runners.

ORDER 3. *Cursores.*—In this group, the wings are quite rudimentary, and the animals included under it are destitute of the power of flight. To compensate for this, they have remarkably strong limbs for running over the plains which they inhabit. Hence their name as an order. Their feathers present some resemblance to hairs.

The Ostrich (*Struthio camelus*) is an inhabitant of the wide-spread plains of Africa and Arabia. It is incapable of flight, but is remarkable for its swiftness of foot, being able to outstrip the fleetest horse. The legs are very strong, and terminated by two toes. It is from seven to eight feet in height.

The Rhea (American Ostrich) inhabits the plains of South America. It is smaller than the

ostrich. The head is feathered, and the feet have three toes each.

Ostrich (*Struthio camelus*).

The Emeu (*Dromaius Novæ Hollandiæ*) is confined to the Australian continent, and attains the height of from five to seven feet.

The Cassowary (*Casuarius galeatus*) is a native of Molucca and New Guinea. The head, which is naked, is surmounted by a horny crest. Its height is about five feet.

The *Apteryx* is confined to New Zealand. Its rudimentary wings are concealed beneath the

Apteryx (*Apteryx Australis*).

general plumage, and each is terminated by a short claw. The beak is long, slender, and slightly curved, and the nostrils are placed at the extremity of the upper mandible. It is nocturnal in its habits, and feeds upon insects and worms. It stands about two feet in height. The fossil remains of some gigantic wingless birds have been found in New Zealand, and have been referred to the genera *Dinornis*, *Palapteryx*, and *Aptornis*. The shin-bone of the *D. giganteus* measured about three feet in length, and the bird itself must have been about ten feet in height.

Rasores, or Scratchers.

ORDER 4. *Rasores* (Scratchers)—nearly corresponding with the *Gallinaceæ*, or Poultry tribes—are land-birds of bulky bodies, generally grain-feeders, gregarious in their habits, and readily domesticable. Their flesh is savoury and wholesome, and their fecundity great. The upper mandible is vaulted, and the nostrils are pierced in a membranous scale at its base. A cartilaginous scale covers the nostril. Their legs are thick and strong, with four toes, each of which is terminated by a strong short claw suited for scratching, hence their name as an order. The heads of many of the males are ornamented with elegant crests. Almost all of them have a large crop, and an extremely muscular gizzard. In general, they construct their nests on the ground. Each male usually associates with many females; he taking no part in constructing the nest or rearing the young, and these are generally numerous, and able to run about and provide for themselves the moment they quit the shell. The young of Pigeons, however, are brought forth in a comparatively helpless condition.

They are divided into two sub-orders—1. The *Gallinacei* or *Clamatores*, the latter name being derived from the character of their cry, including the *Phasianidæ* and *Tetraonidæ*. 2. The *Columbacei* or *Gemitores*, including the Doves and Pigeons.

The *Phasianidæ* (Pheasant or Fowl Family) are distinguished by the shortness of their hind-toe, the presence of spurs on the legs, and the beautiful development of the tail. Excluding the turkey, they are birds of the Old World. The Pheasant (*Phasianus*) derives its name from the Phasis, a river of Colchis, in Asia Minor, from which district it was first introduced into Europe. The Argus Pheasant (*Argus giganteus*), inhabiting

Argus Pheasant (*Argus giganteus*).

Sumatra, has large wings covered with eye-like spots, which give this bird a remarkable appearance. The Peacock (*Pavo cristatus*) is a native of the forests of India. Alexander the Great found it flying in great numbers in India, and introduced it into Europe. Its beautiful train has made this bird a favourite in the ornamental grounds of English country mansions. The Common Fowl (*Gallus domesticus*) are supposed to have originated in the Indian Archipelago, and to have been introduced at a still earlier period into Europe. Their usefulness and general habits are too well known to require description. The Turkeys (*Meleagrinæ*) are the only representatives of this group in the New World, whence they were brought by the early discoverers, and are now quite naturalised in Europe. A more splendid species than the common one has been subsequently discovered in the Bay of Honduras. The Guinea-fowl (*Numida*) is originally a native of

Africa, where it lives in large flocks in the neighbourhood of marshes. The *Megapodidæ*, or Jungle-fowl of Australia, from the size of the feet, may be mentioned along with this group. They are about the size of a turkey, are adorned with a crest, and have strong rasorial claws. Mr Gould says they do not incubate, but deposit their eggs in mounds of mould and vegetable matter; and by the natural heat engendered in these, the eggs are hatched.

The *Tetraonidæ* (Partridge or Grouse tribe) are all of them wild birds, inhabiting uncultivated grounds in the colder climates of Europe, Asia, and North America. They are distinguished by a short hind-toe, a short tail, and comparatively dull plumage. The Red Grouse (*Lagopus Scoticus*), Blackcock (*Tetrao tetrix*), and Ptarmigan (*Lagopus vulgaris*), abound in the Highlands of Scotland; and as the objects of a favourite amusement, give a value to much ground which would otherwise be nearly useless. They feed chiefly on the seeds of wild plants. The largest species of grouse is the Capercailzie, or Cock of the Woods (*Tetrao urogallus*), once abundant in Scotland, and still so in Norway. It feeds on pine-shoots, and grows to the size of a turkey. Nearly all the grouse have the toes and legs more or less covered with soft feathers—a character which disappears in the Partridges, an extensive group, scattered in nearly all parts of the Old World, but unknown in the New. Two species of Partridges are found in Britain—the *Perdrix cinerea*, or Common Partridge, and the *P. rubra*, or Red Partridge. In the Quails (*Coturnix*), we have the miniature resemblance of partridges, but the tail is so short as to be nearly imperceptible.

The family of the *Columbidæ* contains a large number of elegant and lovely birds. They are furnished with strong wings, and are more capable of flight than the other families of the Rasores. Their feet also are more slender, and well adapted for perching. The crop has a *double* dilatation, which expands on each side of the gullet; and the young are fed with grain disgorged from this receptacle by the parent, and impregnated with a secretion which it forms. These birds live invariably in pairs; they nestle in trees or in the holes of rocks, and lay but few eggs, though they breed often. This family includes the whole of the well-known tribe of Pigeons and Doves. The Common Dovecot-pigeon is derived from the Rock-pigeon (*Columba livia*), which naturally breeds principally among the sea-cliffs, and but sparingly inland. But the Ringed-pigeon (*C. palumbus*) is of a different stock; and though it chiefly frequents the districts cultivated by man, it resists his nearer approach. The Carrier-pigeon is not a distinct species, but only a variety of the common one which has undergone a particular training. The Ground Pigeons approach the *Gallinacei* somewhat in their characters. The Crowned Pigeon (*Goura coronata*) of the Indian Archipelago is nearly as large as a turkey. It is proper to mention an extinct species of fowl nearly allied to the pigeon tribe. The Dodo (*Didus ineptus*) existed in the Mauritius till the time of Charles II.; and we only know it now from the descriptions of voyagers, and certain fragments which have happened to be preserved. It was a bird about the size of a swan, with imperfect wings, utterly useless for flight, and only a small bunch of feathers in the usual situation of the tail; a large,

Dodo (*Didus ineptus*).

strong, curved beak; and legs and feet like those of a turkey.

Scansores.

ORDER 5. *Scansores*, or Climbing-birds, are distinguished at once by the structure of their feet. The foot has four toes, two of which are directed forwards and two backwards, so that the birds are specially suited for climbing. They are not good walkers or fliers, and build their nest carelessly; indeed, some of them build no nest, but deposit their eggs in the nests of other birds. They feed on insects and fruit. They are all more or less arboreal.

The Cuckoos (*Cuculidæ*): The Common Cuckoo (*Cuculus canorus*) derives its name from its peculiar cry. It is a migratory bird, arriving in this country about the end of April. It is chiefly

Common Cuckoo (*Cuculus canorus*).

remarkable in that it builds no nest of its own, nor does it hatch its own eggs, but deposits them in the nests of other birds, such as the hedge sparrow, by which they are reared. It deposits but one egg in each nest. The bird is about the size of a pigeon, and of an ash-gray colour.

Family *Picidæ* (Woodpeckers): They are well fitted for climbing trees, and are furnished with a long extensible tongue, covered with a viscid secretion, which they insert into the chinks of timber in search of insects. They make use of their pointed, stiff tail-feathers to assist them in maintaining their position. The Green Woodpecker (*Picinus viridis*), the Greater Spotted Woodpecker (*Dryobates major*), and the Lesser Spotted Woodpecker (*D. minor*), are constantly

resident in Britain. The Wryneck (*Yunx torquilla*) belongs to this family. In England it is called the Cuckoo's Mate, because its arrival and departure coincide pretty nearly with those of the cuckoo.

The *Psittacidæ* (Parrots) are a very extensive family, diffused over the torrid zone, and scarcely known beyond it. Their beak, which they use to assist them in climbing, is stout and large, the upper mandible being longer and larger than the lower, and hooked at its extremity. Their tongue is soft and fleshy. Their feet are specially suited for grasping and climbing. They live for the most part upon succulent fruits. Their larynx or organ of voice is very complicated, so that they can imitate the human voice as well as other sounds. They are nearly all adorned with gorgeous colours, and have been divided into several groups. The True Parrots (*Psittacinæ*) have square tails and no crests, and are found in the hot parts both of the Old and New World. The Cockatoos (*Cacatuinæ*) are also square-tailed, but have crests upon their heads. The white ones inhabit the Indian Archipelago and Australia. The Paroquets (*Pezoposinæ*) have a long-pointed tail, and chiefly inhabit Asia and Australia. The Macaws (*Arainæ*) are exclusively American, and

Macaw (*Ara ararauna*).

are superbly coloured. The Lories (*Lorinæ*) are oriental species, with dense soft plumage, and most gaudily coloured.

The Toucans (*Ramphastidæ*) have bills of enormous size, but the mandibles are to a great extent hollowed out and filled with air. They live upon fruits, and are confined to the warm regions of America. They are in general black, with lively colours on the throat and breast.

Insessores.

ORDER 5. The *Insessores*, or Passerine Birds (Perching-birds)—comprehends an immense number of species, whose characters seem principally negative; for it embraces those birds which are neither swimmers, waders, climbers, rapacious, nor gallinaceous. They have short and slender legs, with three toes before, and one behind. As a rule, the females are smaller, less brilliant in plumage, and less melodious than the males. They are, generally speaking, mixed feeders. They live in pairs, and their power of flight is considerable, and they display great art in the construction of their nests. Many of them are distinguished by their powers of singing. The sub-orders are founded on the form of the beak.

Sub-order 1. *Conirostres*—in which the beak is strong and conical, being broad at the base and tapering towards the apex. They are omnivorous, though a few are graminivorous. The order includes several families.

Family *Corvidæ:* The Common Crows are the most characteristic examples, and have long, strong, and compressed beaks. These animals are constructed for powerful flight, as well as for walking on the ground. They feed indiscriminately on animals or vegetables. They are bold, but wary, live in common societies, and possess great courage. Under the general term Crow are included the Raven (*Corvus corax*), which is the largest of European perching-birds; the Carrion Crow (*C. corone*), which is so destructive to eggs and young game; the Rook (*C. frugilegus*), which chiefly feeds upon grubs; the Hooded Crow (*C. cornix*), which feeds upon molluscs, &c. upon the sea-shore; and the Jackdaw (*C. monedula*), which lives in deserted buildings, but is troublesome on account of its propensity to secrete any small article of value that comes in its way. The Magpies (*Pica caudata*) and Jays (*Garrulus*) are nearly allied to the Crows. The Chough (*Frigilus graculus*) is closely allied to the Crows, but differs from them in having the bill notched at the top. The *Paradiseidæ* (Birds of Paradise) must be classed along with this family, although

Bird of Paradise (*Paradisea apoda*)—male.

they differ considerably from the ordinary *Corvidæ*. They are confined to New Guinea and the neighbouring islands. They feed upon insects and soft fruits, and are captured for their plumage, the extraordinary development of which is well known. The brilliant plumage is confined to the male.

The natives who captured them cut off their legs, so that, for a long time, it was supposed they were destitute of these appendages.

The family of the Starlings (*Sturnidæ*) closely resemble the crows, though they are weaker birds. The only species resident in Europe is the Common Starling (*Sturnus vulgaris*). It includes a number of curious birds, among them the *Icterinæ*, or Hang-nests of South America, which build long purse-like nests, suspended from the slender branches of lofty trees. It also includes the singular Bower-birds of Australia, which construct an elaborate bower, which serves as a sort of playing-ground, and where the birds make love to each other.

The *Fringillidæ* (Finches) are the smallest of this group of perching-birds, and are known by the shortness and strength of their conical bills. The Chaffinches (*Fringilla cœlebs*), Linnets (*Linota cannabina*), Goldfinches (*C. elegans*), Bullfinches (*Pyrrhula vulgaris*), Buntings (*Emberiza*), Sparrows (*Passer domesticus*), and Larks (*Alaudinæ*), all belong to this family. The Canary (*Carduelis canaria*) was originally imported from the Canary Islands. The Weaver-birds (*Ploceinæ*) of tropical climates construct remarkable nests of blades of grass interwoven together.

The *Buceridæ* (Hornbills) are confined to the Old World. They have a huge excrescence on the upper mandible, which is rendered light by the presence of spaces filled with air.

The *Loxiadæ* (Crossbills) are distinguished by a strong curvature of the mandibles, causing their tips to pass each other—a peculiarity which gives them a great advantage in extracting their favourite food, the seeds of the pine-cones.

Sub-order 2. *Dentirostres*—have a notch in the lower margin of the upper mandible near the tip. Although their food consists principally of insects, some of them are carnivorous.

The Shrikes (*Laniidæ—lanius*, a butcher) are highly predaceous, and they kill their prey, which consists of small birds, mice, &c. by repeated blows of the bill on the head. They are commonly called Butcher-birds.

The Fly-catchers, or *Muscicapidæ* (*musca*, a fly, and *capio*, I take), have a depressed beak, armed with bristles at the base. They are migratory, as they must be to obtain their prey. Two species are found in Britain, the Spotted Fly-catcher (*M. griseola*), and the Pied Fly-catcher (*M. luctuosa*).

Of the Thrushes (*Merulidæ*), the Blackbirds (*Turdus merula*) and the Fieldfares (*T. pilaris*) are well-known examples. Of the Thrushes, the best known are the Song-thrush or Mavis (*T. musicus*), the Ring-thrush (*T. torquatus*), and the Redwing (*T. iliacus*), all of which are found in Britain. The Mocking-birds (*Mimus polyglottus*), which are restricted to America, are remarkable for the singular gift of imitating the cries of many other birds. The Orioles are migratory birds, which frequent Southern Europe, where they build their curious hanging nests. The Dipper, or Water Ousel (*Cnidus aquaticus*), also belongs to this group.

The Warblers (*Sylviadæ*) are the most musical of European birds, including the Wagtails (*Motacilla*), Titmice (*Parniæ*), Hedge-sparrows (*Accentor*), Redbreasts (*Erythacus*), &c. The Nightingale (*Philomela luscinia*) is a migratory bird, which visits England in April, and leaves it in August. It builds on trees, and does not sing till the young

Nightingale (*Philomela luscinia*).

ones are hatched. The notes which it then gives forth have in all ages been a theme of admiration.

Sub-order 3. *Tenuirostres* (Slender-billed birds)—are known by possessing a long slender beak, tapering to a point. Their toes are long and slender. Most of them live on insects, though others subsist on the juices of flowers.

The *Meliphagidæ* (Honey-suckers) are chiefly confined to Australia. Their tongue is terminated by a bunch of fine filaments, and the hind-toe is so strong that it serves as a support to the bird while feeding.

The *Trochilidæ* (Humming-birds), so celebrated for the metallic lustre of their plumage, are pre-eminently South American. They have within their long slender beak a bifid tongue, suited for catching insects within the corollas of flowers, or of sucking the juices of the flowers themselves. When hovering over flowers, these birds balance themselves in the air by a rapid motion of the wings, and it is by this movement that the *humming* sound is produced from which they take their name. Some of them do not weigh more than twenty grains when alive. More than 170 species are known.

The family of the *Certhidæ* (Creepers) includes the Nuthatch (*Sitta Europæa*), the Brown Creeper (*Certhia familiar*), and the familiar little Wrens (*Troglodytes*). It also includes the singular Lyre-bird of Australia (*Menura superba*), so called from the peculiar arrangement of its tail-feathers.

The Sun-birds (*Promeropidæ*) represent the humming-birds in the Eastern continent. They are small birds, and the males have the most brilliant colours, rivalling those of the humming-birds, during the breeding season; but the garb of the female, and of the male at other parts of the year, is much more dull.

The Hoopoes (*Upupidæ*) are restricted to the Old World. The Common Hoopoe (*Upupa epops*) annually visits Europe in company with the Bee-eaters.

Sub-order 4. *Fissirostres* (Cleft-beaks)—have the beak deeply cleft, which gives a wide gape, and fits these birds for catching insects on the wing. The gape is usually furnished with bristles, which greatly facilitates the capture of their prey.

The family *Hirundinidæ* (Swallows) are well-known summer visitors of Britain. Their movements in flying are vivid and irregular. The feet

have three toes before and one behind, and all four are armed with strong claws, giving the animal the power of clinging to the faces of perpendicular rocks and buildings. The Martin (*Hirundo urbica*) builds its mud-nest in the sheltered angles of buildings.

The Swifts (*Clypselidæ*) differ from all other birds in having all the four toes directed forwards. The Common Swift (*C. opus*) possesses more enduring powers of flight than the swallow, which is often seen on its long journeys to fall wearied into the sea. The nest of a species of swallow (*Collocalia esculenta*), from the Indian Archipelago, is used by the Chinese for making soup. The nests are composed of a mucilaginous substance, which is secreted by greatly developed salivary glands, and is more or less mixed with grass and other similar materials.

The Goat-suckers (*Caprimulgidæ*) have large eyes, a soft plumage, and fly in the dusk, and

Common Goatsucker (*Caprimulgus Europæus*).

feed on insects, which they seize on the wing. They derive their name from the absurd belief of the ancients, that they injured the teats of goats in their attempts to suck them. Only one species (*C. Europæus*) is found in Britain. It arrives from Africa in May, and takes its departure in September.

The Bee-eaters (*Meropidæ*) are so named because they feed on bees, which they pursue much in the manner of swallows. In spring, they cross the Mediterranean from Africa to the south of Europe, where they breed.

The Kingfishers (*Alcedinidæ*) are generally natives of warm climates. The Common Kingfisher (*Alcedo ispida*) lives upon small fish, and may be seen perching on the stump of a tree which overhangs a stream, watching the minnows, on which it darts with unerring aim. It then returns to its perch, beats its victim to death, and swallows it. The Laughing Jackass (*Dalas gigas*) of Australia, whose song resembles a lengthened hysterical laugh, belongs to this family.

Raptores, or Birds of Prey.

ORDER 6. The *Raptores*—are designed to feed on the weaker animals of their own and other tribes. Their bill is strong, hooked, and sharp pointed. Their talons are sharp, and more or less retractile. They are very muscular birds, and strong on the wing. The female is larger than the male. They form pairs, live solitarily, and do not breed large families. This order comprises two sections.

Section 1. *Nocturnal Raptores*—which hunt by night, and have the eyes directed forward. It includes the single family *Strigidæ* (Owls). They hunt their prey by night, and their flight is noise-

1. Great Eagle or Owl (*Bubo maximus*); 2. Long-eared Owl (*Otus vulgaris*); 3. White or Barn Owl (*Strix flammea*); 4. Foot of Snowy Owl (*Strix nyctea*).

less, as their feathers are very loose and soft. Owls in ancient times were regarded as emblems of wisdom. This family contains only a single genus—*Strix*, which is divided into two sections—Horned or Eared Owls, which have a tuft of long feathers on each side of the forehead; including the Long-eared Owl (*Otus vulgaris*), and the Short-eared Owl (*O. brachyotus*), which are British species; and the Horned Owl (*Bubo maximus*), which is common in the forests of Europe; and the Smooth-headed Owls, which are destitute of these appendages, represented by the Barn Owl (*Strix flammea*), which subsists upon mice and small birds, which it swallows whole. The bones and other indigestible parts are afterwards disgorged in small pellets.

Section 2. *Diurnal Raptores*—in which the eyes are placed laterally, and smaller than in the former group, and the plumage is not soft.

The *Falconidæ* or *Accipitrinæ* (Hawks, Falcons, Eagles) have the upper mandible notched, and their claws strong and retractile. The head and neck are always clothed with feathers. Their flight is graceful, and their courage very great. The Falcons proper (*Falconidæ*) are specially adapted to pursue and bring down their prey on the wing. The Eagles (*Aquilinæ*) are the largest and most powerful of the whole group, and pursue and destroy quadrupeds as well as birds. Their legs are feathered quite down to the toes. They build their nests in lofty and secluded situations, among mountains and precipices, and resist with great courage any attack upon their young. The Hawks, Harriers (*Circinæ*), and Kites (*Milvinæ*) also belong to the family. The Kites have the power of hovering balanced on their wings for a longer time than any of the known birds. The Osprey (*Pandion Haliaëtus*) is aquatic in its habits, living upon the sea-shore, and subsisting principally on fish. It is at once distinguished by the roughness of the under surface of the foot, which assists it in holding its slippery prey.

In the family *Vulturidæ* (Vultures) the eyes are destitute of an eyebrow, and the head and neck are either naked or covered with a short down. Their food consists chiefly of dead carcasses and offal, with which they often gorge themselves to such an extent that they are reduced to stupidity. In hot climates, they are of great service in consuming putrefying bodies, which would otherwise infect the air. No sooner is an animal dead, than its carcass is surrounded by numbers of these birds, which suddenly appear, coming from all quarters, in situations where immediately before not one had been seen. The Bearded Vulture (*Gypaëtus barbatus*), or Lämmergeyer of the Swiss

Lämmergeyer (*Gypaëtus barbatus*).

and German Alps, the largest of the European birds of prey, measures nine or ten feet in the

Secretary Bird (*Serpentarius secretarius*).

expanse of its wings. It feeds upon goats, sheep, &c. which it kills by precipitating them down steep declivities. The Griffon, or Golden Vulture (*V. cinereus*), is also common in the Alps. These species differ from the true Vultures in having the head and neck feathered.

The Condor (*Sarcoramphus*), the king of the Vulture tribe, is peculiar to the Andes. The extent of its wings when expanded is from ten to twelve feet. Borne on these wide-spread pinions, the Condor ascends higher than any other bird, being sometimes found at an elevation of 10,000 or 15,000 feet above the level of the ocean. The Common Secretary Vulture (*Serpentarius secretarius*) of the Cape of Good Hope and the Philippine Islands, derives its name of Secretary from the feathers at its ear presenting the appearance of a pen. Its neck and legs are much lengthened, and it subsists upon poisonous reptiles, hence its generic name. The *Neophron Percnopterus*, or Egyptian Vulture, which is common in the northern part of Africa, subsists entirely upon carrion.

ORDER 8. *Saururæ.*—This order includes only the extinct bird, the *Archæopteryx macrura*, the

Remains of *Archæopteryx* in Solenhofen Stone.

remains of which were found in the lithographic Solenhofen slate (Upper Oolite). It was about the size of a rook, and differed from all known birds in having twenty caudal vertebræ, each of which supported a pair of quill-feathers, and in having two free claws belonging to each wing.

CLASS V.—MAMMALIA, OR SUCK-GIVING ANIMALS.

The Mammalia are universally regarded as the highest group in the Animal Kingdom; because they possess the most complex organisation, adapted to perform the greatest number and variety of actions, and to execute these with the

greatest intelligence. They have a double circulation, and warm blood, and breathe by lungs; but the air-tubes terminate in the air-cells of the lung, and do *not* open on the surface of the lungs as in birds. The skull is articulated to the backbone by two occipital condyles, and the cavities of the thorax and abdomen are separated by a partition or diaphragm, which is not the case in birds. They produce their young alive, and nourish them by a special fluid, the milk, secreted by special glands—the mammary glands, hence the name of the class. Further, some part of the skin is provided with *hair* at some period or other of the animal's life.

Naturalists, in seeking to classify the Mammalia, have to look chiefly to those indications which the teeth, extremities, and other external characters furnish, regarding the general habits and dispositions of the several animals. Thus, keeping out of view minor distinctions, the possession of sharp fangs and claws is a clear mark of carnivorous habits; flat-topped teeth and hoofs, equally a proof of a gentle and herbivorous character. The flapper of the whale shews a fitness for progression in the sea; the development of a wing on the hand of the bat, a design that the animal should make its way through the air.

Teeth are present in most of the Mammalia, and their form, number, and mode of arrangement yield important characters in the classification of this class. In man and most mammals there are two distinct sets of teeth—one set which appears shortly after birth, and which are termed the *milk* or *deciduous* teeth, and a second set, which, after a few years, replaces them, termed the *permanent* teeth. There are four kinds of teeth (permanent set) met with in the jaw of a typical mammal, such as a dog. They are, the *incisors*, which are implanted in the pre-maxillary bones, and in the corresponding part of the lower jaw; the *canines*, or eye-teeth, those next to them in order backwards; the teeth which displace the deciduous molars or grinders are called *premolars;* and the most posterior teeth, which are not displaced, are the true *molars*, which are not represented in the deciduous set. For briefly expressing the number of teeth in any mammal, a *dental formula* is employed. The permanent teeth in man are represented by the formula:

$$\text{I.}\ \frac{2-2}{2-2},\ \text{C.}\ \frac{1-1}{1-1},\ \text{P.}\ \frac{2-2}{2-2},\ \text{M.}\ \frac{3-3}{3-3} = 32;$$

where the letters stand for the four kinds of teeth enumerated above, and where the two terms in each nominator and in each denominator represent the number of each particular kind of tooth in each half of the upper and lower jaw respectively. All the teeth are implanted in distinct sockets in the lower jaw.

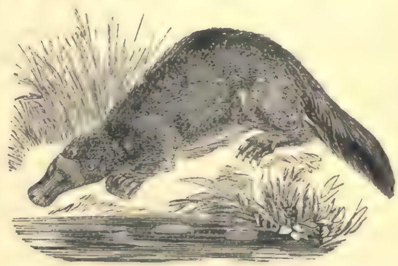
Owen classified this group according to the structure of their brains, and De Blainville founded his leading subdivisions upon the structure of the reproductive organs. The Mammalia are primarily divided into two sections:

Section I.

Implacentalia, including the following two orders, where there is no vascular connection (*placenta*) between the fœtus and the mother, and the young are brought forth in a very immature state of development.

ORDER 1. The *Monotremata* (*monos*, single, *trema*, an aperture)—so named because, as in birds, the excretory organs are united into one—are exclusively Australian, and are represented by two genera.

The Spiny Ant-eater (*Echidna*) is about the size of, and somewhat resembles a hedgehog, has a prolonged snout, and its back is armed with spines. It has no teeth, and its food consists of ants, which it entraps with its long adhesive tongue. It is represented by two species (*E. hystrix* and *E. setosa*). The *Ornithorhynchus* (*ornis*, a bird, and *rygchos*, a beak), or Duck Mole, is so called from its bird-like snout. There is only a single species, *O. paradoxus*. Its body is about the size of



Duck-billed Platypus (*Ornithorhynchus paradoxus*).

a small otter, and is covered with dense fur. The legs are short, and the feet have five toes each, armed with strong nails suited for burrowing. The toes are united by a web, so that the animal can swim. It has no teeth, and its skull bears a strong resemblance to that of a bird. It burrows in the banks of tranquil rivers, and obtains its food by the capture of small aquatic animals.

ORDER 2. *Marsupialia*, or Pouched Animals (*marsupium*, a pouch), derives its name from the remarkable provision which is made for the young after their immature birth. The skin of the parent is so disposed as to form a pouch into which the teats project, in which the immature young are placed after birth, where they remain attached to the teats until they acquire a degree of development comparable to that with which other animals are born. The angle of the lower jaw is always turned inwards.

The geographical range of this order is extremely peculiar. With the exception of the Opossums, which inhabit America, its species are at present almost confined to Australia and the neighbouring islands, where they constitute, with the Monotremata, almost the only mammiferous animals. They have been divided by Owen into families according to their predominating food.

(A.) *Rhizophaga*, or Root-eaters, as the Wombat, which exhibits a curious resemblance to the herbivorous Rodents in its dentition and in its alimentary canal. The Wombat (*Phascolomys fossor*) is about the size of a badger, by which name it is known to the colonists, and is a native of Tasmania. It is a sluggish and nocturnal animal, which burrows in the forests and low grounds, and feeds upon the tougher kind of vegetable substances.

(B.) *Poephaga*, or Grass-eaters, have long incisors, the canines generally wanting, and a complex intestinal canal like herbivorous mammalia. It includes the Kangaroos and the Kangaroo-rat, all of which are inhabitants of Australia and the neighbouring countries. The Kangaroos are remarkable for the enormous length of their hinder feet, whence their generic name, *Macropus* (long-footed), is derived. The hind-legs and tail are also very largely developed; whilst the fore-legs and feet are very small. From this great inequality in the size of the limbs, they advance on all-fours very slowly; but they can make immense leaps with the hind-legs, the tail probably assisting them. The dental formula is:

$$\text{I.}\ \frac{3-3}{1-1},\ \text{C.}\ \frac{0-0}{0-0},\ \text{P.}\ \frac{1-1}{1-1},\ \text{M.}\ \frac{4-4}{4-4} = 28.$$

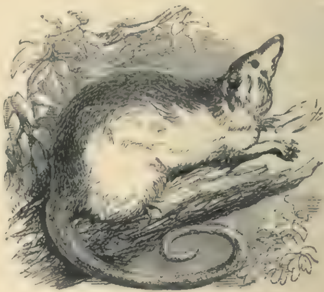
The young ones reside in the maternal pouch until they are able to graze for themselves. The

Great Kangaroo (*Macropus giganteus*).

largest species is sometimes six feet in height, having the bulk of a sheep, and weighing 140 pounds. Its flesh is used as food by the native Australians. The Kangaroo-rat (*Hypsi prynnus*) is a nocturnal animal about the size of a small rabbit. It has canines in the upper jaw.

(C.) *Carpophaga*, or Fruit-eaters, have large and long incisors in both jaws, the canines sometimes absent, and a complicated intestinal canal. They are peculiarly adapted to live among trees, on which they seek their food. The *Petaurus* (Flying Phalanger) of Australia possesses an extension of the skin on each side of the body, between the anterior and posterior limbs, by the help of which it is enabled to take extensive leaps from tree to tree. Like the flying squirrels, they have no true power of flight. It is a nocturnal animal, with a delicate fur. The Phalangers (*Phalangistidæ*) are so called because the second and third digits of the hind limb are joined together almost to their extremities. The Australian Opossum (*Phalangista vulpina*) is hunted for its flesh, which is considered a great delicacy. The *Pholascolarctos*, or 'Koala,' or native sloth' of New Holland, which is nocturnal in its habits, has the gait and carriage of a young bear, and passes its life upon trees.

(D.) *Entomophaga*, or Insect-eaters, have canine teeth in the jaws, and prey on the weaker classes of invertebrate animals. Some live on the ground; while others, such as the opossum, ascend trees in search of food. The Opossum tribe are extensively diffused over, and belong exclusively to, America. They have a long prehensile tail, and the thumb is opposable to the other digits.



Virginian Opossum (*Didelphys Virginiana*).

They are nocturnal animals of slow gait, and nestle upon trees, where they pursue birds, insects, &c. without rejecting fruit. The Virginian Opossum (*Didelphys Virginiana*) is about the size of a cat. The dental formula is:

$$\text{I.}\ \frac{5-5}{4-4},\ \text{C.}\ \frac{1-1}{1-1},\ \text{P.}\ \frac{3-3}{3-3},\ \text{M.}\ \frac{4-4}{4-4} = 50.$$

In some species of opossum, only the vestige of a pouch is present; in these cases, the female supports her young by entwining her tail with theirs. The Banded Ant-eater (*Myrmecobius fasciatus*), remarkable for its large number of molar teeth, and the Bandicoots (*Paramelidæ*) of Australia, also belong to this group.

(E.) *Sarcophaga*, or Flesh-eaters, fill the place held by the carnivora in other parts of the world. Their canines are long and pointed, and their molars are set with cusps, and their stomach is simple. The *Thylacinus* is about the size of a wolf, is a native of Tasmania, and is called the 'hyæna.' The *Dasyurus*, or 'native devil,' is also found in Tasmania, and though smaller than the former, it is very predaceous, destroying sheep, and even invading houses.

Section II.

Placentalia—where the young before birth are connected with the mother by a *placenta*, and are brought forth in a comparatively advanced stage of development. The placenta is 'a structure which is developed by the interlacement of the vessels of the offspring with those of the parent, and by means of which the former is enabled to receive nourishment, and to get rid of effete matters.' The brain also in this section is better developed than in the *Implacentalia*. It includes all the remaining orders of the Mammalia.

ORDER 3. *Edentata*—derive their name from the fact, that in all (with one exception) the incisor teeth are absent. The teeth are simple in structure, and have no roots. Their feet are furnished with long and powerful claws.

The family of the *Myrmecophagidæ*, or Ant-eaters, have a pointed muzzle, with a long, glutinous tongue, admirably adapted for catching burrowing insects, such as ants. The best known is the *M. jubata*, or great Ant-eater, which feeds upon ants. Its body is covered with hair, and its jaws are without teeth. They belong to South America. Nearly allied to this group is the Pangolin (*Manis*), or Scaly Ant-eater, which is confined to Asia and Africa. Its tongue resembles that of *M. jubata*, but its body is clothed with overlapping scales, which constitute a defensive armour when the animals roll themselves up into a ball, as they do when alarmed. Another family of the Armadillos (*Dasypodidæ*), are remarkable

Armadillo (*Dasypus sexcinctus*).

for the dense armour of hard scales arranged in tranverse rows with which they are covered. The molar teeth in *D. gigas* exceed ninety in number. They have short legs, and long and powerful claws suited for burrowing. A colossal extinct form, *Glyptodon*, has been found in South America. It had no bands in its armour, so that it was unable to roll itself up, as the Armadillos do. They feed chiefly on insects, and are confined to South America. The *Bradypodidæ*, or Sloths, have a round head and short face, and the body covered with hair. Their forearms are very long, and armed with long claws, by which the animal is enabled to suspend itself back downward from the trees on which it lives. While walking, and even in sleep, they retain this peculiar position.

Three-toed Sloth (*Bradypus trydactylus*).

They seldom leave a tree unless compelled through force or accident. They are exclusively South American. Fossil remains of two very large animals in this family have been discovered in America—the Megatherium, Megalonyx, and Mylodon—nearly equalling the elephant in size.

ORDER 4. *Cetacea* (Whales)—are in general bulky animals, with a fish-like form, and adapted for an aquatic life. The anterior extremities are fashioned into paddles or 'flippers,' for progression; the posterior pair are absent. The tail is a powerful, *horizontally* flattened organ (the tail of fishes being flattened vertically), which enables the animal to rise from the depths of the ocean to take a breath on the surface, or to dive suddenly below. Underneath the naked skin is a layer of fat or 'blubber,' forming at once an elastic padding, to enable the animal to resist the pressure of the sea at great depths, and a comfortable wrapping, to save its natural heat from escaping into the cold element amidst which it lives. Whales are captured principally for the oil which this blubber yields. Another feature of the whales is the situation of the nostrils terminating at the crown of the head, and forming the *spiracles* or 'blow-holes.' The phenomenon of 'blowing' is caused by the sudden condensation in a cold atmosphere of the watery vapour contained in the expired air.

The family of the *Balænidæ* (Whalebone), or Toothless Whales, which sometimes attain the length of 70 feet, are characterised by the total absence of teeth in the adult, although teeth which never cut the gum are present in the fœtus. Their place is supplied by a series of horny plates, arranged round the jaws, and forming simply a *strainer*. The animal, having taken in a huge mouthful of water, containing small animals, expels the water through this apparatus, leaving the prey behind, which is then swallowed. From this *baleen*, as it is called, is derived the article in common use under the name of *whalebone*. It gives a generic name to the group of animals possessing it. The Common Whale (*Balæna*

Greenland or Right Whale (*Balæna mysticetus*).

mysticetus) is an inhabitant of the Arctic Seas, and its capture is the subject of a great trade. The sailors transfix it with a harpoon, to which a line is attached, and when it rises exhausted to the surface, they kill it, and extract the blubber. The great danger of this business is from the tail of the whale, which is quite able to upset a boat, or even to cut it in two. The Rorqual (*Balænoptera*)

is another species, in the same seas, different chiefly in being longer, with a more slender body. Its whalebone is comparatively valueless.

The family of the *Physeteridæ* (Cachelot or Spermaceti Whales) are inhabitants of the Southern Ocean. They have teeth in the lower jaw, but have no baleen. The best known is the Spermaceti Whale (*Physeter macrocephalus*), from a cavity in the head of which the substance called spermaceti is obtained. They are distinguished by the bulk of their heads, in which a surprising quantity of fat is lodged.

The *Delphinidæ* are smaller animals, generally seen in droves, and are very active and lively in the water. They have teeth in both jaws. The Dolphin (*Delphinus*) and Porpoises (*Phocœna*) belong to this group. The latter are often seen on our shores, to which they come in pursuit of herrings. The Narwhal (*Monodon monoceros*), or Sea-unicorn of the Arctic Seas, has one of the upper incisor teeth developed to the length of six feet, forming a formidable weapon, which is spirally twisted, and grows throughout the life of the animal.

The *Sirenia*, or Sea-cows, correspond with the true whales in the important character of the absence of the posterior extremities, and for convenience may be placed in the same order. The Dugongs (*Halicore*) of the Indian Ocean—the Manatees (*Manatus*) of the Gulf of Mexico—belong to this group. They are herbivorous, living upon submarine plants. They are supposed, from the resemblance which their face and head, when seen above water, presents to the human lineaments, to have given rise to many of the stories regarding mermaids.

ORDER 5. *Ungulata*, or Hoofed Animals—includes the two old orders, *Pachydermata*, or thick-skinned animals, such as the rhinoceros and pigs; and the *Ruminantia*, such as sheep and goats. There is an exceedingly large number of genera and species, and they all present the following characters: All the four limbs are present, and are only useful for support and progression; hence they are destitute of clavicles. There are never more than *four* toes to each foot, and the part of the foot touching the ground is encased in a *hoof*. The molar teeth are broad crowned, and suited for grinding vegetable substances. This order is divided into two sections.

Section 1. *Perissodactyla*—in which the toes or hoofs are *odd* in number (one or three). The animals comprised under this section further agree in having the hind-foot odd-toed in all, and the fore-foot in all except the Tapirs. The thigh-bone has a third trochanter. If horns are present, they are placed in the middle line of the body, and have never a bony core. The stomach is simple, and the cæcum is capacious.

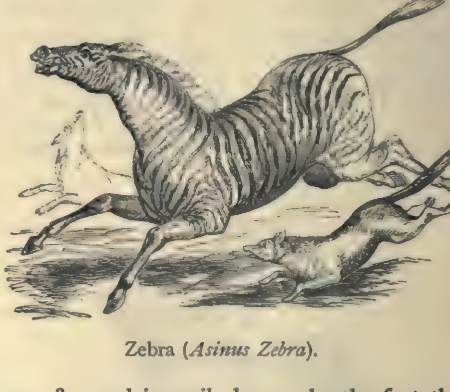
Family 1. *Rhinoceridæ*.—The Rhinoceros is a bulky animal, with a thick skin, which is generally thrown into folds. Its head is furnished with a horn, composed of agglutinated hairs placed in the middle line of the snout. Sometimes a second horn is present; if so, it is placed *behind* the first. They are ferocious, frequenting marshy places, and living on herbage and branches of trees. Several species are known in the tropical parts of the Old World. The best known are the Indian Rhinoceros (*R. Indicus*), and the African form (*R. bicornis*), which is found in the south of Africa. An extinct species, the Wool Rhinoceros (*R. tichorhinis*), formerly existed in England. Its bones are frequently found fossil in caves, such as

Rhinoceros (*Rhinoceros Indicus*).

Kirkdale cave in Yorkshire. The Hyrax, which is about the size of a rabbit, is nearly allied to the rhinoceros. It is found in Syria and Africa, and is supposed to be the 'cony' of Scripture.

Family 2. *Tapiridæ*.—In the Tapirs, the fore-foot has *four toes*, which are unsymmetrical, and the hind-foot has three, all encased in hoofs. The tapirs have a thick hairy skin, a short movable trunk, and a short tail. The Tapir of America (*T. Americanus*) is about the size of an ass, is brownish-black in colour, is strictly herbivorous, and is nocturnal in its habits. The fossil *Palæotherium*, from the gypsum quarries of Eocene age, near Paris, is an allied but larger species, but all the feet have three toes each.

Family 3. *Solidungula*, or *Equidæ*.—This family comprises the Horse, Ass, Zebra, Quagga,



Zebra (*Asinus Zebra*).

Onaga, &c. and is easily known by the fact that each foot has only a single perfect hoof. The dental formula is:

$$\text{I. } \frac{3-3}{3-3}, \text{ C. } \frac{1-1}{1-1}, \text{ P. } \frac{3-3}{3-3}, \text{ M. } \frac{3-3}{3-3} = 40.$$

In the males, canines exist in the upper jaw; but they are absent in the female. From the species of horse, *Equus caballus*, all the varieties of horses are descended. It is a native of Central Asia. The Ass (*Asinus*) and Horse are noted for

their usefulness to man as beasts of burden, docility and strength being combined in them in a remarkable manner.

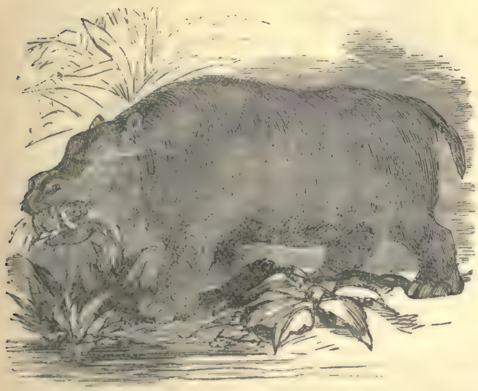
Section 2. *Artiodactyla*—in which the toes or hoofs are *even* in number (two or four). There is no third trochanter to the thigh-bone. When true horns are present, they are paired, and supported by a bony cover. The stomach is complex, and the cæcum is small.

Sub-section Omnivora.

Family 1. *Hippopotamidæ.*—This group contains but one genus, the *Hippopotamus*, or River-horse, &c. It is a massive and unwieldy animal, about 11 feet in length, with a thick skin, which is furnished with a few hairs. Its muzzle is blunt, and its head large. Three kinds of teeth are present in each jaw, the dental formula being :

$$\text{I. } \frac{2-2}{2-2} \ \text{C. } \frac{1-1}{1-1}, \text{M. } \frac{6-6}{6-6} = 36.$$

The canines are very large, and the crowns of its molar teeth are adapted for grinding roots and vegetable substances. The feet have four toes each. Only one species is known (*H. amphibius*), which is confined to Central and Southern Africa.



Hippopotamus (*Hippopotamus amphibius*).

Family 2. *Suida*, or Pig tribe, are characterised by their thick skin, and by the presence of only two functional toes to each foot, the other two toes being rudimentary, and placed some distance above the ground. There are three sorts of teeth in each jaw, and in the males the canines project forward as tusks. The snout is rounded, and resembles a truncated cone. Their food is principally vegetable. The domesticated pig is an omnivorous animal. The Wild Boar (*Sus scrofa*) is a ferocious animal, which abounds in some forests of Europe, and is probably the source from which our domestic breeds are derived. In the Babyroussa (*S. babyrussa*) of the Indian Archipelago, the upper canines are very long, and grow spirally upwards and backwards, and serve as offensive and defensive weapons. In South America this family is represented by the Peccaries (*Dicotyles*), which want the external toe on the hind-feet, of which the commonest species is the Collared Peccary (*D. torquatus*).

The fossil *Anoplotheria*, from the Eocene rocks, exhibited a transition between the *Suida* and the *Ruminantia*. They were slender of form, and the dental formula is :

$$\text{I. } \frac{3-3}{3-3}, \text{C. } \frac{1-1}{1-1}, \text{M. } \frac{7-7}{7-7} = 44.$$

Their peculiarity is that the molars come close to the canines, without leaving an interval, a mode of arrangement found nowhere amongst Mammalia except in man himself.

Sub-section Ruminantia.

Ruminantia, or Ruminant Animals, are the most natural and best determined group of the mammalian class. In a typical ruminant (ox, sheep), there are no incisor teeth in the upper jaw, their place being taken by a hardened pad of gum, against which the lower incisors impinge. In the upper jaw there are only six molars on each side, with double crescentic ridges of enamel, which aid in masticating, but no canines. There are eight incisors in the lower jaw, behind which is a space, and then come six molars on each side. The feet are each terminated by two toes and two hoofs, which present a flat surface to each other, appearing as though a single hoof had been cleft ; hence the names that have been applied to these animals of 'cloven-footed,' &c. There are also usually two vestiges of lateral toes placed at the back of the foot.

The name of the order intimates the singular faculty possessed by these animals of masticating their food a second time, or 'chewing the cud.' This faculty depends on the structure of their stomachs, which are four in number. The food, which is cropped by the incisor teeth, is swallowed almost without mastication, and is moistened in the first stomach or *paunch*. It then passes into the *reticulum*, or honey-comb bag, whose inner surface is divided by ridges into a number of hexagonal cells (hence the name), where, after being rolled into pellets or *cuds*, it is returned into the mouth, to be rechewed while the animal is at rest. It is then swallowed a second time, but this time it goes into the *omasum*, or 'many-plies,' so called because its lining membrane is thrown into folds resembling a book ; finally, it passes into the last cavity, or *ab-omasum*, and then into the intestine, which is of great length. Taken as a group, these animals are timid, and destitute of powerful means of defence against their foes. When feeding, they are liable to many alarms ; and if they were compelled to spend a considerable time in masticating their food before swallowing it, they would often have to leave their pasture before their wants are supplied. They convey a store of food into the first stomach, and then retiring to a secure place, they prepare it for digestion at their leisure.

The Ruminants are, of all animals, the most useful to man. They supply him with a large proportion of his animal food. Some serve him as beasts of burden ; others furnish him with their milk, their tallow, hair, leather, horns, and other useful products.

(A.) The *Camelidæ*, or Camel tribe, differ from the typical Ruminants in having two incisors in

the upper jaw, and canines in both jaws, the dental formula being:

$$\text{I.}\ \frac{1-1}{3-3},\ \text{C.}\ \frac{1-1}{1-1},\ \text{P.}\ \frac{3-3}{3-3},\ \text{M.}\ \frac{3-3}{3-3} = 36.$$

Their head is destitute of horns.

In the true Camels, which are peculiar to Asia and Africa, the two toes are united below by a kind of horny sole, almost to their points, which terminate in small hoofs; and there is a soft cushion beneath the foot, by which it bears upon the sandy surface over which it is formed to move. Two species are known—one called the Bactrian (*Camelus Bactrianus*), or Two-humped

Camel (*Camelus Bactrianus*).

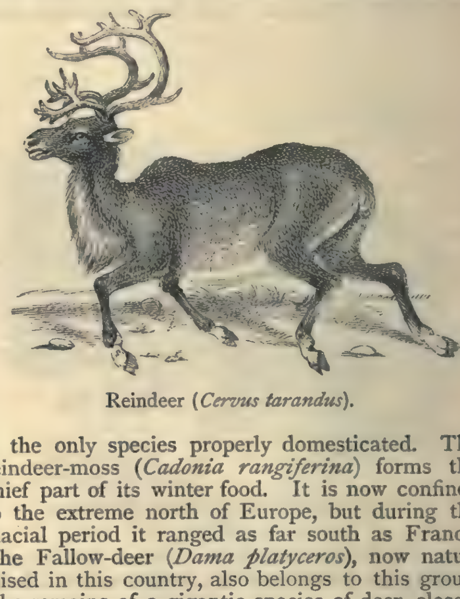
Camel, and the other the Arabian (*C. dromedarius*), or One-humped. Both are completely domesticated, and their utility as beasts of burden is universally known. The Two-humped Camel is the larger and stronger, being capable of sustaining a burden of above 1000 pounds, and is best adapted for rugged ground. The other is the most abstemious, and the best fitted for the sandy desert. The Dromedary is merely a lighter variety of it, possessed of greater fleetness and power of endurance. The flesh and milk of the camel serve as food, and the hair for the manufacture of cloth. Their humps, principally composed of fat, are provisions of superabundant nutriment, as they are noticed to diminish much in size on long journeys. By resting on their callosities, camels are enabled to repose on a scorching surface, and their stomachs are adapted to contain a supply of water sufficient for several days.

The place of the camels is taken in the New World by the Llama and Alpaca (*Auchenia*). They have no hump, nor is the sole of the foot provided with a pad. They are smaller than the camels, and are used as beasts of burden.

(B.) The *Moschidæ*, which includes the Musk Deer (*Moschus moschiferus*), are characterised by the absence of horns, and by the presence of canine teeth in both jaws, these teeth assuming, in the upper jaw of the male, the form of tusks. The male has a glandular sac in the abdomen, which secretes the well-known perfume musk, hence the name. They are elegant and nimble little animals, confined to the mountainous parts of Central Asia.

(C.) The family *Cervidæ* includes the numerous tribe of the true Deer. They are distinguished by the character of their horns, or, as they are called in this tribe, *antlers*, which are composed of solid bone, and are at first mere prominences on the frontal bones, covered with a hairy skin (the *velvet*), having at their base a ring of bony tubercles, which periodically enlarge and compress the nutrient vessels, so that the antlers are shed annually, to be reproduced in a larger and more branched form each year at the breeding season. With the exception of the female reindeer, all the females are destitute of horns. All the deer tribe have a sebaceous gland placed beneath the eye, which secretes a strongly smelling waxy substance. Of the species with round antlers, which are very numerous, only the Roebuck (*Capreolus capræa*), and the Stag, or Red-deer (*Cervus elephas*), are natives of Britain. The Wapiti, or Canadian Stag (*C. Canadensis*), is a larger species, found in North America.

In the following genera, the antlers are more or less flattened and palmated: of these, the Elk or Morse Deer (*Alces palmatus*), which is one of the largest existing species, has the antlers large and very broad, with tooth-like projections on the outer edge. The Elk is found in the northern parts of Europe, Asia, and America. The Reindeer (*Cervus tarandus*), which is so useful to the Laplanders,



Reindeer (*Cervus tarandus*).

is the only species properly domesticated. The reindeer-moss (*Cadonia rangiferina*) forms the chief part of its winter food. It is now confined to the extreme north of Europe, but during the glacial period it ranged as far south as France. The Fallow-deer (*Dama platyceros*), now naturalised in this country, also belongs to this group. The remains of a gigantic species of deer, closely allied to the former, are frequently found in recent deposits, more especially the peat-bogs in Ireland, where it is called the Irish Elk (*Megacros Hibernicus*). Some of the antlers which have been discovered measured thirteen feet between the tips.

(D.) The *Camelopardalidæ* includes only a single living species, the Giraffe or Camelopard (*C. giraffa*). It derives its name from the skin being spotted like a leopard, and its neck long like that of a camel. It differs from the deer in the permanence of its horns, which are covered by hairy skin. The length of its fore-limbs and neck (which contains no more than the normal seven cervical vertebræ) are well known. It measures about eighteen feet in height, and feeds on leaves, which it strips off branches at a considerable height above the ground by its long prehensile tongue. It is gentle and inoffensive,

although capable of powerfully defending itself by kicking. It is a native of Africa.

Giraffe (*Camelopardalis giraffe*).

(E.) The *Cavicornia*—including Sheep, Oxen, Goats, and Antelopes—are the most typical Ruminants, and those of most service to man (*vide* dental formula and characters of a typical ruminant). Their horns are essentially bony prominences from the frontal bone. This bony prominence, or *core*, is permanent, and is covered by a sheath of *horn*. The Cavicornia comprises three families:

The family *Antilopidæ*, which contains upwards of seventy species, are characterised more or less by their simple, cylindrical horns, the core of which is composed of solid bone. They are remarkable for their slenderness of form and swiftness of foot. The speed of the swiftest species surpasses that of every other mammiferous animal. The antelopes are very numerous in individual species, and are chiefly found in Africa; but one species, the Chamois (*Rupicarpa tragus*), inhabits the mountainous parts of the south of Europe. Among the African species are the Eland (*Boselaphus Oreas*), the largest species of the family; the Gazelle (*Gazella Dorcas*), noted for its beautiful eyes, and the Spring-bok (*G. euchore*), which occasionally visits cultivated

Gnu (*Catoblepas Gnu*).

lands during seasons of drought, in innumerable herds, causing devastation wherever they pass. Allied to the antelopes is the curious genus Gnu of South Africa. The body and crupper, also the tail, neck, and mane, resemble those of a horse; whilst its horns are like those of the Cape Buffalo; and its legs are slender and light as those of a

Nyl-Ghau (*Portax picta*).

stag. The Nyl-Ghau (*Portax picta*) is common in the northern parts of India.

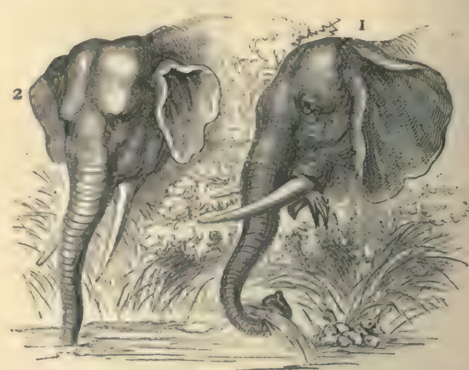
The family of *Ovidæ* includes only the Sheep and Goats, which have horns turned upwards and backwards. Horns are generally present in both sexes, but they are largest in the male. The original stock of the domestic breeds of the goats (*Capra*) appear to be indigenous in Persia, where it inhabits the mountains in large troops. The goats of Angora, Tibet, &c. celebrated for the fine quality of their hair, are merely varieties of the common species (*C. hircus*). The Ibex (*C. Ibex*) is found in the Alps and Caucasus, and is distinguished by the strength and size of its horns. Numerous varieties of the domestic sheep (*Ovis aries*) are known, but their relation to each other is uncertain. The Merino Sheep (a Spanish variety) are specially celebrated for their fine wool. The sheep appears to have been domesticated by man at a very early period; and on the uses of this family to him there is no need to enlarge in this place.

The family of *Bovidæ*, or Oxen, have rounded horns, directed upwards and forwards, the bony core being cellular. They are large animals, with a broad muzzle, robust form, and stout limbs. Without exception, of all the animals which man has reduced to his service, the ox is the most useful. Many breeds or races of oxen exist in different parts of the world, which were probably all descendants from one stock, and yet differ considerably from one another. Most of those inhabiting the torrid zone have a lump of fat upon the shoulders, which increases in size in proportion to the abundance of their food. This is especially remarkable in the Indian or Brahmin Bull, Zebu (*Bos Indicus*), which is regarded as sacred by the Hindus. Amongst the undomesticated species of this family may be noticed the Aurochs, or Lithuanian Bison (*Bos bison*), which was formerly spread over Europe, but is now restricted to the Caucasus; the American Bison, commonly called Buffalo (*Bison Americanus*),

which inhabits all the temperate parts of North America; the Common Buffalo (*Bubalus bubalis*), of which there are several different races, some having been domesticated; the Cape Buffalo (*B. Caffer*), an extremely ferocious animal, with large horns, first directed downwards so as nearly to cover the forehead, inhabiting the woods of Caffraria; and the Musk Ox (*Oribos moschatus*), a species inhabiting the coldest regions of North America, with short legs, and long hair reaching to the ground, which diffuses more strongly than the rest the musky odour common to the whole genus, and which is particularly noticeable in the European bison. The original wild stock of our domestic breeds (*Bos taurus*) is uncertain.

American Bison (*Bison Americanus*).

ORDER 6. *Proboscidea.*—Of this group, the Elephant (*Elephas*) is the only living genus; other species, as the Mammoth and Mastodon, having become extinct in not very remote times. The varieties yet surviving are animals of huge size, which subsist in the great forests of India and Africa by feeding on the leaves of trees and long grass. The incisor teeth in the upper jaw, two in number, grow from persistent pulps, and form enormous tusks. Canines are absent in both jaws, and the molars are few in number, composed of plates of enamel cemented together by dentine. These grinders are in constant progress of removal, and they succeed each other by being pushed forwards from behind in proportion as the tooth before each is worn away. In none of the living forms are there incisors in the lower jaw. The nose is greatly elongated, forming a movable cylindrical trunk (*proboscis*), terminated by a finger-like process, which is very sensitive. The nostrils are placed at the extremity of the proboscis. The 'trunk' is admirably adapted to serve both as a means of laying hold of food and imbibing water: when the capacious nostrils are charged, the animal bends the trunk towards the mouth, and discharges the liquid into its throat. By this organ, the shortness of the neck—rendered necessary by the weight of the head—is fully compensated. The cavity for the brain by no means corresponds with the external form of the skull, the two tables of which are separated by a considerable interval filled with bony cells. The elephant has not a complete hoof, but five toes to each foot, which are only distinct in the skeleton, the whole being enveloped in callous skin, excepting the nails at the extremities. Two species of elephants exist at the present day, both of which inhabit tropical climates—one in Asia (*E. Indicus*), the other in Africa (*E. Africanus*). Remains of the Mammoth (*E. primigenius*) are found chiefly in the north of America and in Siberia; and from a nearly perfect specimen, which was discovered frozen in the ice near the mouth of the river Lena, it appears that this species was adapted to live in cold climates—the skin being densely covered with hair of two kinds. The head of a remarkable fossil form, Deinotherium, has been found in the Miocene deposits of France, &c. It had molars in each jaw, and two incisor teeth in the lower jaw, like the elephant, but these were deflected downwards at right angles to the body of the jaw.



1, Head of Asiatic Elephant (*Elephas Indicus*); 2, Head of African Elephant (*Elephas Africanus*).

ORDER 7. *Carnivora*—are distinguished by characters which point them out as especially formed for the pursuit and destruction of large animals. They possess in the upper and lower jaw six incisor teeth; a large, strong, and pointed canine tooth on each side; and molar teeth which are evidently formed for cutting and tearing, rather than for bruising or grinding. The form of these teeth varies, however, in the different genera, in accordance with their several habits. In the typical species, as the Lion and Tiger, the last tooth but one in the upper jaw, and the last tooth in the lower jaw, are known as *carnassial*, or flesh-teeth, because they have sharp trenchant edges for dividing flesh. In this group, clavicles are wanting or rudimentary. The toes are furnished with strong and sharp claws. The intestines are short, in accordance with the easily digested character of the food.

This order is divided into three sections:

Section 1. *Pinnigrada*, or *Pinnipedia*—comprising the Seals and Walruses, which are Carnivores suited for leading an aquatic life. The fore and hind feet are short, and fitted for swimming, being spread out into fin-like paddles; and the hind-feet are placed far back, nearly in a line with the body, and attached by the integuments to the tail. Their bodies are elongated and fish-like in form, and covered with a close-set fur, sitting flat upon the skin. They pass the greater part of their time in the water, which they only quit to bask in the sunshine and to suckle their young.

The *Phocidæ*, or Seals, have incisor teeth in both jaws, and in them the canine teeth are not excessively developed. The head of the seal resembles that of a dog, presenting the same

mild and expressive physiognomy. These animals seem to possess considerable intelligence; they are easily tamed, and become much attached to

Harp Seal (*Phoca Grœnlandica*), attitude on land.

their feeder. They subsist on fish, which they always devour in the water, closing the nostrils by a kind of valve. They are found chiefly in the Arctic and Antarctic Oceans, but one species (*Phoca vitulina*) is found on the northern shores of Scotland.

The Walrus (*Trichecus rosmarus*), Morse, Sea-horse, or Sea-cow, resembles the seals in the

Walrus (*Trichecus rosmarus*).

form of its body and limbs, but differs in its dentition. The lower jaw has neither incisors nor canines, and is compressed laterally to pass between the two enormous upper canines, which are directed downwards, sometimes attaining a length of two feet. They seem to be used by the animal for hooking up the sea-weeds upon which it partly feeds, and to assist it to get out of the water upon the ice. They are bulky animals, sometimes attaining the length of twenty feet. They are found in all parts of the Arctic Seas, chiefly living in herds.

Section 2. *Plantigrada.*—In the animals of this section, the whole or greater part of the sole of the foot rests on the ground, and the part of the sole so employed is, as a general rule, devoid of hairs. The whole sole being applied to the ground in these animals, is favourable to the maintenance of a firm position, but prevents great activity of progression. The typical family, the Bears (*Ursidæ*), have the molar teeth more or less tuberculated, in accordance with their omnivorous habits. The bears are slow in their movements, and the species which inhabit cold countries pass the winter in a dormant state. Their claws are strong and curved, but not retractile, and the nose is elongated, forming a movable snout. The Brown

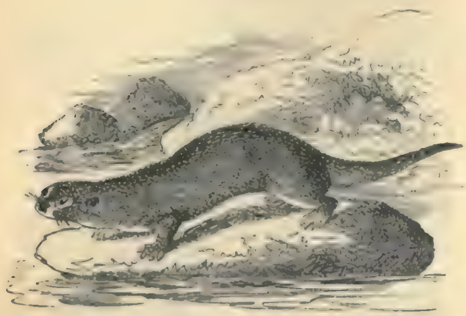
Brown Bear (*Ursus Arctos*).

Bear (*Ursus Arctos*), the commonest species; the Black Bear (*U. Americanus*); the Grisly Bear of America (*U. ferox*); and the White or Polar Bear (*Thalassarctos maritimus*)—which is exclusively carnivorous, and confined to the arctic regions, has the soles of the feet covered with hair, giving it a more secure footing upon the ice—may serve as examples of the bear tribe. Nearly allied to the bears are the Racoons (*Procyon*) of North America. The bones of an enormous species, *U. spelæus*, or Cave Bear, have been found in the caves of Britain and Europe.

The family of the *Melidæ*, or Badgers, have the carnassial tooth formed partly for cutting. These animals have elongated bodies, and, by means of the long claws of their fore-feet, can burrow with great facility. They go in search of food by night, and devour small mammals or vegetables almost indifferently. They can emit a fetid odour at will. The Common Badger (*Meles Taxus*) is a well-known British species. The Glutton, or Wolverine (*Gulo luscus*), which is found in the north of Europe and America, is reputed to be a ferocious animal.

Section 3. *Digitigrada.*—In this group the ends of the toes only touch the ground, the heel being considerably raised into the air, so that thus the limbs can be used to much greater advantage in running and springing than in the former section. Some families exhibit transitional characters between this and the last group, and they are called *Semi-plantigrada;* such are the family of *Mustelidæ*, or Weasels, which, on account of their length of body and their short limbs, being enabled to pass through small openings, are called Vermiformes. They are the most *blood-thirsty* of all the Carnivora; but they are not so well adapted for devouring flesh as the Felidæ. The Weasel (*Mustela vulgaris*) of this country is one of the most sanguinary of all, but it chiefly destroys mice, rats, moles, &c. The Ferret, Marten, and Polecat (*M. putorius*), the last of which is a great enemy to the game-preserve and warren, also belong to the family. All these animals emit a

strong and disagreeable odorous exudation from glands under the tail. The Skunks (*Mephitis*) are an American tribe, and are remarkable for the intensity of their nauseous suffocating stench. The Ermine (*M. Erminia*) and Sable (*M. zibellina*) are valued for their splendid fur. Also belonging



Otter (*Lutra vulgaris*).

to the same family are the Otters (*Lutra*), distinguished by their webbed feet and horizontally flattened tail. The British Otter (*L. vulgaris*) frequents the banks of streams, and lives chiefly upon fish.

The *Viverridæ* is the second family of Semi-plantigrades. They are small animals, with a pointed muzzle, and are either striped or spotted. In the true Civets (*Viverra Civetta*) there is a pouch near the tail which yields the 'civet' of commerce, which is valued as a perfume. They are natives of India and Africa, are easily tamed, and feed partly on fruits. Allied to these is the celebrated Ichneumon (*Herpestes Ichneumon*) of Egypt, which is highly carnivorous, is about the size of a cat, and as slender as a marten. It feeds largely on crocodiles' eggs, by destroying which it prevents the excessive multiplication of these animals. It is easily domesticated, and lives upon small reptiles and mammals.

Connecting the Viverridæ with the Felidæ, is the family of the *Hyænidæ*, which alone of all the

Striped Hyæna (*Hyæna striata*).

Carnivora have only four toes on each foot. The dental formula is:

$$\text{I. } \frac{3-3}{3-3}, \text{ C. } \frac{1-1}{1-1}, \text{ P. } \frac{3-3}{3-3}, \text{ M. } \frac{2-2}{1-1} = 34.$$

the last upper molar being tuberculate. As the fore-limbs are longer than the hind pair, the body slopes towards the hind quarters. Their claws are non-retractile. Their jaws are short and powerful, and peculiarly adapted for crushing bones. They are nocturnal in their habits, and extremely ferocious. Two species are known, which are confined to the Old World—the Striped Hyæna (*H. striata*), which is found in Asia and Africa, and the Spotted Hyæna (*H. crocuta*), which is confined to Africa. The bones of an extinct species (*H. spelura*), or Cave Hyæna, have been found in the caves of Britain, associated with bones of the Cave Bear.

The family *Canidæ*, or Dog tribe, are digitigrade, and have the muzzle pointed, their claws non-retractile, and the tongue smooth, and two of their molars are tuberculate. The animals of this family agree in their greater or less adaptation to a mixed diet. The fore-feet have five toes, and the hind-feet four. The Wolf (*C. lupus*), Fox (*Vulpes vulgaris*), and Jackal (*C. aureus*) are the animals which most nearly approach the dog; and the first of these is regarded by some naturalists as being really identical. The Arctic Fox (*V. lagopus*) is normally of a blackish-brown colour, but on the approach of winter the fur becomes white and very long, forming an excellent protection against the cold in those high latitudes. The breeds of the Common Dog (*Canis familiaris*) are all believed to have had the same origin.

The last family of the Digitigrada is the *Felidæ*, or Cat tribe, which are characterised by their rounded head and powerful jaws, their retractile claws—which, when not in use, are drawn within a sheath so as to prevent them from being blunted—and the adaptation of their teeth for cutting. Only the last molar in the upper jaw is tuberculate. The fore-feet have four toes, and the hind-feet five. Their tongue is roughened by horny papillæ, thus rendering it more efficient for rasping the flesh off the bones of their prey. They steal upon their prey unawares, and seize it with a sudden spring, often slinking off when once baffled. Most of them are sufficiently well known to render any peculiar description unnecessary. It may, however, be remarked, that some species are found in almost all tropical and temperate

Bengal Tiger (*Felis tigris*).

countries, and that those of different parts of the globe *represent* each other in a remarkable

manner. Thus, the Lion (*Felis leo*) and Tiger (*F. tigris*) are inhabitants of Africa and tropical Asia; in America, they are replaced by the Puma (*F. concolor*) and Jaguar (*F. onca*), which are confined to that continent. In the same manner, we find the Panther and Leopard (*F. leopardus*) spread over tropical Asia and Africa; the Ounce, inhabiting the Asiatic mountains; the Caracal, in Turkey and Persia; and the Lynx, in Northern Europe. These are represented by the Ocelot in South America, the Lynx of Canada (differing from the European), and other less-known species. The Lynxes have short tails and a pencil of hair at the tip of their ears, while the Cats (*F. catus*) have a long tail, and the ears want the pencil of hair.

ORDER 8. *Rodentia*—take their name from their gnawing habits, for which they are fitted by the possession of two long curved incisors in each jaw. There are no canines, and a considerable interval intervenes between the incisors and the molars, which are few in number. These incisors are constantly wearing away, but as constantly growing from persistent pulps; so that when one is lost or broken, its opposite, having nothing to wear it down, becomes developed to an enormous extent. The incisor teeth consist anteriorly of a hard plate of enamel, and posteriorly of a softer substance (dentine), which wears away more rapidly than the enamel, so that the teeth are always kept sharp, and bevelled away behind, so as to be chisel-shaped. To assist the action of these teeth, the lower jaw is articulated to the skull by a transversely elongated condyle, which allows it to move backwards and forwards.

Family 1. *Leporidæ*—are distinguished by the presence of two small incisors behind the rodent teeth. The form and habits of the typical genus are sufficiently well known in the Hare (*Lepus timidus*) and Rabbit (*L. cuniculus*) of this country. There is a species, *L. variabilis*, or Alpine Hare, in this country, whose fur is brown in summer, and white in winter. The *Lagomys*, or Rat-hare, has the fore-legs almost as long as the hind. It is a native of the colder regions of the north, and stores up a large quantity of fodder for the winter.

Family 2. *Cavidæ*—in which the body is covered with hair, and the tail is short, contains the Capybara (*Hydrochærus capybara*), the largest animal of the order, being about three feet in length, and of the size of the Siamese pig. Its semi-aquatic habits are shewn by the webbing of the feet. It is found on the sides of nearly all the rivers of South America. The *Cavia Aperæa*, or Guinea-pig, a South American species, is now quite domesticated in Europe. The Agouti (*Dasyprocta*) also belongs to this family.

Family 3. *Hystricidæ*—including the Porcupine, which are distinguished by being armed by stiff and pointed quills, or spines. The name porcupine is corrupted from the French *porc-épine*, a term expressive of the pig-like aspect and grunting voice of these animals, as well as of their spiny covering. They live in burrows, and have very much the habits of rabbits. The best known species inhabits the south of Italy, Sicily, and Spain. In the Common Porcupine (*Hystrix cristata*), the tail is non-prehensile; but in the American genus, *Cercolabes*, which is

Porcupine (*Hystrix cristata*).

fitted for an arboreal existence, it is long and prehensile.

Family 4. *Castoridæ*.—The Beaver (*Castor fiber*) is probably the type. It is distinguished from all other rodents by its horizontally flattened tail, which is of a nearly oval form, and covered with scales. The hind-feet are webbed, by means of which and the tail these animals obtain considerable swimming powers. They chiefly subsist on bark and other hard substances, and, owing to the size and strength of their incisor teeth, they can fell trees of considerable size, of which they use the bark and twigs as food, employing the stems in the construction of their remarkable habitations. The flattened tail is employed by them as a kind of trowel, with which they plaster the walls of their houses. The Beaver is an aquatic and social

Beaver (*Castor fiber*).

animal, and is hunted for the sake of its skin, and for the substance, *castoreum*, which is secreted by peculiar glands, and is employed in medicine.

Family 5. *Muridæ*—are the smallest and most prolific of the Mammalia. In this family, the tail is long, and thinly covered with hair, though sometimes scaly. No undomesticated animals are better known than Mice and Rats. The Brown Rat (*Mus decumanus*), which is believed to have originally come from Persia, is speedily replacing the Old English or Black Rat (*M. rattus*), which, being of smaller size, is not a match for the usurper. The Harvest-mouse (*M. messorius*), the Long-tailed Field-mouse (*M.

sylvaticus), and the Common Mouse (*M. musculus*) are British species, and are too well known to require any description. A great number of species exist in different parts of the world, differing little from each other. Belonging to the same family are the Lemmings or Scandinavian Rats (*Myodes lemmus*), which are remarkable for their occasional migrations in immense bodies. They are stated to advance in a straight line, regardless of rivers and mountains; and while no insurmountable obstacle impedes their progress, they devastate the country through which they pass. The Hamsters (*Cricetus*) are nearly allied to the rats, but their tail is short and hairy, and they have cheek-pouches, in which they can stow away grain for transport to their nests. They abound in Asia, but one species is found in the sandy plains of the north-east of Europe. The Voles (*Anicola*), including the Short-tailed Field Mouse (*A. agrestis*), and the Water Rat (*A. amphibia*) are forms intermediate between the *Muridæ* and *Castoridæ*.

Family 6. *Dipodiæ*, or Jerboas—characterised

Jerboa (*Dipus Ægyptius*).

by the enormous length of the hind-legs as compared with the fore-limbs, which are very short, and armed with claws with which they dig burrows in which they live, like most of the species of this order. They live in troops, and inhabit Russia and North America. They hop along on their hind-legs much after the manner of a kangaroo.

Family 7. *Myoxidæ*—represented by one British species, the well-known Dormouse (*Myoxis avellanarius*), which must not be confounded with the true Mouse, nor with the Shrew-mouse.

Family 8. *Sciuridæ*, or Squirrel tribe.—The characters and habits of the Common Squirrel (*Sciurus vulgaris*) are too well known to require description. The *Pteromys*, or Flying Squirrel, is aided in leaping from tree to tree by an extension of the skin of the flank between the fore and hind legs, which serves as a parachute. It is an inhabitant of Southern Asia and Polynesia. The Marmots (*Arctomys*) differ from the squirrels in being fitted for living on the ground, and even in burrows beneath it. A remarkable species is the *A. ludovicianus*, or Prairie Dog, or Barking Squirrel, so called because its bark resembles that of a small dog. It lives in great troops in immense burrows on the plains of the Missouri. They are connected with the former tribe, however, by an elegant little animal termed the

Flying Squirrel (*Pteromys volucella*).

Ground-squirrel (*Tamias*), partaking of the habits of both: this is a native of Eastern Europe. Like the Dormice, all the members of this family pass the winter in cold climates in a state of lethargy. The rodents of the first, second, and third families are destitute of clavicles, while the remaining families possess them.

ORDER 9. *Insectivora*—are small animals, subsisting chiefly on insects and vegetable substances. Their molar teeth are provided with numerous small cusps, suited for bruising insects. They are all nocturnal and subterranean in their habits, and most of them spend the winter in a state of sleep. Clavicles are present in the entire order.

Family 1. *Erinaceidæ* (Hedgehogs).—These animals are called Hedgehogs because they prefer the roots of hedges as their hiding-places, and from a superficial resemblance which they bear to pigs. Nature has provided them with a bristly coat of armour, which, by strong cutaneous muscles, they can draw over every part of the body, or every part which is accessible, so as effectually to protect themselves from their enemies. They roll themselves up into a ball at the approach of danger. They live on fruit and the eggs of small birds, and are torpid in winter. Our only British species is the *Erinaceus Europæus*, which is too well known to require description.

Family 2. *Talpidæ* (Moles) live chiefly underground, feeding on insects, worms, and roots. Their feet, which are provided with strong curved claws, are admirably adapted to their subterranean mode of life. From the smallness of their eyes, which are scarcely perceptible, it was long considered that the Moles were blind; but it is now ascertained that they are by no means deficient in the sense of sight. Moles have no external ears; but, from the tympanum being large, their sense of hearing is nevertheless very acute. The only British species is the Common Mole (*Talpa Europæa*).

Family 3. *Soricidæ* (Shrews) are small animals, having soft hair, well-developed eyes, and external ears, and the feet are not adapted for digging.

They are very widely distributed, and the Common

Common Shrew (*Sorex araneus*).

Shrew (*Sorex araneus*), and Water Shrew (*S. fodiens*), may serve as examples.

ORDER 10. *Cheiroptera* (Bats)—are suited for an aerial life, and have the four digits of the fore-limb greatly elongated, the thumb being short, and terminated by a hook-like nail, which serves the animal for climbing on precipices. Across the lengthened fingers is stretched a membrane, which is continuous with the sides of the body, and extended between the fore and hind limbs. The hind-limbs are short, and all the toes are furnished with claws, by which the bats suspend themselves from the trees or walls on which they rest, hanging with the head downwards. The bats have the power of true flight, like birds, and, from some peculiar sensitiveness of wing, they can make their way, while deprived of eyesight, and even of hearing, among a confused variety of objects, without ever coming in contact with any. In many of the insectivorous bats, the organ of smell is furnished with curious leaf-like appendages, formed of the integument, doubled, folded, and cut into curious and most grotesque forms. The *Cheiroptera*, inhabiting temperate climates, all remain in a torpid state during the winter. They are nocturnal in their habits, and may be divided into two divisions, according as their diet consists of insects or of fruits.

Section (A). *Insectivora*—which feed upon insects, and have the molar teeth tuberculate, like the order Insectivora, and the intestines short. It comprises three families :

Family 1. *Vespertilionidæ*—which includes most of the bats of temperate climates. At least fifteen species exist in this country, the largest of which

Long-eared Bat (*Plecotus auritus*).

is the Noctule, or Great Bat (*Vespertilio noctula*), which seeks its retreat under the eaves of houses and in hollow trees, and measures fifteen inches in the expanse of wing. The Long-eared Bat (*Plecotus auritus*) is not uncommon, and is distinguished by the character implied in its name. The commonest species is the Pipistrelle (*V. pipistrella*).

Family 2. *Rhinolophidæ*—contains the Greater and Lesser Horse-shoe Bats, which are found in the darkest and most secluded retreats of our own country ; their name is derived from the complex leaf-like form of the anterior nasal appendage. In the *Megaderma*, an Indian and African genus, the ears are so large as to unite over the forehead.

Horseshoe Bat (*Rhinolophus Ferrumequinum*).

Family 3. *Phyllostomidæ*—which have a nasal leaf-like appendage, and short ears. It includes the well-known Vampire Bat (*Phyllostoma spectrum*), which exhibits a considerable degree of ferocity, and has the habit of sucking blood from sleeping animals. It attains a considerable size, the wings, when expanded, measuring about two feet and a half. The Vampires are confined to South America.

Section (B). *Frugivora*—in which the molar teeth have flattened crowns, suited for grinding fruits, and the stomach is complex. It includes but one family, the *Pteropidæ*, or Fox-bats, which have the ears short, the head long and pointed, and bearing some resemblance to that of a fox. The tail is either short or absent. They are widely diffused throughout warm climates, and contain some of the largest species of the order —the *Pteropus edulis*, or Kalong of Java, measuring five feet across its expanded wings. Where they abound, they are eaten as food by the inhabitants. They are specially characteristic of the Pacific Archipelago.

Head of Pteropus.

ORDER 11. *Quadrumana*, or Monkeys—have an interest for us beyond most orders of Mammalia, on account of their being the animals nearest to man in external form and in intelligence. They are omnivorous animals, dwelling chiefly in the forests of warm countries, and spending much of their time on the branches of trees, among which they are well fitted to move by reason of the grasping power of their extremities. They are characterised by having the innermost toe of the hind-limb separate from the other toes, and opposable to them, so that the hind-feet become converted into prehensile hands. When the innermost toe of the fore-limb is present, it also is opposable to the other toes, so that the animals are really *four-handed*, hence the name. All of these, like man, possess three sorts of teeth ; the canines, in the full-grown animal, are much more developed than in man ; and there are intervals between them and the other teeth

which are not present in his jaws, but exist in all other Mammalia.

Owen has divided them into three groups, according to their anatomical characters and their geographical distribution :

Section (A). *Strepsirhina*, or *Prosimiæ*—comprising the Lemurs and their allies, have the muzzle prolonged, and the *curved* nostrils placed at its extremity. All the four thumbs are well developed and opposable, and the fore and hind limbs have five toes each. The claw-like aspect of the nail of the second digit of the hind-limb is one of the most easily recognised characters of the section. Madagascar is their chief geographical centre.

In the true Lemurs (*Lemuridæ*), all the digits except the second toe of the hind-feet are covered with flat nails. They have very large and handsome prehensile tails, which are elevated when the animal is in motion. They are about the size of a cat, but have longer limbs, and are exclusively confined to the forests of Madagascar, where they spring about from tree to tree in search of their food, which consists principally of fruits. They are nocturnal in their habits, and are exceedingly active.

The *Nycticebus* or *Loris*—of which the *Stenops tardigradus*, or Slow-paced Lori, is the best known example—have short ears, no tail, and large approximating eyes, and are inhabitants of India and the Eastern Archipelago. They are nocturnal in their habits, and very slow in their movements, hence they are called 'Slow Lemurs,' and they feed principally on insects.

With this group may also be placed the Aye-aye (*Cheiromys Madagascarensis*), which has no canine teeth, and a considerable interval between

Aye-aye (*Cheiromys Madagascarensis*).

its incisors and the molars. It is about the size of a squirrel, and has a bushy tail. It feeds upon larvæ and insects, which it picks out of the crevices of the bark of trees by night with its long slender fingers.

For convenience, we may place in this group a remarkable animal, which seems to connect the Insectivora with the Quadrumana. It is the *Galeopithecus*, or Flying Lemur, which has the integument stretched from the nape of the neck to the fore-limb, and from the fore-limb to the hind-limb. This is simply an integumentary expansion, similar to that of the Flying Phalanger and the Flying Squirrel, with which the animal can take leaps from tree to tree. It feeds upon insects, fruit, and eggs, and inhabits the Indian Archipelago.

Section (B). *Platyrhina*, or New-World Monkeys.—In the animals of this group, owing to the septum of the nose being broad, the nostrils are placed widely apart. In general, the thumbs of the anterior members are not opposable, and they are sometimes absent. Their tails are generally prehensile. They are confined to the woods of South America. They are divided into two families.

Family 1. *Halpalidæ.*—They have ten grinders in each jaw, like the Old-World monkeys, their dental formula being :

$$\text{I.}\ \frac{2-2}{2-2},\ \text{C.}\ \frac{1-1}{1-1},\ \text{P.}\ \frac{3-3}{3-3},\ \text{M.}\ \frac{2-2}{2-2} = 32.$$

Their tail is long, and usually bushy, but never prehensile. The thumb of the hind-foot has a flat nail, but all the other toes are unguiculate. They are all diminutive animals, of pleasing forms, and very active movements. The best known species is the Common Marmoset (*H. penicillata*), which is often domesticated or kept as a pet. Upwards of thirty species have been described.

Family 2. *Cebidæ*, in which the grinders are more numerous than in the Catarhina and in Man, the dental formula being :

$$\text{I.}\ \frac{2-2}{2-2},\ \text{C.}\ \frac{1-1}{1-1},\ \text{P.}\ \frac{3-3}{3-3},\ \text{M.}\ \frac{3-3}{3-3} = 36.$$

They have neither cheek-pouches nor callosities, which are usually present in the Old-World Monkeys. The tail is prehensile, and capable of being twisted round branches so firmly as entirely

Spider Monkey (*Ateles paniscus*).

to support the weight of the animal. They subsist

chiefly on vegetable substances. They are found in troops in the vast forests in South America, climbing amongst the trees. The largest of them are the *Myceti*, or Howling Monkeys, which derive their tremendous powers of voice from a sort of hollow drum connected with the larynx, which is peculiar to them amongst the Cebidæ. Humboldt says that the noise so produced can be heard at the distance of nearly a mile. They are shaggy animals about the size of a fox. The *Ateles*, or Spider Monkeys—remarkable for the length of their prehensile tails, and for the absence of thumbs in the anterior extremities—the Capucin Monkey (*Cebus*), and the Squirrel Monkey (*Callithmi*), all belong to this family.

Section (C). *Catarhina*, or Old-World Monkeys. This is the highest section of the Quadrumana, and the animals composing it are entirely confined to the Old World. The nostrils are oblique, and placed close together. The thumbs of all the feet are well developed and opposable, except in the genus *Colobus*, in which the anterior thumbs are absent. The number of teeth is the same as in man, but they are in an uneven series, interrupted by an interval. The canines, especially in the males, are long and pointed. The tail is never prehensile, and is sometimes absent. They have *natal callosities*, or hard spots on their haunches destitute of hair. Cheek-pouches are often present. They are all natives of Asia or Africa, except the monkey inhabiting the rock of Gibraltar. They are divided into three groups :

Group 1. The *Long-tailed Monkeys*, in which the tail is long, and there are both callosities and cheek-pouches, including the genus *Semnopithecus*, of which *S. entellus*, or Sacred Monkey of the Hindus, is the one best known. It is considered a capital crime to kill one of these monkeys. In the genus *Colobus* alone, the thumb of the fore-foot is absent. The species of the genus *Macacus*, which have a short tail (Macaque), are found in Asia and Africa; but one, the *M. Inuus*, or Barbary Ape, is found on the Rock of Gibraltar, and it is the only wild monkey in Europe.

Group 2, including the Baboons (*Cynocephalus* and *Papios*), in which the tail is short, the muzzle protuberant, and the aspect ferocious. The canine teeth are generally large and strong.

Mandrill or Rib-nosed Baboon (*Papio Mormon*).

The callosities are of great size, and usually adorned with some bright colour. The Baboons have a large bag connected with the larynx, by the resonance of which the power of their loud and discordant cries is greatly increased. They can run upon all-fours with great ease. They all inhabit Africa, and one of them, the Mandrill (*Papio Mormon*), is a ferocious-looking animal, about the height of a man, and distinguished from other baboons by a ridge on its cheek, which is covered with a naked skin of a bright-blue colour. In the Drill (*P. leucophæa*), this ridge is black.

Group 3, containing the Anthropoid or Anthropomorphous Apes, or those which approach most nearly in their structure to man. These apes are distinguished by the absence of a tail and cheek-pouches—the callosities are sometimes absent also—and by the predominance in length of the fore-arms over the hinder ones. The thumbs of the hind-limbs are opposable, and the animal can assume a semi-erect attitude.

In the Gibbons, or Long-armed Apes (*Hylobates*), which are the smallest and slenderest of the man-like apes, the arms are so long that they touch the ground when the animal is in a semi-erect attitude. In this genus, callosities are present. The best known is the *H. syndactylus*, or Siamang, and there is pretty good evidence that it assumes the erect position. Several species are found in Asia, Java, Borneo, &c. In the Orang (*Simia satyrus*), the haunches are covered with hair, and there are neither callosities nor cheek-pouches. The arms are excessively long, reaching below the knee when the animal is erect. There is a remarkable difference between the young and the adult form of the skull—the young bearing the greatest resemblance to that of man, whilst in the adult the muzzle is so much prolonged, and the canine teeth are so much developed, as to give the face much more the aspect of that of the baboon. It is more sluggish in its movements than the active and agile Gibbons. It is about four feet in

Gorilla (*Troglodytes Gorilla*).

height, and clothed with a reddish-brown fur. It is confined to Borneo and Sumatra, where it

receives from the Dyaks the name of *Mias*. The genus *Troglodytes* contains the Chimpanzee and the Gorilla. The latter, which is excessively strong, and extremely ferocious, is a native of New Guinea, and is now regarded as the most human of all the anthropomorphous apes. It attains a height of fully five feet, and when erect, the arms reach to the middle of the leg. The two hinder limbs are not intended by nature to serve as a support to the entire weight of the animal. It only puts the outside to the ground, and seems awkward and insecure unless it has the fore extremities also employed in its support or in progression.

By Linnæus, the Quadrumana and Bimana were united under one order, the *Primates*, and this arrangement is followed by some eminent modern zoologists, but chiefly by the advocates of the theory of progressive development.

ORDER 12. *Bimana*.—At the head of the Mammalia, and consequently of the entire Animal Kingdom, stands the order BIMANA, implying Two-handed Animals, but in reality composed of but one genus—MAN (*Homo*). In this place we have to consider man solely as a part of the Animal Kingdom. The study of man's psychical endowments and his physical structure belongs to other departments of science. Zoologically considered, man is distinguished by his habitually erect posture, and by the two hinder limbs being devoted solely for support and progression, while the two anterior extremities are fitted for prehension alone. By the upright position, his upper extremities are left at entire liberty, whilst his organs of sense are most favourably situated for observation. The hand of man is adapted to a far greater variety of purposes than that of the monkeys, in which it is most perfect; its power consists chiefly in the size and strength of the thumb, which can have its tip brought into opposition with that of any of the fingers; and all these are capable of being moved separately. In none of the monkeys can the thumb be opposed to the fingers with any degree of force; and in many, their tips cannot be brought into contact; so that, though admirably adapted for clinging round bodies of a certain size, such as the small branches of trees, their hands can neither seize very minute objects, nor support large ones. In man, also, the toes of the fore and hind limbs are covered by nails, but in the hind-limbs the great toe is not opposable to the other digits. The foot is broad, and the whole sole is applied to the ground in walking.

The dentition consists of thirty-two teeth in an even and uninterrupted series, without any interval, the dental formula being:

$$\text{I.}\ \frac{2-2}{2-2},\ \text{C.}\ \frac{1-1}{1-1},\ \text{P.}\ \frac{2-2}{2-2},\ \text{M.}\ \frac{3-3}{3-3} = 32.$$

The brain of man is much more highly developed; its convolutions are more numerous, more pronounced, and its size is greater relatively than in any other mammal. He is the only terrestrial mammal whose body is not furnished with a covering of hair. Man is distinguished from other mammals not so much by his anatomical and structural qualities as by his high psychical endowments. He may be comprehensively described as a being fitted to live upon almost all kinds of food, and in every part of the earth except those constantly under snow; of an extraordinary intelligence, and tendency to social life; eminent in power over all other animals, and endowed with the greatest ability to turn the objects and forces of physical creation to his own benefit. Besides all this, we believe there is a spiritual being within us, vouchsafed to no other species, by which we are brought into peculiar relations to the Divine Author of nature, and which will survive the frail tenement in which we live.

Flying Fox or Roussette (*Pteropus rubricollis*).

NATURAL PHILOSOPHY—MATTER, MOTION, AND HEAT.

As man contemplates the bodies that make up the universe, and the endless movements and changes they undergo, he becomes impressed with the conviction that these *phenomena* (appearances), as they are called, are not simply a collection of individual things ruled by chance, but that there are fixed connections—in other words, order and uniformity among them; and he feels irresistibly impelled to trace out these connections, or *laws* of nature, as they are called, wherever they can be discovered. In this pursuit we have Natural Philosophy in its widest sense.

Some phenomena depend upon the peculiar kind of substance of which the body manifesting them is composed, and consist in changes of its constitution. The facts of this class form the separate science of *Chemistry*. Organised bodies—that is, plants and animals—also manifest a peculiar set of appearances which are summed up in the word *life*. The consideration of *vital* phenomena belongs to the department of science called *Physiology*, sometimes *Biology*.

But there is a large and important class of phenomena of a much less special kind, and which belong to matter in general, and to all bodies composed of it, whatever be their peculiar constitution, and whether organic or inorganic. Thus, a stone, a piece of sulphur, a drop of water, a plant, an animal, all fall to the earth if unsupported, are all capable of being divided into small parts, all reflect more or less light, &c. It is the investigation of universal laws of this kind, where no change of constitution is concerned, that constitutes Natural Philosophy, in its narrower sense; for which the term *Physics* is now more generally used, as being more precise. Of those physical phenomena, again, some have a higher generality than others, and it is these most general laws of the material world that naturally fall to be discussed in this introductory treatise. They may be arranged under the heads of *General Properties of Matter*, *Motion and Forces*, and *Heat*.

GENERAL PROPERTIES OF MATTER.

Matter, or that which composes all bodies, has certain *properties;* by which is meant, that it has the power of making certain impressions upon our senses, or of exciting in us *sensations*. As to what matter is in itself, beyond its power of affecting our senses, we know nothing. The something, whatever it is, in which this power is conceived to reside, is called *substance*. Some philosophers deny the existence of anything beyond the properties. So far as natural science is affected, the question is of no moment; what really concerns us is, how matter appears and acts, and not what it is. The more important of the properties of matter are—Impenetrability, Extension, Divisibility, Indestructibility, Inertia, Porosity, Compressibility, Elasticity, Attraction, States of Aggregation, Malleability. We shall describe and illustrate them in succession, classing such qualities together as seem to be naturally connected.

Impenetrability is that quality of bodies by virtue of which each occupies a certain portion of space, to the exclusion of all other bodies; it expresses the fact that two bodies cannot be in the same place at the same time. In the popular sense of the word, matter is anything but impenetrable. The hand can be thrust into water, a nail can be driven into wood. But all these are instances merely of displacement. That the most movable and unsubstantial substances, when displacement is prevented, occupy space as effectually as the most solid, is seen in a blown bladder, or in an air-cushion. This property of air is taken advantage of in the diving-bell.

Extension or *Magnitude*, and *Form*.—Magnitude or size is one of those simple ideas that do not require or admit of explanation, because there is nothing simpler to explain them by. It is chiefly by their extension that bodies make themselves known to our senses.

Divisibility.—There is no known limit to the divisibility of matter. A chip of marble may be broken from a block, and that chip may be crushed to powder. The smallest particle of this powder discernible by the naked eye, when examined by the microscope, is seen to be a block having all the qualities of the original marble, and capable, by finer instruments, of being divided into still smaller blocks, which may be again divided; and so on, with no other limit than the fineness of our senses and instruments.

The unlimited degree to which matter may be comminuted is yet more strikingly seen in other ways. When a substance is dissolved in a liquid, or water rises in vapour, the particles become so minute as to be invisible with the most powerful magnifiers. The microscope, again, has revealed the existence of animals, a million of which would not occupy more space than a grain of sand. Yet these animalcules, as they are called, have limbs and organs, and display all the appearances of vitality. How shall we conceive the smallness of the tubes or vessels in which their fluids circulate, and the minuteness of the particles of matter composing these tubes and fluids!

Divisibility thus extends far beyond the limits perceptible to the senses. Are we, therefore, to assume that it is without limits—that matter is infinitely divisible? This would be a rash assumption. On the contrary, there are many reasons for believing that there is a limit somewhere, and that there are ultimate particles, of a determinate size and shape, incapable of further subdivision. These assumed ultimate particles are called *atoms*, from a Greek word signifying indivisible. Their existence is inferred from a number of facts connected chiefly with crystallisation and chemical combination, which cannot be otherwise explained. These ultimate particles or atoms, it is assumed, first form definite groups,

varying in number and arrangement in different substances; these groups are called *molecules*, and bodies are held to be built up of aggregations of such molecules.

But whether the ultimate component particles of bodies have a fixed size and shape or not, we know that they are *indestructible.* This is not, indeed, what a first impression suggests, for nothing is more common than for bodies to decay, dissolve, evaporate, and disappear. But it can be proved that in no case is anything lost. Water disappears in invisible vapour when heated; but if the vapour is carefully collected and cooled, the water reappears without loss of weight. The substance of the coal burned in our fires is not annihilated; it is only dispersed in the form of smoke or particles of soot, gas, and ashes or dust.

Inertia or *Inactivity.*—The term inertia or inactivity is meant to express the fact, that an inorganic body has no power to change its state. If it is at rest, it cannot put itself in motion; if it is in motion, it cannot bring itself to rest; any change must come from some external cause. It hardly gives a correct notion to say that bodies are quite passive to a change of state; for they *resist* the change, with a force depending upon the mass of matter they contain and the amount of motion sought to be given to them or taken away. No one term conveys all that is meant; *persistence* has been suggested as less objectionable than inertia, inactivity, or passiveness.

The following instances illustrate the action of this property of matter: A great force is necessary at first to set a vehicle in motion; but when once this is effected, it goes onward with comparative ease; so that, in fact, a strong effort is necessary before it can be stopped. If a person be standing in it when it is suddenly set agoing, his feet are pulled forward, whilst his body, obeying the law of inertia, remains where it was, and he accordingly falls backwards. On the other hand, if the vehicle be suddenly stopped, and the individual be standing in the same position as formerly, the tendency which his body has to move forward—for it acquired the same motion as the carriage by which it was borne along—will cause him to fall in that direction. A man jumping from a coach at full speed falls prostrate on the ground; for his body has the same motion as the coach; and when the feet arrive at the ground, they are arrested, while the rest of the body moves on; and thus he finds himself thrown down.

The process of beating a carpet, or dusting a book, rests on the same principle. When a dusty book is struck against a table, the book and the dust are first brought into rapid motion together, and the book being then arrested by the table, the dust continues in motion by its inertia, and is thus detached.

It is a common impression with those who have never reflected upon the subject, that bodies are more inclined to rest than to motion. This arises from the fact, that while no body begins to move or increase its speed without some cause for the change being apparent, all the motions that come within our observation on the surface of the earth do actually come to an end, most of them gradually, and without any very apparent cause. Thus the notion is begotten, that rest is the natural state to which all matter, when left to itself, seeks, as it were, to return. But a little consideration shews us that the retardation and stoppage of motion are as dependent on causes as its beginning is. A ball rolled on the rough earth soon stops; on a wooden floor, it continues longer; and on smooth ice, longer still. This shews that one cause of the arrest of terrestrial motions is friction. Another constant impediment is the resistance of the air. A pendulum set in motion in an exhausted receiver, will continue to swing, without the help of clock-work, for a whole day, having nothing to resist its motion but the small amount of friction at its point of suspension. Finding thus that motion is prolonged in proportion as we diminish obstructions to it, though we can never completely remove them, we conclude, that if they were removed, motion once begun would go on for ever.

It is in the heavenly bodies, however, that we find complete proof of this truth. They move without friction, and unresisted by any fluid manifest to the senses, and no appreciable slackening of their speed has yet been detected; they retain the amount of motion they had from the beginning.

Compressibility, Contractibility; Expansibility, Dilatability.—When a body is forced by mechanical pressure into less space than it previously occupied, it is said to be *compressed;* when any cause not mechanical, such as loss of heat, causes its volume to diminish, it is said to be *contracted. Expansion* and *dilatation* are used to express enlargement of volume or bulk. Now, all bodies whatever are liable to these two opposite kinds of change—without any addition to, or deduction from, the matter composing them. Even those substances which we consider as types of solidity are compressible. A piece of iron, when squeezed in a vice or hammered, loses in bulk, and becomes more compact.

The most compressible substances are air and other gases. A moderate pressure will force a quantity of air confined in a vessel into half its volume; and as the pressure is increased, the volume goes on diminishing almost without limit. By pressure and cold combined, several gases have been reduced to the liquid form. Compared with gases, or even solids, liquids have little compressibility. (See HYDROSTATICS.)

Expansion or dilatation is chiefly seen in the case of heat being applied to bodies (see page 204). Gases are unlimitedly dilatable. (See HYDROSTATICS and PNEUMATICS.)

Elasticity.—Some bodies, when compressed, recover their former size when the pressure is removed. Such bodies are called *elastic;* and those which remain as the compressing force put them, are *non-elastic.* Air and other gases afford the best examples of elasticity. Caoutchouc, ivory, and steel are among the most elastic of solid substances. But no solid body is perfectly elastic, nor are any completely non-elastic; so that elasticity may be considered as general a property of matter as compressibility. The cause of elasticity is not well understood.

Porosity and *Density.*—In common language, a pore is a small hollow space or interstice between the particles of a body, large enough to be seen, or to admit the passage of liquids or gases. In this sense, some substances, such as sponge, wood, sugar, &c. are called *porous*, and others

are contrasted with them as *solid*. But experiment and reflection lead us to the conclusion that all bodies are porous. We have seen that bodies are made up of indefinitely small molecules; and the fact that all bodies admit of compression and expansion, makes us believe, that in no case do these molecules fill the whole space occupied by the body, but have interstices of greater or less size between them; so that when a body is compressed, its molecules are only more closely packed. There is nothing, then, that is not porous, in this sense; and one body is more dense or solid than another, only because it is less porous. *Density* thus means the comparative closeness of the molecules of a body; and a dense body contains, bulk for bulk, more molecules, that is, more matter, than one that is less dense, or, in other words, more porous. As weight depends upon the quantity of matter, density and weight thus go together.

In comparing the densities of different substances, that of distilled water is taken as a standard, and called 1. If a cubic inch, then, of any substance weigh twice as much as a cubic inch of water, its comparative density is expressed by 2; and this is generally called its *specific gravity*. The following table exhibits the specific weights of a few of the more familiar substances:

Platinum, coined	22·100	Flint Glass	3·375
Gold, coined	19·325	Boxwood	1·330
Mercury	13·598	Oak, old	1·170
Lead	11·352	Milk	1·030
Silver	10·474	Sea-water	1·026
Copper, hammered	8·878	Water, distilled	1·
Iron, wrought	7·788	Alcohol, absolute	·800
" cast	7·207	Beech, dry	·590
Diamond	3·520	Cork	·240

Attraction and *Repulsion*.—The term attraction is applied to a great many phenomena, which we must regard as of different kinds, or produced by different causes. The force, whatever it is, that makes a stone fall to the earth, is called the *attraction of gravitation*, because it is the cause of *gravity* or weight. Sir Isaac Newton demonstrated that the same force acts on the moon, drawing it towards the earth; and on the earth, drawing it towards the sun: or rather, that the attraction between any two heavenly bodies is mutual, making them approach each other. It is now established as a fundamental law, not only of our globe, but of the universe, that every atom of matter is attracted towards every other atom. The effects of this law, in causing the fall of bodies and weight, will be considered under Terrestrial Gravity in this number. See also ASTRONOMY.

When a loadstone or a magnetic needle is brought near to a piece of iron, the two bodies, if free to move, will come together and adhere to each other. Also, if a stick of sealing-wax is rubbed with silk, it will draw a light feather to it. These two forms of attraction—the *magnetic* and the *electric*—will be particularly described in the numbers on ELECTRICITY and MAGNETISM.

The kinds of attraction already mentioned act between bodies at a distance, as well as near. But there are forces at work in matter which act only at insensible distances, and between the adjacent atoms and molecules; they are hence called *atomic forces* and *molecular forces*. They are spoken of under the names of Cohesion, Adhesion, Repulsion, and Chemical Attraction.

Cohesion is that force that binds together particles or molecules of the same kind of matter, so as to form masses or bodies. Without some force to hold the molecules together, we could not have bodies, but mere heaps, as of sand. Cohesion acts only when the particles are at distances so minute as to be insensible to us: when removed beyond that distance, it has no influence whatever; and when the molecules of a solid body are once separated, it is in most cases impossible to bring them near enough again to make them cohere.

The three *states of aggregation*, as they are called—that is, the *solid*, *liquid*, and *aëriform*—are owing to differences in the strength and manner of acting of cohesion. It is commonly said that its force is greatest in solids, less in liquids, and altogether wanting in gases. But this account does not explain all the differences of these states. If the smallest quantity of air, or any other gas, is admitted into the exhausted receiver of an air-pump, it does not remain at the bottom, but spreads itself instantly and uniformly through the whole space, as if its particles wished to remove from one another as far as possible. There seems no limit to the space over which the smallest portion of gas will thus spread itself, so that it shall be found in every part of it. We cannot help inferring from this, that the molecules of a gas, instead of attracting, actually *repel* one another with a force sufficient to overcome their own weight—for gases have weight as well as solids and liquids. The dilatation of solid bodies by heat, and the recoil of elastic bodies after compression, would also seem to imply some repulsive force at work.

Again, some gases, when compressed with great force, have their molecules forced so near that they become liquid; and in this condition they are seen to cohere and form drops, thus shewing that they are not destitute of attractive force. The natural conclusion from these and other observed facts is, that among the molecules of all bodies there are two opposing forces at work—an attractive force, and a repulsive force—that when attraction considerably predominates over repulsion, a solid body is the result; when there is almost a balance of the two forces, we have a liquid; and when the repulsive force has the upper hand, we have a gas. Many substances are seen to assume all three forms in turn. Liquid water turns at one time into solid ice, at another into vapour or steam. Greater extremes of cold and heat have the same effects on mercury. Several gases, by applying great pressure and cold, have been rendered liquid, and one at least even solid; and thus it becomes probable that all substances are capable of existing in any one of the three states under certain conditions.

From the fact that the increase of heat regularly increases the energy of repulsion, heat and the repulsive force may be considered one and the same thing. The subject of HEAT will be more fully considered under a separate head.

In solids, the cohesion is exerted in such a way as not only to keep the atoms from separating, but also to retain them in the same relative position; in liquids, on the contrary, the atoms, while still kept from separating, are allowed to move or slide freely upon one another in all directions. This free motion of the molecules upon one

another, rather than want of cohesion, is the grand characteristic of liquids as well as gases; it is one of the causes of drops being spherical. Differences of cohesion give rise to such distinctive qualities of bodies as the following:

Hardness.—This quality depends not so much upon the force with which the particles resist separation, as upon their resisting displacement or alteration of relative position. Softness implies the opposite. Hardness is tested by one body scratching another. It does not correspond with density. Thus, glass scratches gold, and even platinum. Steel has its hardness modified by tempering.—*Malleability* is a distinguishing quality of some metals, and means the capability of being extended into thin plates or leaves by hammering. It depends upon the union of softness and tenacity; the particles shift their position without separating. The most malleable metal is gold.—*Ductility* is the property by which a metal admits of being drawn into wire. The most malleable metals are not the most ductile. Iron is much more ductile than tin or lead, though not so malleable. The most ductile metal is platinum.—*Tenacity* expresses the quality by which a body resists being torn asunder, and depends upon the intensity of the cohesive force. It is not the opposite of *brittleness.* Brittleness is associated with hardness and unyieldingness, except within narrow limits. Glass is brittle—that is, is easily broken by bending or crushing—but a glass rod will sustain a great weight without being *torn* asunder. Thus it is both brittle and tenacious. The most tenacious of all substances is steel.

Adhesion, or, as it is sometimes called, heterogeneous cohesion, is the term applied to the attraction which makes two different substances stick to one another by their surfaces. Cohesion acts between the particles of the same kind of substance; adhesion, between dissimilar kinds of matter. Though the same force probably causes both, yet the effects are so different that it is convenient to consider them separately, and give them different names.

Adhesion between solids.—Particles of dust on an upright pane of glass, chalk-marks on a wall, sealing-wax on paper, cement, are all instances of adhesion between substances of different kinds. Adhesion between surfaces is the chief cause of friction, and unctuous substances are interposed to prevent it.

Adhesion of liquids to solids takes place much more readily than that of solids to solids, because in the case of a liquid and a solid the surfaces come into more complete contact. When the hand or a rod of metal is dipped into water, a film of the water adheres to the surface, and is borne up against its own weight; nor can any force shake it all off. Plunge a bit of gold, or silver, or lead, into mercury, and a portion of the mercury will in like manner adhere. Wherever we have *wetting*, we have a case of adhesion of a liquid to a solid. It is the cause that in pouring water over the edge of a vessel, the water is apt to run down the side of the vessel rather than fall perpendicularly.

But liquids do not always wet solids, or adhere to them. A rod coated with grease, or the wing of a water-fowl, remains dry when plunged in water. Mercury does not adhere to a porcelain cup, or to a rod of iron or platinum. The explanation is simple. There is in every case an attraction between the solid surface and the liquid, but it is opposed by the attraction of the particles of the liquid for one another, and there can be actual adhesion only when the former prevails over the other.

Capillary attraction is only a particular effect of adhesion. A tube with a small bore, like a hair, is called a capillary tube, from *capilla*, the Latin word for a hair. If the end of such a glass tube is dipped in water, the water is seen to rise in the tube above the level of the rest of the surface, as in fig. 1. In a series of tubes of different diameters, the liquid ascends highest in the smallest; or the heights are inversely as the diameters. Water will be seen to rise in a similar way between two glass plates placed as in fig. 3, with two of the upright edges touching, and the other two slightly apart. The sustained film rises higher as the plates approach, assuming the form of a particular curve. The fluid rises also slightly on the outside of the tubes and plates, and the surface of the sustained column within the tube is seen to be hollow like a cup.

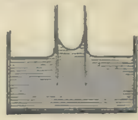


Fig. 1.

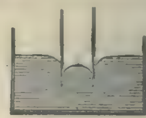

Fig. 2.

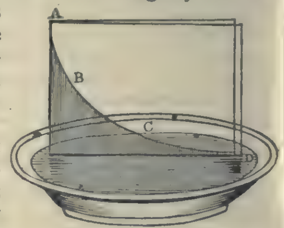

Fig. 3.

But liquids do not always ascend in narrow tubes or spaces; it is only when they wet the solid substance that they do so. If a greasy glass tube is dipped in water; or, still better, if a clean glass tube is dipped in mercury, the liquid inside, instead of rising, sinks below the general level; the surface of the column, too, becomes convex instead of concave, as represented in fig. 2.

The rise or the depression depends upon the adjustment between the forces of adhesion and cohesion, as in the case of wetting. When the liquid wets the tube, the particles next its surface have part of their weight taken away or supported by adhesion, and thus a longer column is required to balance the pressure of the rest of the fluid. In cases where the cohesive attraction of the liquid particles within the tube for one another is too strong to permit them to adhere to its surface, that cohesion tends to draw them away from it, and downwards; while the tube prevents them from receiving the support they would have from the liquid particles around them, if it were not there.

Capillary attraction is exemplified in many familiar appearances, and plays an important part in nature. If a piece of sponge or a lump of sugar be placed so that its lower corner touches the water, the fluid will rise up and wet the whole mass. In the same manner, the wick of a lamp will carry up the oil to supply the flame, though the flame is several inches above the level of the oil. If one end of a towel happens to be left in a

basin of water, while the other hangs over below the level of the water, the basin will be emptied of its contents; and, on the same principle, when a dry wedge of wood is driven into the crevice of a rock, and afterwards moistened with water, it will absorb the water, swell, and sometimes split the rock.

Endosmose or *Osmose.*—Connected with capillary attraction is *endosmose.* If two liquids be separated by a piece of ox-bladder, the one below the membrane being pure water, the other above being a solution, say of sugar, the water will pass through the membrane against gravity, and raise the solution above its former level. A smaller portion of the solution finds its way into the water. This remarkable phenomenon is known as *endosmose* and *exosmose,* or simply as *osmose.* It is not yet fully understood, but is believed to play a part in the passage of the fluids through the membranes of living animals and plants.

Adhesion between Solids and Gases.—In making barometers, it is found that air adheres so firmly to the surface of the glass, that the mercury must be boiled in the tube before it can be expelled. Some porous solids, such as charcoal, absorb air and other gases to an amount many times their own bulk, the force of adhesion condensing the gases on the surface of their molecules.

Chemical attraction is a force whose effects are of a different kind from those of cohesion. If we divide a piece of marble by breaking it into parts, however small, each part is still marble. But the chemist takes it to pieces in a different way. Out of a piece of marble he will produce three distinct substances, altogether unlike the original body—a metal not unlike silver, a black body called carbon, and a gas resembling air. Most of the substances of which our earth is made up are thus composed of two or more different substances or elements. Such unions are chemical unions; the ultimate particles that join to form them are called *atoms;* and the force that binds them, *atomic* force, or *chemical attraction.* The investigation of changes that thus alter the constitution of bodies, belongs to the science of CHEMISTRY.

MOTION AND FORCES.

Motion is change of place, and its opposite is rest. Motion in any one body has always reference to the place of other bodies, and various distinctive terms are used indicative of this reference. A man sitting on the deck of a ship has a *common* motion with it; if walking on the deck, he has *relative* motion to the vessel. *Absolute* motion means change of place with respect to space itself. But we have no means of marking a fixed point in space, and therefore can never observe such a motion; we know only relative motions. As little do we know of absolute rest. The earth is in constant rotation and also revolution round the sun; and the sun himself is in motion, we know not whither. Motion, and not rest, is the great law of the universe.

Velocity, or speed of motion, is measured by the space passed over in a given unit of time; as when we say that a man walks three miles an hour; or that sound travels 1120 feet in a second. The velocity is *uniform,* when equal spaces are always passed over in equal times; it is *accelerated,* when gradually increased, and *retarded,* when gradually diminished. If the increase or diminution is equal in equal times, the motion is said to be *uniformly accelerated* or *uniformly retarded. Force* is any agency that produces or tends to produce motion in a body, or to change or stop its motion; when the body is not free to move, the force exerts a *pressure.* Force and pressure are often used indifferently. The amount of a pressure is measured by the weight it can support, which is stated in pounds, ounces, &c. A force causing motion is measured by the quantity of motion or *momentum* it can communicate in a given time. Momentum does not depend upon velocity alone. Of two balls moving at the same rate, but the one having twice the mass of the other, the larger has just twice the momentum. Momentum, then, is made up of velocity and quantity of matter taken together. To get the comparative momenta of two bodies in numbers, we multiply the weight of each by its velocity.

LAWS OF MOTION.

The leading truths respecting the movements of bodies have been summed up in the shape of a few axioms, or propositions, which were first put into shape by Newton under the name of *Laws of Motion.* We shall give them as laid down by Newton, and then follow them up with observations on each.

1st. Every body continues in its state of rest, or of uniform motion in a straight line, except in so far as it may be compelled to change that state by forces impressed upon it.

2d. Change of motion is proportional to the impressed force, and takes place in the direction of the straight line in which the force is impressed.

3d. To every action there is always an equal and contrary reaction; or the actions of two bodies upon each other are always equal, and oppositely directed.

FIRST LAW.

This law is little else than a definition of the property of Inertia or Inactivity. There are three things to be attended to in this law—namely, the *persistency* of matter, both in rest and motion, when not acted upon by external agency; the *uniform* velocity; and the *straight* direction of motion when once begun and left to itself. The first has been already illustrated under the head of Inertia; and when we say that unobstructed motion is naturally *uniform,* we are only repeating in a different form the same truth.

A little reflection brings out the truth of the third point—namely, that motion is naturally *straight.* If a ball projected forward is seen to bend to the right or the left, we infer at once that something interfered with it. That it bends downwards, we know to be owing to the attraction of the earth. Motion therefore requires force to bend it.

SECOND LAW.

That every change of motion is proportional to the force that produces it, is involved in the way of measuring force, which is by the quantity of motion it gives or takes away. As to the *direction* of the resulting motion, the law requires careful explanation. When the body is previously at rest, it is self-evident that, if unobstructed, it will follow the direction of the force that begins to act

upon it; but if it is already in motion in one direction, and a force then comes to act upon it in another direction, it is not so clear what course it will take. To determine the path or line in which a body will move when thus acted upon by more forces than one, is one of the fundamental problems of the science of mechanics. It is usually treated under the title of the

Composition and Resolution of Motion.

Let the ball, B, be moving along the line AC with a velocity that would carry it from B to C in two seconds, and when at B let it receive a blow that would carry it from B to E in the same time; the question is: How will the ball now move? This is best understood

Fig. 4.

by supposing it placed, not on a plane surface, but in a groove in the upper side of a movable bar lying on a table. The ball being then set rolling at the same rate as before along a groove in the bar AC, let the bar be made at the same time to slide across the table, keeping parallel to itself, and carrying the ball along with it, so as to arrive at the position ED in two seconds. The common motion of the bar and the ball will not in any way interfere with the motion of the ball in the groove, any more than the common motion of a ship and a man on board of it interferes with the man in walking across the deck. The ball will be at the end of the groove at the end of the two seconds, just as if the bar had been at rest; it will, therefore, as a result of the two movements, be found at the point D.

If the position of the ball on the table is observed at the intermediate points, it will be found to describe a straight line from B to D; for since we have supposed both motions uniform, the bar will, at the end of the first second, be in the position *gf*, midway between BC and ED, and the ball will at the same instant be half-way from *g* to *f*, at *k*; and it can be proved that *k* is in a straight line between B and D. The same could be shewn as to any intermediate stage.—When both motions are not uniform, the body moves in a curve, as will be seen in speaking of projectiles.

The movable groove is introduced to make the effect of two movements conjoined more readily conceived; to shew palpably, as it were, that a body may be moving in two directions at one and the same time. But if it receive the second impulse by a blow while rolling freely on the table, it will still arrive at D by the same path.

In any case, then, when two impulses act upon a body, if we draw two straight lines, AB and AC, in the directions of the two impulses, and make the lengths AD and AE in proportion to the velocities that the forces would give to the body if acting separately; then if we draw EF and DF parallel to AD and AE, and join AF, this line, which is called the *diagonal*, gives the direction that the body will move

Fig. 5.

in, and also its velocity. A figure thus formed represents both the velocities and the impulsive forces that produce them, and is called the *parallelogram of velocities*, or the *parallelogram of forces*. AD and AE are called the *components*, and AF the *resultant*.

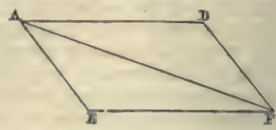

Fig. 6.

In figs. 4 and 5, the forces are represented as acting at right angles to one another; but the angle may vary, as in figs. 6 and 7, and the learner should observe the effect on the resultants as he draws parallelograms with angles still narrower or still wider.

Fig. 7.

We arrive at a similar result if, instead of motions, we consider a set of forces acting against one another so as to prevent motion. When forces thus balance one another, they are said to be in *equilibrium;* and the investigation of such cases forms the part of Mechanics called *Statics* (from a Greek word signifying 'to stand'), while the consideration of force producing motion belongs to *Dynamics* (from the Greek word for 'power').

Two strings fastened to the ring R, and drawn in opposite directions by equal forces, F and F′, will keep the ring at rest, and the forces are then in equilibrium.

Fig. 8.

Now, it is evident that for one of the two forces we could substitute two other forces, as in fig. 9, pulling in the directions R*f*, R*f′*, which, if

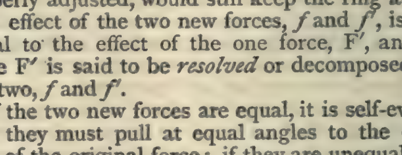

Fig. 9.

properly adjusted, would still keep the ring at rest. The effect of the two new forces, *f* and *f′*, is thus equal to the effect of the one force, F′, and the force F′ is said to be *resolved* or decomposed into the two, *f* and *f′*.

If the two new forces are equal, it is self-evident that they must pull at equal angles to the direction of the original force; if they are unequal, that the greater must be more nearly in that direction than the other, as is represented in the figure. The exact proportion of the two to each other and to the one original force, may be determined thus: Supposing that F′ was a force of six pounds, set off a length of six parts from R to *a*, and then draw *ab*, *ac* parallel to R*f* and R*f′*. We have then a parallelogram of forces. R*c* represents the magnitude of the force *f*, R*b* that of the force *f′*, and R*a* is the resultant, and represents the amount of their combined effect in the direction of RF′. The truth of this may be proved both by mathematical demonstration and by actual

trial. The experimental proof is better suited to our present purpose, and any one may make it for himself. Over two pulleys, A and B, let a string be passed, having two weights, w, w', attached, one at each end, with a small ring in

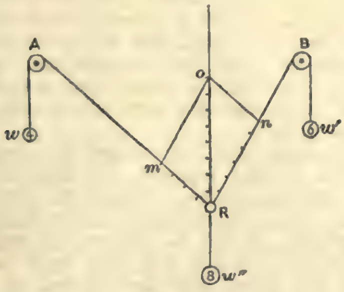

Fig. 10.

the middle, and to this ring let another weight, less than the sum of the other two, be suspended. This third weight will pull down the ring R a certain way, and at last take up a position of rest; the three forces will be in equilibrium. If the weights w and w' are equal, it is evident that w'' will hang midway between the pulleys. But we suppose them unequal; and then every one's experience will tell him that the ring will be drawn nearer to the greater. Suppose $w = 4$ pounds, $w' = 6$, and $w'' = 8$; draw on paper the exact figure made by the strings; take any small unit of length, and set off 4 such units from R to m, and 6 from R to n; through m and n draw mo and no parallel to Rn and Rm, and join Ro. It will be found that Ro is in the same straight line with Rw'', and also that it contains 8 units of length.

As ba in fig. 9 is equal to Rc, and in the same direction, the two component forces and their resultant are represented by the three sides of the triangle Rba; and the resolution of forces is thus often represented by the half of the parallelogram of forces, to save drawing the whole.

The following is an example of the resolution of forces:

Let TP be a ship, SL its sail, WA the direction of the wind, and let the length of WA represent the force of the wind. WA can be resolved into AB perpendicular to the sail, and BW parallel to

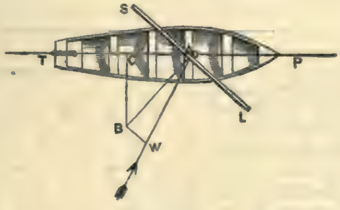

Fig. 11.

it, the latter of which has no effect in pressing on the sail; therefore AB is the effective pressure on the sail. Were the vessel round, it would move in the direction BA. Let BA be resolved into CA and BC, the former, CA, acting in the direction of the keel or length of the vessel, or in the direction CA, and the latter perpendicular to it, or in the direction of the breadth. The former pressure, CA, is the only pressure that moves the vessel forward, the other, BC, makes it move sideways. From the form of the vessel, however, this latter force, BC, produces comparatively little lateral motion; any that it does occasion is called *leeway*. —By a similar double resolution, we may represent how much of the actual force of the wind is effective in turning round the arms of a wind-mill.

THIRD LAW.

If a man standing in a boat attempt to push off another boat of the same size that is alongside, both boats will recede equally from each other; if he pull the other boat towards him, his own boat advances half-way to meet it. A magnet draws a piece of iron towards it; but the magnet is also drawn towards the iron, as is seen when they are both suspended so as to move freely. In all these cases, we see that the body that we consider as acting upon the other, is itself acted upon in turn, and in the opposite direction: this is what is meant by *reaction*.

In saying that the action and reaction are *equal*, it is meant that the momentum produced or destroyed on both sides is the same. If the magnet and the piece of iron above spoken of are of the same weight, they move to meet each other with equal velocities, for thus only can the momentum be the same in both cases. If the magnet is three times the weight of the piece of iron, the iron must move with three times the velocity of the magnet in order to have equal moving force; and so it is found to do.

In the last instance, both motions would still be visible. But let a boat of a ton weight be pushed away from the side of a ship of a thousand tons' weight, and then only one seems to move; for while the boat moves off a yard, the ship recedes only the thousandth part of a yard, which it would require minute observation and measurement to render apparent. From this we can pass to the extreme case of a boat pushed off from shore. Where is the evidence of reaction here? We see none, it is true; still, the consideration of the cases already adduced, and of a thousand similar, lead us irresistibly to believe that the shore, if it is free to move, must recede from the boat. We cannot help believing, then, that when a stone falls—in other words, when the earth draws a stone towards it—the earth is itself drawn, or falls, towards the stone.

COMMON MOTION.

When a system of bodies has, from any cause, received a common motion, their positions, with regard to one another, remain unaffected by it, and in considering their relative motions, we may leave their common motion out of account; everything is as if the system were at rest. This arises from the property of inertia, as already expounded. When a ship is going steadily, all things go on in the cabin as in a room. On deck, a ball thrown upwards comes down in the same spot; the deck has not slipped away from under it. The *motal inertia* of the ball carried it on while in the air with the motion it had acquired from the ship.

The feats of equestrians depend upon this law of common motion. Riding at full speed, they throw up balls, which return into the hand. The

rider springs right up from the saddle, and alights on it again without falling behind the horse. Additional illustrations of this law will be found under METEOROLOGY and PHYSICAL GEOGRAPHY.

TERRESTRIAL GRAVITY.

It is a law, as we have seen, wide as the universe, that every particle of matter acts upon every other particle by the force known as gravitation, which draws them one towards another. We are now to consider the laws of this force, and explain the more important phenomena it gives rise to.

The attraction of gravitation is always in proportion to the mass of the attracting body. This will be readily admitted. A force is exerted by each atom, and the more atoms the more force. It is not the volume or bulk of the body, but its quantity of matter, that decides its effect. Gravitation, again, acts at all distances, but with diminished effect as the distance increases. The decrease, however, does not go on in a simple proportion; twice the distance does not give simply half the attraction. If, at the distance of a foot, the force of attraction between two bodies were a pound, at the distance of 2 feet, it would be $\frac{1}{4}$ of a pound; at 3 feet, $\frac{1}{9}$th of a pound; at 4 feet, $\frac{1}{16}$th of a pound. This is expressed by saying that attraction varies inversely as the squares of the distances between the bodies.

The distance between two mutually attracting globes is measured from centre to centre. The attraction of the earth, then, on a body at its surface is exerted at the distance of about 4000 miles, which is the length of its *semi-diameter;* at the height of 4000 miles above the surface, or at the distance of two semi-diameters from the centre, the attraction is reduced to one-fourth. The moon being at the distance of sixty semi-diameters, the earth draws it with a force which is only a 3600th part of what it would be, were the moon at the earth's surface. It belongs to astronomy to treat of gravitation as ruling the planetary motions; we have here to speak of the phenomena it produces on bodies at or near the earth's surface.

The attraction of the earth for bodies on its surface is so strong, owing to its overwhelming mass, that it overpowers their attraction for one another, and renders it in most cases inappreciable. But a plumb-line suspended near a large mountain is sensibly drawn from the perpendicular; and by a delicate instrument, called the torsion-balance, the action of a large ball upon a small one has been measured. The *weight* or gravity of a body is another name for the force with which it is drawn towards the earth.

Falling Bodies.

Perhaps nothing explains more phenomena than the complete understanding of what takes place when a body falls; for half the motions in the world are caused, directly or indirectly, by falling. Falling is the best instance of a *uniformly accelerated* motion. Gravity not only puts a body in motion, but *continues* to act on it with equal force after it is in motion, and thus is uniformly adding to its speed. This acceleration is seen in every body dropped from a height through the air; and no less in a rock rolling down a declivity, which continually gathers force as it descends, till its energy is sufficient to shatter itself and everything it encounters to pieces.

All bodies, heavy and light, would fall equally fast if the resistance of the air were removed. A ball of lead two pounds' weight does not fall faster than a ball of one pound. A gold leaf, however, will fall considerably slower than the same gold in a solid state, because it exposes much more surface to the air. That this is the cause of the difference, is shewn by an experiment with the air-pump, in which a guinea and a feather are dropped in a vacuum, and fall to the bottom together.

It has been well ascertained by observation, that when a body begins to fall from a state of rest, it descends 16 feet 1 inch in the first second of time. (This measurement varies slightly with the latitude, as will be afterwards explained.) Suppose that no fall had ever been observed beyond that point, and that we had to find by reasoning what the body would do during the next second. The first consideration is, How far would the body fall, if gravity were to cease?—in other words, What velocity has it acquired? It would not be unnatural to say 16 feet (we omit the 1 inch), since that is the space it fell in the second that is ended; but reflection shews that this cannot be the case. During the first half of the second, it made very little way, and the greater part of the distance was passed over in the last half; 16 feet expresses the mean velocity, or the velocity it had at the middle of the second, and at the end it must have been moving with a velocity just double the mean. The velocity acquired, then, at the end of the first second is 32 feet; and if gravity were to cease, it would, by the law of inertia, move over 32 feet in the next second. But gravity still acting, will make it fall another 16 feet in addition to the 32, or 48 feet in all; and will create as much velocity in addition as it created in the first second, so that if it were to cease at the end of the second second, the body would move 64 feet in the third second. Thus, during the second second, the body will fall through three spaces of 16 feet, and at the end of it will have its velocity double of what it was at the end of the first second. The whole space fallen during the two seconds will thus be four spaces of 16 feet.

We arrive at this result by reasoning, and observation proves it correct. Without giving the steps of the investigation for the succeeding spaces of time, the results may be exhibited in the following table:

Number of Seconds.	1	2	3	4	5	&c.
Velocities at the end of number of seconds in spaces of 16 feet,	2	4	6	8	10	&c.
Spaces fallen through during each successive second,	1	3	5	7	9	&c.
Spaces counted from beginning of fall,	1	4	9	16	25	&c.

For example: The third column, headed 3 (seconds), informs us that at the end of 3 seconds a falling body is moving (for the instant) at the rate of 6 spaces of 16 feet—that is, of 96 feet—a second; that during the third second it falls 5

spaces, or 80 feet; and that the whole distance fallen during all the three seconds is 9 spaces, or 144 feet.

The distances that bodies fall, then, do not increase simply as the times, but as the *squares* of the times. To find, therefore, how far a body will fall in any number of seconds, multiply the number of seconds by itself, and that product by 16. Thus, in 7 seconds, a body will fall $7 \times 7 \times 16 = 784$ feet. The height of a precipice might be roughly measured in this way, by observing how many seconds a stone takes to reach the bottom.

As a body in descending to the earth receives increasing accessions to its velocity during every successive second, so, when a body is projected upwards from the surface of the earth, its velocity decreases in the same proportion till it comes to a state of momentary rest, when it instantly begins to descend with a gradually increasing velocity, which at any point in the descent is equal to its velocity at the same point when ascending. In this calculation, however, we omit the influence of the atmosphere.

Projectiles.

Any heavy body launched or *projected* into the air with an impulse, is a projectile; and to investigate the motions of such bodies forms a distinct branch of the science of motion.

Suppose a cannon-ball fired from the top of a tower, whose height is represented by the line A4′, in the direction of the horizontal line AB. The

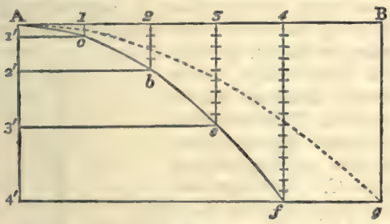

Fig. 12.

force of the gunpowder ceases to act as the ball leaves the cannon, and the ball retains a uniform velocity which would carry it over equal spaces in equal times. Let A1 be the space the ball would describe in a second if acted on only by the projectile force, and set off a number of equal spaces along AB. Now, from the moment the ball leaves the mouth of the cannon, it is acted on by gravity; and while moving in the direction of AB, also falls; so that at the end of a second it must be 16 feet lower than it would have been if gravity had not acted—that is, if we take the perpendicular line 1*c* to represent 16 feet, the ball will at the end of the first second be at *c*. The horizontal motion being uniform, the ball at the end of the second second would be at 2, or twice as far towards B; but its downward accelerated motion has in the meantime dragged it down through three spaces more—in all four spaces—of 16 feet below the horizontal line. Making 2*b*, therefore, equal to four times 1*c*, gives *b* as the point where the ball will be at the end of the second second. By similar reasoning, if 3*e* is made equal to nine times 1*c*, 4*f* equal to 16 times 1*c*, &c. according to the law of accelerated motion; *e*, *f*, &c. will be the points at which the ball will be found at the end of the third, fourth, &c. seconds. The resultant of these two dissimilar motions, the one uniform, and the other uniformly accelerated, is a curve of the kind called a parabola, as represented in the figure.

From the above investigation, this remarkable consequence follows: that a body projected horizontally from a height above a level plane, comes to the ground as soon as if it were let fall perpendicularly. The ball reaches *f* in the same time that it would fall from A to 4′. A greater velocity of projection would make it take a wider flight; but its horizontal motion does not interfere with its downward motion, and at the end of four seconds it must be at some point in the same horizontal line—at *g*, for example. Two balls, then, projected horizontally from the same height above a level plane, though the one may range only a mile, and the other two miles, will reach the ground at the same time.

Projectiles are mostly thrown, not horizontally, but in an oblique direction. We arrive, however, at the path described in the same way as in the last case.

The laws above arrived at respecting projectiles are strictly true only on the supposition that the movements are made in empty space. But every projectile has to encounter the resistance of the air; and that resistance becomes so great when the velocity is very high, that in the practice of gunnery the theory is of little value. With a small velocity, however, a body thrown through the air describes a path not differing much from a parabola.

Since the distance of the flight, and the width of the curve described by a projectile, increase with its initial velocity, we can conceive the velocity increased until the curve became as large as that of the earth itself. If this were the case, the projectile, instead of falling, would, if the resistance of the air were removed, continue to go round and round the earth for ever. We thus arrive at the idea of planetary motion. The moon, for instance, is constantly falling towards the earth, like a cannon-ball shot horizontally; but the projectile velocity which it had from the beginning, and which, as it moves in empty space, it retains undiminished, is sufficient to carry it clear round in the curve called its orbit.

Centre of Gravity.

The centre of gravity of a body is that point about which the body balances itself in all positions. When a rod of uniform thickness and density is suspended by its middle point, it remains at rest. There is as much matter on the one side as the other; the atoms balance one another in pairs; and it is as if the whole were collected at the point of suspension. The centre of gravity of such a rod is the central point at its middle part; and if the substance of the rod is pierced, and this central point rested on a fine needle, the rod will remain immovable in whatever position it is put.

Whenever bodies are regularly shaped, and of uniform density, their centres of gravity may be found by mathematical measurement, as in the case of the rod. Thus the centre of gravity of a globe is evidently in its middle point, or centre of dimension.

The position of the centre of gravity in a triangular-shaped body is not so obvious. It is thus found. If ABC represent the surface of a thin triangular board, we may suppose it composed of a number of small rods laid side by side, the line AB representing the first, and the others gradually diminishing in length to the top. Now, the centre of gravity of the rod AB is in its middle point D; and if we join the points D and C, the line will pass through the centres of gravity of all the other rods; because it is a property of a line drawn from the top of a triangle to the middle of the opposite side, to bisect or pass through the middle of all lines in the triangle parallel to that side. The centre of gravity of the whole, therefore, must lie somewhere in the line CD. Again, by conceiving the triangle made up of rods parallel to the side CB, and drawing a line from A to the middle point E, we see that the centre of gravity must, in like manner, lie somewhere in the line AE. Now, since it lies also in CD, it can lie only where the two cross—namely, at *g*. We have thus found the centre of gravity of the surface, as it were; and if the board have any sensible thickness, its actual centre of gravity will lie behind *g*, at the distance of half the thickness. It is one of the properties of the triangle, that the line D*g*, determined as above, is always one-third of the whole line DC; thus the centre of gravity of a triangle is readily found.

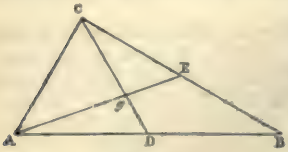

Fig. 13.

When two balls are connected by an inflexible rod, they form but one body, and the common centre of gravity is not situated in either, but between them in the rod joining their centres. If the balls are equal in mass, it will evidently be in the middle of the rod; but if they are unequal, the point where they balance each other is found to lie nearer to the larger mass. See MECHANICS.

The centre of gravity has always a tendency to seek the lowest point, and this enables us readily to find the centre of gravity of an irregular body. For example, let a painter's pallet be suspended from the thumb-hole, as in the figure; we know that the centre of gravity must be perpendicularly below the point of suspension, and if we allow a plumb-line or a straight rod to hang down from that point in front of the pallet, and mark the line under it, the centre of gravity must be on that line. Next, suspend the pallet from any other point, D, and apply the plummet as before, and another line is found also containing the centre of gravity, which must therefore be where the lines cross. If a third line of direction is tried, it will be found to pass through the same point.

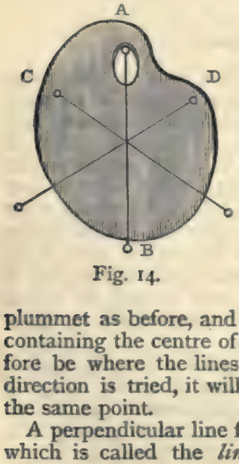

Fig. 14.

A perpendicular line from the centre of gravity, which is called the *line of direction*, must fall within the base of any object resting on the ground, otherwise it will fall. A structure may overhang its base within certain limits. In A (fig. 15) the line of direction falls within the base,

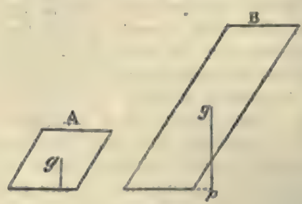

Fig. 15.

so that the centre is still supported, and would have to *rise* before the body could tumble; in B, the centre is unsupported, and moves in a descending curve from the first. The instability here arises from the *height* of the object, for the slope and base are the same in both.

This explains why vehicles when loaded high, or made *top-heavy*, are so easily upset.

The Pendulum.

Any heavy body, such as a ball, suspended by a string or rod, so as to swing freely, constitutes a pendulum. Swinging is no less an effect of gravity than falling; and from the importance of the pendulum, as a measurer of time, the phenomenon deserves attentive study.

In the accompanying cut, a pendulum of the most common construction is represented, suspended at A. When the ball or bob, C, is drawn to one side, as to D, gravity urges it downwards, while the tension of the rod draws it towards A. The composition of the two forces makes it describe a descending curve to C. But the ball does not stop here; it goes on, by the law of inertia, in the ascending curve CD′, until gravity destroys its acquired motion. If friction and the resistance of the air did not interfere, the ball would reach the same elevation as it started from. But these causes gradually render the ascent less and less, and at last bring the pendulum, when it has no maintaining power, to a state of rest.

Fig. 16.

One sweep of a pendulum from D to D′ is called an *oscillation*. The most remarkable property of the oscillations of the pendulum, and that on which its use as a regulator of movement depends, is that, whether long or short, they are all performed in very nearly the same time. If we observe the vibrations of any body set swinging, we find that, though the arc it describes is continually diminishing, there is no sensible shortening of the time in which the single sweeps are accomplished. As the journey becomes less, so does the velocity. Galileo is said to have been the first that distinctly noted and investigated this important fact. It is easy to see, in a general way, that the wider the sweep of the ball, the steeper is its descent at the beginning; and that the greater velocity thus acquired must more or less compensate for the longer journey; but the mathematical proof that

the times are thus exactly equalised would be out of place here.

It is only short oscillations that are thus *isochronous*, as it is called; when the arcs are large, the steepness does not increase in exact proportion to the length, and therefore the isochronism is not perfect. Accordingly, pendulums are made to swing in short arcs; and then, though no contrivance could make the extent of the oscillations exactly uniform, the times are virtually equal.

But though the time of oscillation is not affected by the largeness of the arc, it is by the length of the pendulum itself. Long pendulums vibrate more slowly than short ones. Though the balls B and D in the fig. have the same amplitude of vibration, or go over corresponding arcs, the journey of the one is longer than that of the other. But the steepness of descent, or inclination of the path, is the same in both; therefore B must take longer time to perform its journey than D. We must not, however, conclude that when the length of the arc, or, which is the same thing, of the pendulum, is doubled, the time of oscillation is also doubled. The motion of the pendulum is an accelerated motion; and, as in all other uniformly accelerated motions, the spaces described are as the squares of the times. To give double the time of vibration, then, requires the pendulum to be four times as long; treble the time, nine times as long; and so on. A pendulum of a little more than 39 inches beats seconds, and one of one-fourth that length beats half-seconds.

Fig. 17.

When we say that the seconds pendulum is always of the same length, we must be understood to speak of the same place. In different places, its length varies. At the equator, owing to the shape of the earth, we are thirteen miles further from the centre than at the poles; the force of gravity is therefore less, and thus the seconds pendulum must be somewhat shorter at the equator, and grow gradually longer as the latitude increases.

The length of a pendulum is measured from the point of suspension, not to the bottom, or even the centre of the ball, but to a point called the *centre of oscillation*, where the whole mass of the swinging body—rod and ball together—may be supposed concentrated. The determination of this point is a matter of some difficulty. The use of the pendulum in regulating clocks is considered in the number on HOROLOGY.

CENTRIFUGAL FORCE AND CIRCULAR MOTION.

Motion in a circle, or in any other curve, is something constrained. When we make a ball whirl round rapidly at the end of a cord, we feel the cord stretched with a sensible force; the ball is pulling outwards, and the hand is pulling inwards. The outward pull of the ball is called the *centrifugal*, or centre-flying force; the inward pull of the hand, the *centripetal*, or centre-seeking force. The tension of the cord is the measure of both forces.

When a body, constrained to move in a circle, is released from the restraint, what is the result? Suppose the ball B retained by the cord AB, and moving in the direction CEG, &c.; if relieved from the restraint of the cord, it does not fly directly away from the centre, in the line AB prolonged. It has still its onward motion in the direction of the curve, and the only effect of the release from the centripetal force is, that that motion ceases to be bent, and goes on straight in the direction it had at the instant. Now, at any point in a circle, the direction of the curve is that of a straight line drawn through the point at right angles to the diameter. Such a straight line is called a *tangent;* and thus motion in a circle, when released from the constraining force, becomes motion in the tangent, or flies off at a tangent. At C, for instance, the direction of the ball, when set free, would be CD; at I it would be IK.

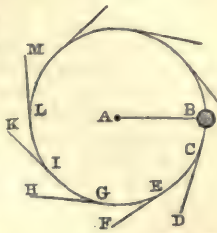

Fig. 18.

The tendency to fly off from the centre and at a tangent, is exemplified in a multitude of phenomena. A stone let go from a sling is the most familiar instance. When a vessel with water in it is rapidly turned round like a horizontal wheel, the water recedes from the centre, and rises up round the sides.

In equestrian performances in a circus, both rider and horse incline their bodies inwards; they are leaning against a force which is impelling them outwards, and which thus sustains a part of their weight. A skater must do the same in describing a curve. If a round ball of soft clay be turned rapidly on a spindle, it ceases to be perfectly round in all directions: it bulges out at the middle and shortens in the direction of the spindle. This has happened to our earth; and to a still greater degree to Jupiter and Saturn, which have a more rapid rotation on their axes.

The centrifugal force of a body moving in a circle increases as the mass of the body, and as the square of the velocity. It is calculated that if the rotation of the earth were seventeen times faster than it is, centrifugal force at the equator would be equal to gravity; in other words, all bodies would be completely without weight, and a little increase of velocity would throw them off, to circle round like small satellites.

HEAT.

To account for the appearances presented by matter in its several forms of solid, liquid, and gas, we have seen it necessary (p. 195) to assume that there is a *repulsive* force at work among its molecules, counteracting and modifying the attractive forces. This repulsive force would seem to be identical with heat. Heat expands bodies; it overcomes the cohesion of their particles, converting solids into liquids, and liquids into gases; without it, there would be only one form of matter, the solid, and all life would cease on the earth.

As to the nature of heat, there have been two theories. The prevailing theory at one time was, that it was a distinct material substance, though imponderable; a subtle fluid stored up in the spaces between the atoms of the grosser kind of matter. The universal view now is, that *heat is a mode of motion*. When a lump of lead is allowed to drop from a considerable height upon a hard body, it is found to be sensibly heated. In this case the motion of the lead has been arrested, but not destroyed. *Motion, like every other form of energy, is as indestructible as matter itself;* it is only the form of it that has been changed.* The motion of the mass has been transferred to the atoms or molecules, which are made to move or vibrate to and fro, each by itself; and it is this movement of the atoms and molecules that affects the nerves with the sensation of heat. These molecular motions are, like the molecules themselves, far too minute for actual observation; so that we cannot say whether they are revolutions in an orbit, or oscillations backwards and forwards; but the assumption of a motion of some kind seems necessary to the explanation of the observed facts.

Perhaps no class of natural laws are more interesting in themselves, or more practically important, than the laws of heat. A knowledge of them is of direct application in every art and handicraft, as well as necessary for domestic economy and personal comfort. A full discussion of the subject would require a volume; it is only the most general facts that the limits of this tract permit to be stated.

EXPANSION.

As a rule, all bodies, whether solid, liquid, or gaseous, which are not decomposed by heat, are expanded by it. Solids expand least, gases most, and liquids—speaking generally—are intermediate between them in expansibility.

To illustrate the expansion of solids, a rod of iron may be taken, and its length and diameter exactly measured at the temperature of the air. If it be now raised to a red heat, it will be found to have suffered an increase in length, and to be too wide to fit an aperture through which it passed before. When allowed to cool to its original temperature, it will exactly recover its previous dimensions.

The expansion of liquids is familiarly illustrated by heating a glass flask filled with any liquid. The liquid rapidly expands, and manifests its expansion by running over. If a bladder three-fourths filled with air is held near a fire, it becomes quite stretched, and may be made to burst, thus illustrating the expansion of gases.

Nearly every solid and liquid has an expansibility peculiar to itself. Among solids, the metals are the most expansible bodies. Zinc expands most, platinum probably least among bodies of the metallic class. Glass, brick, porcelain, marble, and stone, have small expansibilities. If a rod of iron which measures 819 lines in length when as cold as melting ice, is made as hot as boiling water, it is found to measure 820 lines. Between the freezing and boiling points, then, iron increases $\frac{1}{819}$ of its length; for the same increase of heat, glass expands only $\frac{1}{1147}$ of its length.

Among liquids, we find those which are most volatile more expansible than others. Gases, unlike solids and liquids, have not specific expansibilities, but each undergoes almost the same amount of expansion for the addition of the same amount of heat.

When heated from 32° to 212°, mercury dilates $\frac{1}{55}$ of its bulk, and alcohol $\frac{1}{9}$; air or any other gas about $\frac{1}{3}$. An increase of 1° of temperature, therefore, increases a body of air by $\frac{1}{480}$ of its bulk.

The mechanical theory of heat, that is, the theory that it is a mode of motion, quite accounts for the phenomena of expansion. If heat consists of vibrations of the particles of matter, to increase it is to increase the rapidity and width of the vibrations. Thus the particles are made to urge one another farther apart, and the volume of the body is increased. Further, as the force of cohesion which opposes this separative tendency differs in different substances, we should expect the expansive effect of heat to be greater in one case than another; and this is what, in fact, happens. The liquid and gaseous forms of matter are readily explained as still further effects of these molecular motions. In solid bodies, we may conceive that the force of cohesion, while allowing to each molecule a power of vibration within certain limits, yet holds the orbits or paths of these vibrations together in fixed positions relatively to one another. But as the particles continue to be urged farther apart by fresh accessions of heat, cohesion becomes too weak to hold them in fixed positions; they are now at liberty to roll or glide around each other; in other words, the substance has melted or become liquid. If urged yet farther asunder, they get beyond the sphere of cohesion, and seek to fly away into space, and in this condition they constitute gas or vapour.

Water presents a singular irregularity in its expansions and contractions. If boiling water is taken, and allowed gradually to cool, it follows the general law, and goes on contracting until it is within a few degrees of freezing (at 39°); it then begins to dilate, and continues to do so till it come to 32°, the freezing-point. At the moment of becoming solid, it undergoes a sudden enlargement. It is this enlargement of freezing water that causes it to burst pipes and vessels in which it is confined; it is also the reason that ice is lighter than water, and floats on the surface. Ten cubic inches of ice weigh as much as nine cubic inches of water.

In laying the rails on a railway, and in all structures where metal is used, allowance must be made for the expansion and contraction of the metal by change of temperature. The practical mechanic avails himself of the law of expansion in putting on the tires or rings of wagon-wheels and iron hoops on vats. Being made a degree too small at first, the tire or hoop is heated to redness, and in this state driven on; it is then cooled with water, when it contracts, and draws the parts of the wheel or vessel together with an irresistible force.

THE THERMOMETER.

The thermometer is an instrument in which *temperature*—that is, *the intensity of heat*—is measured by the amount of expansion it produces.

* This is the doctrine embodied in the phrase, *The Conservation of Energy*, which will be further exemplified in treating of Light and Electricity.

The most convenient substances for the construction of thermometers are found to be mercury and alcohol, or spirit of wine. For ordinary temperatures, mercury is preferable; but when too much heat is withdrawn, it freezes or becomes solid, and therefore, for very low temperatures, alcohol is used, which cannot be congealed by any known cold. The mercury or alcohol is inclosed in a glass tube with a hollow bulb at one end, the other being closed. It is then graduated by first plunging it in melting ice, and marking on the glass, or on an ivory scale attached to it, the point at which the mercury comes to stand. This mark is the *freezing-point* of water, for water freezing and ice melting have the same temperature. The thermometer is next placed in boiling water, when the mercury rises to a certain height, and then continues steady. A second mark is here made, which is the *boiling-point*.

The space between these two points is then divided into a number of equal parts, called *degrees*, and parts of the same length are set off above and below the boiling and freezing points, as far as required.

In the thermometer used in this country, the space between the freezing and boiling points is divided into 180 equal parts, and we begin counting at 32° below the freezing-point. A cipher is placed there, and it is called the zero or nothing-point of the thermometer. The freezing-point of water thus comes to be marked by the number 32°, and the boiling-point, which is 180° higher, by 212°. In the thermometer chiefly used on the continent, the space between the freezing and boiling points of water is divided into 100 equal parts, and the graduation begins at the freezing-point, which is marked 0°, or zero. According to this thermometer, which is called the centigrade, water freezes at 0°, and boils at 100°.

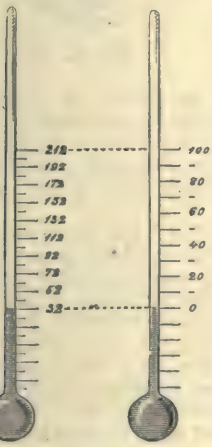

Fig. 19.

The centigrade thermometer is now much employed in scientific researches in this country. To prevent any confusion arising from its being mistaken for the thermometer first described, which is called, from its original maker, Fahrenheit's, or the Fahrenheit thermometer, the letter F is placed after temperatures indicated by his thermometer, and the letter C after those denoted by the centigrade.

From its zero-point each thermometer counts downwards as well as upwards; and to distinguish the degrees below zero from those above it, the former are distinguished by prefixing to them the minus sign —. Thus, mercury is said to freeze at − 40° F.; that is, at 40° below Fahrenheit's zero.

Another scale much used in Germany is that called Réaumur's, in which the freezing-point is marked 0°, and the boiling-point 80°. The degrees on this scale are thus larger than those of Fahrenheit, or even of the centigrade: 9° F. = 4° R. or 5° C.; and by means of these proportions, a temperature stated in one scale may be reduced to either of the others, care being taken to allow for Fahrenheit's scale commencing, not at the freezing-point, as the others do, but 32° below it.

Fahrenheit chose the temperature of 32° below freezing as the zero-point of his scale, because it was the lowest that had then been observed, and was considered to indicate the complete absence of heat; but it is now known that there are natural temperatures at least 90° below this; and by artificial mixtures, a cold has been produced of −146° F.

SPECIFIC HEAT.

Different substances require different quantities of heat to raise them to the same temperature. This is expressed by saying that each possesses a *specific capacity* for heat, or, more shortly, a *specific heat*. The fact can be proved in a variety of ways. Thus, if we cause equal quantities of bodies which have all been raised to the same temperature, to melt ice, we shall find that a much greater weight of it will be melted by one body than by another. Thus, mercury at 212° will melt much less ice than an equal quantity of water at the same temperature will, for the mercury has much less heat to give out, so as to produce liquefaction, than the water has.

Specific heats are generally stated with reference to equal weights, rather than to equal measures, of bodies. Thus, a pound of water in rising to a given temperature, absorbs thirty times more heat than a pound of mercury in rising to the same temperature; so that the capacity of water for heat exceeds that of mercury thirty times; and if we call the specific heat of mercury 1, that of water will be 30.

The mechanical theory of heat affords a satisfactory explanation of this difference in bodies. Chemistry establishes that the atoms of different substances differ greatly in weight; an atom of oxygen, for example, has sixteen times the weight of an atom of hydrogen. Now, experiment seems to prove that when two substances are at the same temperature, the ultimate particles of both have each the same amount of the motal energy we call heat, the smaller particles making up for want of weight by greater speed. But, as it requires sixteen times more atoms of hydrogen to make a pound than it does of oxygen, a pound of hydrogen must thus contain sixteen times as much heat as a pound of oxygen. It follows that to raise the temperature of a pound of hydrogen through, say, 10°, requires sixteen times as much heat added as is required in the case of oxygen. Thus, the specific heat increases as the atomic weight diminishes.

The great specific heat of water has a most important relation to the welfare of the living creatures on the globe. The sea, and other great beds of water, which spread over so large a portion of the earth, cannot in the hot seasons of the year become rapidly raised in temperature; in the cold seasons of the year, on the other hand, they cool slowly, and, moreover, in cooling, evolve much heat, which equalises the temperature of the air as well as that of the land.

PROPAGATION OF HEAT.

Heat is transferred from one portion of matter to another in three different ways, which are termed conduction, convection, and radiation. *Conduction* implies the passage of heat from one particle of matter to another in physical contact with it. *Convection* is the conveying or carrying of heat by particles of matter raised in temperature, and set in motion. *Radiation* is the emission of heat by a body such, for example, as a mass of red-hot iron at rest, and not in physical contact with the substances to which it communicates heat. The heat passes in radii, or rays, like those of sunlight, which can find their way even through a vacuum, and do not appear to require the assistance of ponderable matter to determine their transference.

Conduction.

Conduction is best seen in solids, and particularly in metals, which are the best conductors. A rod of iron placed with one extremity in the fire speedily becomes hot at the opposite extremity, owing to the conduction of heat from particle to particle along the rod. Dense bodies are generally the best conductors; light and porous ones the worst; but this rule does not always hold. Feathers, down, fur, flannel, and most of the fabrics used for winter dresses, owe their so-called warmth to their low-conducting power for heat. Their action is altogether negative, being limited to the prevention of the rapid escape of heat generated by the living beings whose bodies they cover. Hence the best way to preserve ice is to wrap it in flannel, or other so-called warm covering; for the same means that retard the escape of heat from the living body, retard the access of heat from the air and surrounding objects to the ice.

The relative conductivities of the principal metals are exhibited in the following table:

Silver	100	Iron	12
Copper	74	Lead	9
Gold	53	Platinum	8
Brass	24	German Silver	6
Tin	15	Bismuth	2

On the same scale, the conductivity of marble would be expressed by ·8, of porcelain by ·6, of brick earth by ·55. Wood conducts fully twice as well in the direction of the fibre as transversely.

Vessels of porcelain and glass are liable to crack when hot water is suddenly poured into them, because these substances conduct heat slowly, and thus the part first touched by the water becomes expanded, while the parts adjoining are yet cold and unexpanded.

Liquids and gases are very bad conductors of heat, although, from the rapidity with which they rise in temperature, when heat is applied to them, they appear to be among the best conductors.

Convection.

Liquids and gases rise in temperature chiefly in consequence of the convection, not the conduction of heat by their particles. If a spirit-lamp is applied to the top of a tube filled with water, the upper portion of the liquid is soon heated to boiling, while hours will elapse before even a slight degree of heat will reach any distance down the column. But if the lamp is applied at the bottom of the tube, the heat is soon felt at the top, and the whole liquid is made to boil in a few minutes. This remarkable difference is owing to a motion that takes place among the particles of the liquid. The portions resting on the bottom, being expanded and made lighter by the heat, begin to ascend, and thus circulating currents are established which *convey* the heat to all parts of the mass. This circulation may be made visible in a glass flask (fig. 20) nearly filled with water, having a few bits of blue litmus swimming in it, and with a spirit-lamp below.

Fig. 20.

Air and other gases are raised in temperature in the same way that liquids are. They conduct heat with extreme slowness, as may be proved by applying heat to the top of an air-tight glass vessel with a thermometer suspended a little below the heated portion. But when the heat is applied from below, currents of circulation immediately begin, as in the case of a liquid.

Our sensations lead us into many errors regarding the temperature of bodies, which attention to their different conducting and conveying powers enables us to correct. Thus, of the several articles in the same room, the table feels colder than the cloth that covers it, and a marble slab colder than the table. They are, in fact, all of the same temperature—the temperature, namely, of the air in the room; but the marble being the best conductor, robs the hand most quickly of its heat.

The cooling effect of a liquid or fluid is much increased by motion, as when the hand is moved through cold water, thus bringing fresh unwarmed portions in contact with it in rapid succession. It is on this last principle that a degree of cold may be borne with a calm atmosphere, which becomes quite killing with even a moderate wind. When air is confined and prevented from circulating, it forms a non-conductor and a warm protection. Hence the effect of double-windows, and of plaster put on laths, so as to inclose a plate of air between it and the wall, instead of being laid on the wall itself. Woolly coverings and furs imprison the air within their substance, and prevent it from circulating, while they afford but few points of solid contact for the direct conduction of heat. These two circumstances combined, give them their remarkable power in arresting the escape of heat; and that power is greater the finer and lighter their texture. Swan's-down is said to be the most perfect insulator of heat. From the same causes, snow is an excellent non-conductor, and, like a fleece of wool, protects the earth from any cold much below 32°.

Radiation.

Every hot body in the act of cooling, besides losing heat by the conductive and convective action of the solids and fluids in its neighbourhood, parts with much heat by radiation. Rays of heat pass away from the hot body till it has reached the temperature of the air or surrounding medium. In proof of this, it is only necessary to hang a hot body in the vacuum of the air-pump, when it rapidly cools, although it does not lose heat by either conduction or convection.

The rate of cooling of a hot solid body, so far as radiation is concerned, is remarkably influenced by the state of its surface, and, in the case of liquids and gases, by the state of the surface of the vessels containing them. Thus, hot water placed in a tin vessel coated externally with lampblack, cools twice as fast as it does in a bright tin vessel. From these observations, it appears that a kettle covered with soot is much less suited for retaining water warm, than if it had a polished metallic surface. So, also, metallic tea-pots and coffee-pots are preferable to those of porcelain and stoneware.

Absorption and reflection of Rays of Heat.—Rays of heat follow almost the same laws as to reflection, absorption, refraction, &c. as rays of light. In fact, radiant heat is manifestly identical with light, differing from red light, for instance, as red light differs from blue—that is, by having longer waves (see SOUND AND LIGHT). When heat-rays fall on the surface of a body, they either enter it or are *reflected*. Those, again, that enter are either *transmitted*, like light through glass, or are retained and *absorbed*. It is only the rays that are absorbed that warm the body; those that are reflected off, as well as those that are transmitted, produce no effect on the temperature.

Surfaces that radiate heat best, are found also to imbibe it most readily. If a table, then, is formed of substances according to their power of radiating heat, the same table will serve for their power of absorption. The following is such a table, the radiating and absorbing power of a surface of lampblack being expressed by 100:

Lampblack	100	Tin	14
White-lead	100	Brass, polished	7
Writing-paper	98	Copper	7
Glass	90	Gold	3
Polished Iron	23	Silver	3
Mercury	23		

Since all the rays not absorbed by a surface must be reflected, this table, read from the bottom upwards, will give the same surfaces in the order of their reflecting powers. It thus appears that the best protection for the head from the burning rays of the sun is a polished metal helmet.

Colour has comparatively little influence on the radiation or absorption of heat so far as *obscure* or non-luminous rays are concerned. In the above table, lampblack and white-lead rank equal; and two garments of the same material, the one white and the other black, dissipate the heat of the body at the same rate, and afford the same protection from the rays of a hot stove. But in regard to *luminous* heat, the case is different. A beam of the sun contains both invisible and visible rays—the former, however, being much greater in amount than the latter. Now, when such a beam falls on two pieces of cloth, one black and the other white, the effect of the obscure rays is the same on both; but the black surface absorbs also the luminous rays, while the white rejects them. The black is thus more heated than the white. As a protection against the direct rays of the sun, light-coloured clothing is thus better than dark.

All bodies, even the coldest, are constantly radiating off more or less heat, according to their temperature; all are therefore both giving and receiving rays; but the warmer give more than they receive, the colder receive more than they give. A surface presented towards the open sky, with nothing to radiate or throw back the rays it is emitting, soon becomes cold; but the slightest curtain, such as a net, hung up before it, sensibly arrests the dissipation of heat. It is in this way that clouds act as warm curtains to the earth, and often prevent frosts in spring and autumn nights. The different radiating powers of bodies explains why dew is sooner deposited on some substances than on others. Those that are good radiators lose their heat most quickly, and thus condense the vapour of the atmosphere.

Transmission of Thermal Rays.—Some substances, it has been observed, allow heat to pass through them, as light passes through glass; such substances are called *diathermanous*. Bodies are not diathermanous and transparent in the same degree; for black glass transmits heat well, and water, which is highly transparent, is the least diathermanous of liquids. Of solid bodies, rock-salt is the most diathermanous, alum the least so. The powers of gases and vapours to transmit radiant heat have recently been investigated by Professor Tyndall, with very striking results. The most important are those concerning the component elements of our atmosphere. Oxygen, nitrogen, and hydrogen transmit almost perfectly, and so does pure air, which is a mixture of oxygen and nitrogen. All the other gases absorb more or less of the rays. If the absorption of air is stated as 1, that of carbonic acid is 90, and of ammonia is 1195. But this is nothing to the absorbing power of the vapour of water. When the atmosphere is in an average state of humidity, the invisible aqueous vapour contained in it absorbs 72 times as much radiant heat as the air itself, although the quantity of the latter is 200 times that of the former. The consequences of this are of vital importance to the inhabitants of our globe. If the atmosphere were without vapour, the sun's rays, both luminous and obscure, would pass through it without warming it, and without losing any of their power, and would scorch the earth's surface while exposed to them; while in the absence of the sun, the radiation from the earth would escape without obstruction, and rapidly produce excessive cold. This effect is partially experienced in elevated positions, where the vapour is comparatively rare; on lofty mountains, the direct rays of the sun are intensely hot, while the air is cold. The vapour of the air thus acts as a blanket to the earth, tempering the direct rays of the sun, and again intercepting the earth's radiation.

Glass transmits luminous rays, but is athermanous to obscure rays; hence, a glass frame, in gardening, has been called 'a trap to catch sunbeams.' The light of the sun passes through the glass, and is absorbed by the earth as heat; but

when this heat seeks to escape by radiation, the glass refuses to retransmit it.

LATENT HEAT.

When a solid body, such as ice, is watched whilst melting, a large quantity of heat is observed to enter it without raising its temperature in the slightest degree. This heat which enters the body serves only to melt or liquefy it, without rendering the liquid the least hotter than the solid was which yielded it. The water which flows from the melting ice is no warmer than the ice. The heat which thus renders a body liquid without warming it, is called *latent* or *insensible* heat, because it does not affect our sensations, and does not raise the thermometer. The fact of heat becoming latent, is most decisively demonstrated by mixing a certain quantity—say an ounce by weight—of ice, or, still better, from its state of division, of snow at 32°, with an ounce of water at 172°. The result will be found to be, that the snow is all melted, and two ounces of water are procured at the temperature of 32°. The hot water in cooling from 172° to 32°, has lost 140° of heat, which changes the snow into water, but does not raise its temperature above that originally possessed by the snow.

What we have illustrated here with ice, holds good for all solids. Each one of them renders latent a certain quantity of heat in becoming liquid, and retains that heat so long as it remains liquid; when the liquid solidifies, it is again given up. Thus, when water freezes, the 140° of latent heat all abandon it, and manifest themselves as sensible heat. It is this necessity of absorbing such a quantity of heat, and getting rid of it again, that makes the processes of thawing and freezing go on so slowly.

In evaporating a liquid, a similar disappearance of heat takes place. In boiling off a pound of water, or converting it into vapour, it can be shewn by experiment that as much heat is absorbed as would have raised its temperature about 1000°, if it had not gone off in steam. Yet the water rises no higher than 212°, however hot the fire is, and the steam is of the very same temperature as the water it rises from. Thus 1000° have disappeared or become latent in the steam; and before the steam can be condensed into water again, all this heat must be given out. See STEAM-ENGINE.

The same is true of the vapour that rises slowly and silently from water at temperatures below boiling (see METEOROLOGY). This absorption of latent heat is the cause of the cold which always accompanies evaporation. By placing water in a shallow vessel under the receiver of an air-pump, and withdrawing the vapour as fast as it rises, evaporation may be made to go on so rapidly that the water freezes.

Heat which thus becomes latent, is not lost; it has done work in producing a change of state in the substance—in loosening the atoms from the rigid bond of cohesion, and remains a fund of potential energy, like a bent bow, ready to become heat again, or be converted into mechanical power, as in the steam-engine. This is another instance of the conservation of energy.

SOURCES OF HEAT.

Next to the sun (see ASTRONOMY), chemical combinations are the chief sources of heat. When two substances unite chemically, their temperature is almost always raised. When the heat is evolved so rapidly as to render the substances luminous—which most substances become when heated to a certain degree—the process is called *combustion* (see CHEMISTRY). *Fire* is a solid rendered luminous or incandescent by combustion; *flame* is gas at a white heat.

Animal heat has the same source as the heat of a fire or of a candle; it arises from a species of combustion. The oxygen taken into the body by the lungs unites with the carbon and hydrogen of the waste parts of the blood and solids, and converts them into carbonic acid and vapour of water—burns them, in short, and thus produces heat. (See PHYSIOLOGY.)

Heat can also be produced by mechanical means, such as compression, percussion, and friction. A piece of iron may be rendered hot by hammering; and axles of carriages often ignite from friction. It is found that the amount of heat thus produced is always in proportion to the mechanical energy expended in the process.

MECHANICAL EQUIVALENT OF HEAT.

The exact relation of the heat to the work that produces it is expressed in what is called *the mechanical equivalent of heat*. A unit of work is the amount expended in raising a pound-weight to the height of a foot, and 10 pounds raised 1 foot, or 1 pound raised 10 feet, makes 10 units of work, or 10 foot-pounds. Now, it has been determined by accurate experiments that 772 foot-pounds of work produce heat sufficient to raise a pound of water one degree in temperature; and 772 foot-pounds constitute the mechanical equivalent of heat. Another way of stating the same thing is to say, that a pound-weight falling from a height of 772 feet against the earth, generates heat sufficient to raise a pound of water one degree; or conversely, that the heat that raises a pound of water one degree in temperature, would, if it could be all used mechanically, raise 772 pounds a foot high. In this way it has been calculated that if our earth were 'to strike against a target strong enough to stop its motion . . . the amount of heat thus developed would be equal to that derived from the combustion of fourteen globes of coal each equal to the earth in magnitude. And if, after the stoppage of its motion, the earth should fall into the sun, as it assuredly would, the amount of heat generated by the blow would be equal to that developed by the combustion of 5600 worlds of solid carbon.'

MECHANICS—MACHINERY.

THE application of the laws of motion and forces to objects in nature, or contrivances in the arts, constitutes the branch of Natural Philosophy usually treated under the head MECHANICS, MECHANICAL POWERS, or ELEMENTS OF MACHINERY.

GENERAL DEFINITIONS.

It is seldom that a force is made to act directly on the body that is to be moved, or the resistance that is to be overcome. In raising coals from a coal-pit by steam-power, the expanding steam is not put below the load of coals, and made to blow it up the shaft, as it were. The steam first raises a piston, which then moves a beam, which in its turn moves a rod connected with a crank; and thus the motion is propagated from one piece of matter to another until it arrives at last at the load. During this transmission the force undergoes various changes which make it act more advantageously for the end in view.

Instruments thus interposed between the moving power and the resistance, with the view of changing the direction of the force or otherwise modifying it, are called *machines* (Gr. *mechanē*, contrivance); and to explain the laws of their action and their various applications forms the subject of the present treatise. Mechanics, in the narrower sense of the term as here used, is understood to treat of the abstract theory of machines, or those general principles, mathematical and physical, on which their action depends; the special application of these principles is the subject of Practical Mechanics, Mechanism, or Machinery.

Machines are of various degrees of complexity; but the simple parts or elements of which they are all composed are few. These are strictly only three in number—namely, 1. The *Lever;* 2. The *Pulley;* and 3. The *Inclined Plane.* These may be called the Primary Mechanical Powers; and from two of them, the Lever and Inclined Plane, other three are formed, as follows: 1. The *Wheel* and *Axle*, from the *Lever;* 2. The *Wedge*, from the *Inclined Plane;* 3. The *Screw*, from the *Inclined Plane.* These may be called the Secondary Mechanical Powers. The six altogether form the most usually occurring elements of complex machinery.

THE LEVER.

When a box, or other heavy body, is lifted in the hands, the power is applied to the weight directly; it acts without the intervention of machinery. But when a bar is used, as represented in the figure, resting on a support F, we have an instance of a machine interposed between the power and the weight. The effect of this machine is to modify the power in more ways than one. When the hand lifts the weight directly, it pulls upwards at the same point and with exactly the same force with which the weight pulls downwards. But with the machine the hand pushes or pulls downwards as well as the weight, and one effect of the solidity of the rod and of the fixed prop is to convert the downward force at P into

Fig. 1.

an upward force at the other end. And not only this, but when the prop is nearer to the weight than to the power, the power seems to be increased; a downward pressure of one pound at P, causes an upward pull of, it may be, two or more pounds at W.

A rod or bar used in this way is called a *lever*, from the French word for 'to raise.' The point of support is called the *fulcrum*, and the distances from the fulcrum to the points of the lever where the *power* and the *weight* act, are called the *arms* of the lever. The lever is the most important of the simple machines, or mechanical powers, and, in its various modifications, enters most extensively into the composition of complex machinery. The law by which it acts, therefore, deserves attentive consideration. To comprehend thoroughly the nature of the *advantage* conferred by the lever, is to comprehend the fundamental principle of all mechanics.

In treating of the *theory* of the mechanical powers, certain assumptions are made. Thus the object of the lever is to *move* the weight; but the question really examined in the theory of the lever, is not what power is necessary to move a certain weight, but what power is necessary to balance it; what force at P will just keep W at rest, or suspended, if unsupported below. The subject is thus considered as belonging to Statics, or the doctrine of forces in equilibrium. It is obvious that when P and W once balance one another, the least additional force to P will suffice to begin motion. Again, it is assumed that machines are themselves without weight; that the rod or lever, for instance, is a mere rigid line. This is done for simplicity; in practice, the weight of the bar itself has an effect on the resistance, and must be allowed for. Another assumption is, that machines move without friction. A certain amount of force is always necessary to turn the lever about its axis or point of support; but this we do not take into the account. The amount of power consumed in overcoming friction, and the means of diminishing it, are questions for practical mechanics.

Law of the Lever.—When the fulcrum of a lever is placed as in the annexed figure, so that one of the arms, FA, is double the other, FB, it is found by experience that a weight of one pound at P

will balance a weight of two pounds at W. And if the arms are in any other proportion—if, for example, AF were made seven feet long, while FB were only two feet; then two pounds at P would balance seven pounds at W. In general, *the power and the weight are to one another inversely as their distances from the fulcrum.* From this it follows, by the well-known property of proportion, that the weight multiplied by its distance from the fulcrum, is equal to the power multiplied by its distance.

Fig. 2.

It looks at first sight like magic that a weight of one pound should be made equal in effect to one of two pounds. It seems as if the lever gave us the means of multiplying force to any amount; as if the strength of a boy might be put on a footing with that of a man. It is necessary to get over this false impression. There is no creation or multiplication of force in the lever, or in any other machine, as will appear from the following considerations. If we suppose the power slightly increased beyond what is necessary to balance the weight, it will begin to descend; but in descending six inches, for example, it will raise W only three inches, as represented in fig. 1. What is thus gained in one way, is lost in another; if we make a small force raise a great weight, the force must be exerted through a proportionally great space. One pound will lift ten pounds; but to lift the ten pounds through one foot it must descend ten feet. The two weights, when thus in motion, have equal momenta; the power multiplied into its velocity, is equal to the weight multiplied into its velocity. Since the velocities are in proportion to the distances from the centre of motion, this is the same as to say, the power multiplied into the length of its arm, is equal to the weight multiplied by its arm.

The comparative spaces through which P and W would move in the first instant of time if their equilibrium were disturbed, are called their *virtual* velocities; and the principle that when P and W balance each other, P multiplied by its virtual velocity is equal to W multiplied by its virtual velocity, is called the Golden Rule of Mechanics, and is true not only of the lever, but of all the other simple machines. This is otherwise, and perhaps better, expressed by saying, that the *rate of doing work* during the movement is the same in the case of the two forces.

The law stated above—namely, that the weight multiplied by its distance from the fulcrum is equal to the power multiplied by its distance, furnishes an easy rule for finding what force is necessary to move a given weight, with a given length of lever; or what weight a given force will move.

Example 1.—Suppose a log of wood, weighing a ton, or 2240 pounds, has to be raised by a lever whose arms are 20 feet and 3 feet respectively, what force must act on the longer arm? Here the product on the one side is $2240 \times 3 = 6720$; what number multiplied by 20 will produce the same product? This is found by dividing 6720 by 20. The quotient 336 is the number of pounds at the long arm, that will balance 2240 pounds at the short one.

Example 2.—Two boys, the one 80 pounds and the other 60 pounds weight, are playing at see-saw with a beam 28 feet long; what point of the beam must rest on the support? The beam must evidently be divided by the fulcrum in proportion to the weights, that is as 80 to 60, or as 8 to 6; which is done thus: $8 + 6 : 8 : : 28 : \frac{28 \times 8}{14} = 16$ feet, the long arm. The short arm is therefore $28 - 16 = 12$. The products on both sides will be found equal; $16 \times 60 = 960$, and $12 \times 80 = 960$.

The power does not necessarily act at the long arm of the lever. The larger weight W (fig. 2) may be used to raise the less P, as well as P to raise W. When the power acts at the short arm, it requires, of course, to be greater in amount than the resistance it has to overcome; but a small motion of the power in this case makes the weight move over a great space; what is lost in power is gained in velocity. This is often as great an object as an increase of power.

As yet we have represented the prop or fulcrum as situated between the power and the weight.

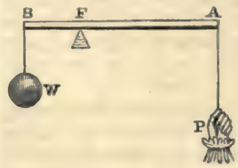

Fig. 3.

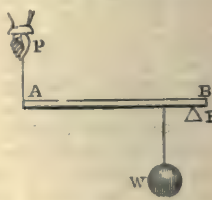

Fig. 4.

This constitutes a *lever of the first kind*, as in fig. 3. But the power and weight may be both on the same side of the fulcrum. In this case, when the weight is between the power and fulcrum, as in fig. 4, the lever is *of the second kind;* and when the power is between the weight and fulcrum, as in fig. 5, it is a lever *of the third kind.*

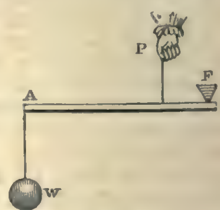

Fig. 5.

These different arrangements make no alteration in the principles already laid down. The effect of each of the forces, P and W, is still measured by its distance from the fulcrum. This distance forms its *leverage* or advantage; and the greater the leverage of either force, so much less does it require to be to balance the other.

The following are examples of implements which act, more or less, on the principle of the lever, beginning with the lever of the first kind.

When the common spade is used in delving, the blade is first forced into the soil by the foot, the handle is then pressed back, the edge of the undelved ground becomes a fulcrum, and the lever-power of the long handle enables a moderate pressure to dislodge the earth from its place. Fig. 6 represents an equally familiar example—namely, a wood-sawyer or carpenter moving a log of timber from its place, by means of a long pole or beam of wood. Stone-masons use a lever of

iron of this description, called a crow-bar. Pincers, scissors, and similar instruments are levers of the

Fig. 6.

first kind with two arms, the rivet at the centre being the fulcrum of both.

A common scale-beam for weighing is an example of the first kind of lever, formed with two arms of equal length.

There is another kind of balance, called a *steel-yard*, which consists of a lever with arms of unequal length, and acts upon the principle of distance from the fulcrum on the long arm compensating for weight on the short arm, as already defined. Fig. 7 is a representation of the steel-yard balance, in which the weight, W, is suspended from the short arm, CA. On the long arm a number of divisions are set off, marked 1, 2, 3, &c.; C1 being equal to CA, C2 equal to

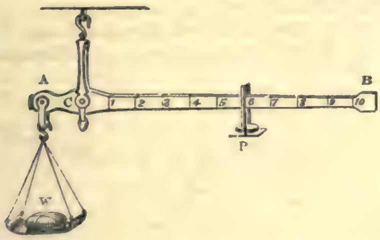

Fig. 7.

twice CA, &c. P is a weight of a certain heaviness, and being movable by a ring, it can be slipped along the bar to any required point. In proportion as the article to be weighed in the scale W is heavy, so is the weight P slipped along to a greater distance from the fulcrum, C; and when it is brought to a point where it balances the article, the figure on the bar at that point indicates the amount of the weight. If P be one pound, and if, when suspended from the division at 6, it balance the weight at W, it is evident that the weight will be six times P, or six pounds. And so on with all the other divisions.

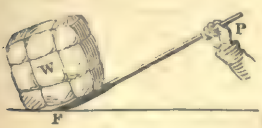

Fig. 8.

The steelyard, though not so ancient as the common balance, is of considerable antiquity. It was used by the Romans, and has long been in use among the Chinese.

Examples of the second kind of lever-power are also common. One of the most familiar is that of a man pushing or lifting forward a bale of goods, as represented in fig. 8, in which the bale or weight W presses against the lever between the power P and the fulcrum F.

Two men carrying a load between them on a pole is also an example of the second kind of lever. In the case of porters carrying a barrel slung from a pole, each man acts as the power in lifting the weight, and at the same time each man becomes a fulcrum in respect to the other. If the weight hang fairly from the centre of the pole, each man will bear just a half of the burden; but if the weight be slipped along, so as to be nearer one end of the lever than the other, then the man who bears the shorter end of the pole supports a greater load than the man who is at the long end. In yoking horses to the extremities of cross-bars in ploughs, coaches, or other vehicles, if the cross-bar is not attached to the load by its middle point, one horse will have to pull more than the other.

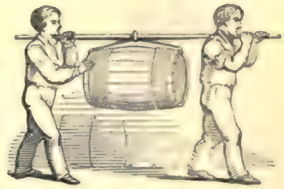

Fig. 9.

The instrument used for cracking nuts (fig. 10) is an example of the second kind of lever with two arms or limbs. The oar of a boat in rowing is also a lever of this kind. The hands of the sailor who pulls, constitute the power; the boat is the weight to be moved; and the water against which the blade of the oar pushes, the fulcrum.

Fig. 10.

In a lever of the third kind, the power must, from its position, be always greater than the weight; and from this circumstance it has sometimes been called the *losing* lever. But this gives a wrong impression; for what is lost in the amount of the power is gained in the velocity, or in the space over which the resisting force is made to move. Levers of this kind are used where the object is not to gain power and overcome great resistance, but to produce rapid motion where the resistance is comparatively small.

An example is found in the footboard of the turning-lathe (fig. 11). The foot of the workman presses on the board or plank near the end which rests on the ground, or fulcrum, and, at the cost of a short movement of its own, causes the opposite extremity of the board to move in a downward direction over a considerable space.

Fig. 11.

The movements in the limbs of animals are mostly produced by the action of levers of the third kind. The tendons or ropes which move the bones are attached near the joints, which are the pivots or fulcra of the bone-levers. The structure of the human arm (fig. 12) is a very good example. The fulcrum is the socket, C, of the

elbow-joint; the power is the strong muscle called the *biceps*, which passes down the front of the *humerus*, and is attached at A to the *radius*, one of the two parallel bones composing the forearm;

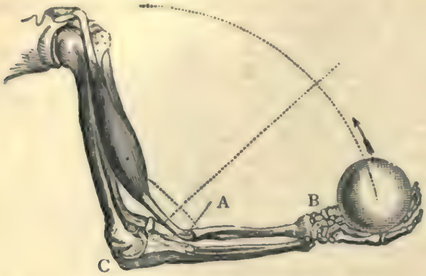

Fig. 12.

the resistance is the weight of the forearm, together with anything held in the hand, the two being supposed combined in one weight acting at B. In this way, the contraction of the muscle to the extent of an inch will raise the hand through an arc of twenty inches. It will be readily seen, that as the angle at the elbow-joint is enlarged, the tendon of the muscle pulls more obliquely to the bone of the forearm, and thus acts at an increasing disadvantage; hence the arm held out straight has comparatively little power to sustain a weight.

Combinations of Levers.

By disposing a number of simple levers, so that the one shall act on the other, the effect of the power may be increased to any desired degree. Fig. 13 represents a combination of three levers of

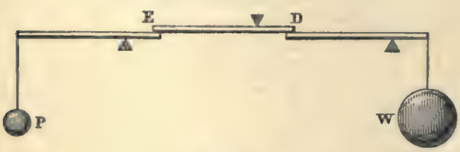

Fig. 13.

the first kind. They are supposed, for simplicity, to be of equal length, the long arms being six inches each, and the short ones two inches each; required—the weight which a moving power of 1 pound at P will balance at W. In the first place, 1 pound at P would balance 3 pounds at E, according to the rule of calculation for the simple lever; for $1 \times 6 = 3 \times 2$. This upward pressure of 3 pounds at E is next converted, by the second lever, into a downward pressure at D three times as great, or equal to 9 pounds; and, lastly, the downward pressure of 9 pounds at D is converted, by the third lever, into an upward pull at W of 3 times 9, or 27 pounds. Thus, 1 pound at P will balance 27 pounds at W.

The general rule for combinations of levers, whether equal or not, is, that the power multiplied successively by all the arms next it in the system, is equal to the weight multiplied by all the other arms. From this equation we may find what power will be necessary to raise any given weight, or what weight any given power will raise.

Machines for weighing loaded wagons, frequently seen at toll-bars, consist of a system of levers arranged below a table or platform on the level of the road. The wagon being wheeled upon the platform, is balanced by a comparatively small weight attached to the extremity of the system. The balance of Quintenz, much used for weighing luggage at railway-stations, is an ingeniously arranged combination of levers. The principle of the steelyard is frequently superadded to a combination of levers in these weighing-machines, so that one counterpoise serves for all cases.

So long as a force acts perpendicularly to the straight arm of a lever, its effort to turn the lever about the centre is the same, whatever angle that arm makes with the other arm. If the equal forces, P, Q, act perpendicularly to the equal arms CA, CB, of the bent lever ACB (fig. 14), they will keep each other in equilibrium on the same grounds as when the lever is supposed straight; namely, that there is no cause why the one should prevail over the other. And if we suppose the arm CA removed and again fixed in the position CA′, with an equal force P′ acting in the perpendicular line A′P′, the force Q will still be balanced as before; that is, the effort of the force P to turn the lever is the same in its new position as it was in its old.

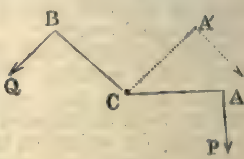

Fig. 14.

Suppose, now, that two unequal forces, P and Q (fig. 15, *a*), hold one another in equilibrium on the

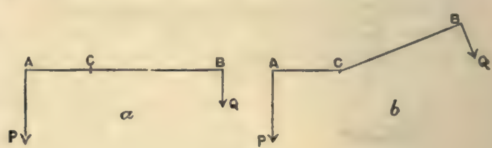

Fig. 15.

unequal arms AC and CB, and let the arm CB take the position shewn in *b*, the effort of Q to turn the lever will not be altered by its new position any more than in the case of the equal arms; so that Q and P still balance each other. It is thus of no consequence what angle the two arms of a lever make with each other, so long as the forces act at right angles to the arms; $P \times AC$ is still equal to $Q \times BC$.

But when a force acts obliquely to its arm, part

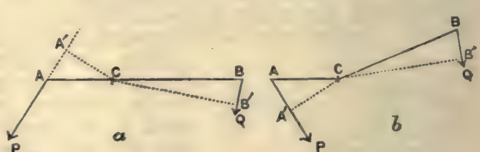

Fig. 16.

of it is wasted in pulling or pushing against the fixed centre, and the virtual or effectual leverage

is found by drawing a perpendicular from the fulcrum or centre to the direction of the force. In fig. 16, *a* and *b*, CA′ and CB′ are the virtual arms, and P . CA′ = Q . CB′.

When a force thus exerts an effort to turn a lever or any system about a centre, the value of the effort is found by multiplying the force by the perpendicular drawn from the centre upon the direction of the force. This product is called the *moment* of the force.

THE WHEEL AND AXLE.

Let the larger circle in the fig. represent the rim of a wheel, and the smaller the section of the cylindrical axle on which it is fixed. A small weight, P, attached to a cord wound round the wheel, is sufficient, by its descent, to wind up a large weight, W, attached to another cord wound round the axle. It is evident that the two forces here act on the unequal arms, FA, FB, of a lever whose fulcrum is F; therefore P × AF = W × FB. As the system turns round, the points A and B, at which the forces act, are constantly changing, and there is a succession of new levers, as it were, the arms, however, continuing always of the same length; the machine is therefore sometimes called the *perpetual lever*.

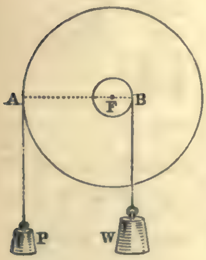

Fig. 17.

We can conceive the wheel removed, and nothing left but the axle and one radius or spoke, FA. If now a projecting handle is inserted into the end of FA, the weight P may be dispensed with, and the force of a hand of equal amount applied at A will turn the axle round and wind up W. Such a spoke and handle attached to an axle is called a *winch*, and is another form of perpetual lever.

The principle of the wheel and axle, or perpetual lever, is introduced into various mechanical contrivances, which are of great use in many of the ordinary occupations of life. One of the simplest machines constructed on this principle is the common windlass for drawing water from wells by a rope and bucket. Coal is lifted from the pits in which it is dug by a similar contrivance, wrought by horse or steam power.

The capstan in general use on board ships for hauling or drawing up anchors, and for other operations, is an example of the wheel and axle, constructed in an upright or vertical, instead of a horizontal, position.

There are combinations of the wheel and axle, as there are combinations of the simple lever. Cranes, watch and clock work, and wheel-machinery in general, mostly consist of such combinations. The parts are usually made to act upon one another by means of projections called *teeth* or *cogs;* or, when at a distance, by straps. In any case, the advantage is calculated in the same way as in combinations of the lever. For illustration, let us take the combination of three wheels and axles represented in fig. 18; and suppose that the radii of the wheels A, B, and C are 12, 15, and 20 inches respectively; those of the pinions F and G, 3 inches each, and that of the axle E 2 inches—the radii of the toothed-wheels and pinions being measured from the centre to the point of contact of the teeth. By the principle of the lever, the downward force of P becomes an upward pressure on the teeth of wheel B, and is increased as 3 to 12, or made fourfold. Similarly, the upward pressure on the teeth of wheel B becomes a downward pressure on those of C, and is increased as 3 to 15, or five times; that is, it is equal to 20 times P. Again, this downward pressure of 20 times P upon the teeth of C becomes an upward force at E, increased as 2 to 20, or 10 times; so that W is sustained by a force equal to 200 times P.

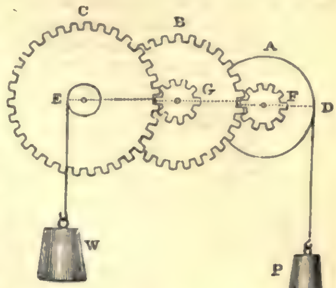

Fig. 18.

The object of wheel-work is often, not to gain power, but to gain velocity at the expense of power. In this case the moving force is applied as at W, and the gain in velocity in the revolution of the last wheel in the system, might be calculated from the radii, in much the same way as the gain in power is calculated. It may also be calculated from the number of teeth in the several wheels and pinions.

THE PULLEY.

The pulley consists of a small wheel, called a sheaf, turning on an axis in a block, with a flexible cord resting in a groove in the circumference of the wheel. There are two kinds of pulleys—the *fixed* and the *movable*.

The annexed cut represents a pulley, A, fixed by its block or frame to a beam or roof, B, and having two weights attached to the ends of the cord. In order that P and W may be in equilibrium in this case, it is evident that they must be equal. This appears from the wheel acting as a lever with equal arms, so that neither P nor W has any advantage. It is also plain that the cord, being free to move either way, must be equally stretched, or have the same *tension* throughout its whole length. A fixed pulley, therefore, does not increase the power; it only serves to change the direction in which the power acts. This is often as great a gain as increase of power would be. A force, for instance, at P, pulling downward, can raise W upward.

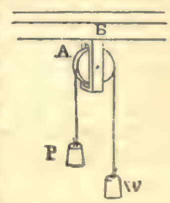

Fig. 19.

The wheel is not an essential part of the pulley, in theory at least. The same object might be gained by bending the cord over the axis of the wheel, or over any bar, and making it slide on it; but in this case the friction of the cord on the surface of the bar would cause great resistance, and would chafe the cord; and it is to obviate this that the

wheel is used. Theoretically, then, the whole virtue of the pulley resides in the flexible cord.

It is only with the movable pulley that there is a gain of power. The movable pulley is generally attached to the weight or resistance, and moves along with it. In the annexed cut, a cord is carried from a fixed point at A round a pulley B, from which the weight is suspended; it is then made to pass over a fixed pulley at C, and the power is represented by a hand drawing downwards. The parts of the cord BA and BC being equally stretched, each sustains evidently *half* the weight; but the part of the cord PC has the same tension as the rest, therefore P pulls down with a force equal to half the weight. A single movable pulley, then, *doubles* the effect of the power. The only effect of the fixed pulley C is to change the direction; if the hand were at C pulling upwards, it would sustain just half the weight.

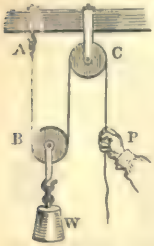

Fig. 20.

When the two cords, BA, BC, are not parallel, besides sustaining the whole weight, they pull against each other to a greater or less degree, and are therefore stretched with a tension greater than that due to half the weight. Part of the advantage, then, is lost when the strings attached to the movable pulley are not parallel.

The secret of the saving of power in the movable pulley lies in making the hook in the beam at A support the half of the weight. It is as if there were two hands, one at A, and another at C, sustaining the weight between them; but, although the hook A can thus act as a substitute for a hand to sustain W at rest, it can take no share in *lifting* W. In order to lift W one foot, the hand at C must rise through two feet, or—which is the same thing—the hand at P must descend through two feet. We thus find the same principle in the pulley that has been illustrated regarding the lever.

Technically, the wheel of a pulley is called a *sheaf;* for protection and convenience, this sheaf is ordinarily fixed with pivots in a mass of wood called a *block;* and the ropes or cords are called a *tackle.* The whole machine, fully mounted for working, is termed a *block and tackle.* By causing a wheel and axle to wind up the cord of a block and tackle, the power of the lever is combined with that of the pulley in the operation.

Systems of Pulleys.

Several pulleys are often used in combination, forming a *system of pulleys.* There are various modes of arrangement. One of the most common is that represented in fig. 21, and called the 'First System,' in which the same cord passes over all the pulleys, and the pulleys are divided into two sets—one set working in the same fixed frame or block, and the other set in a movable block to which the weight is attached. The cord being the same throughout, the tension of all its parts is the same; and, therefore, neglecting any slight want of parallelism among the cords, the weight is equally distributed among the cords 1, 2, 3, and 4. As the cord at P has the same tension as the others, being, in fact, a continuation of the same cord, P thus sustains a fraction of W, depending upon the number of cords that join

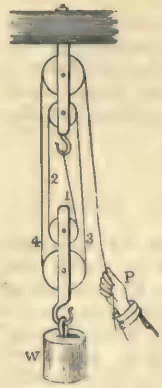

Fig. 21.

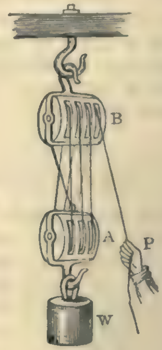

Fig. 22.

the movable block. In the present case, P is one-fourth of W, or $P = \frac{W}{4}$, or $4P = W$; so that a weight of a cwt. at W would be sustained by a weight of 28 lbs. at P.

Fig. 22 represents another mode, commonly used in practical operations, of constructing a system of pulleys on the principle of the same cord passing over all the sheaves. As seven cords join the lower block, $P = \frac{W}{7}$.

THE INCLINED PLANE.

If AB (fig. 23) represent a horizontal plane, AC will represent a sloping or *inclined* plane. If we suppose AC to be a plank resting on the ground at A, and with its other end at C on the edge of a platform, it is a familiar fact, that a man can roll a heavy cask from A to C, which it would be far beyond his strength to lift perpendicularly from B to C. In such a case, the inclined plane is used as a mechanical power.

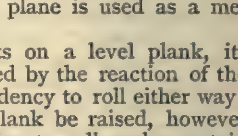

Fig. 23.

When a cylinder rests on a level plank, its whole weight is supported by the reaction of the plank, and it has no tendency to roll either way; but if one end of the plank be raised, however slightly, the cylinder begins to roll, and a certain force is required to keep it at rest. As the end is more and more elevated, the restraining force requires to be increased, and at the same time the pressure on the plane becomes less, until, when the plank comes into the upright position, it ceases to sustain any pressure, and a force equal to the whole weight of the cylinder is required to keep the latter in its position.

In order to find the relation of P to W in a given inclined plane, we have recourse to the resolution of forces. In fig. 24, which represents a cylinder resting on a plane, and kept from rolling down by a weight suspended over a pulley at *p*, so placed that *cp* is parallel to AB; let *cf*, drawn

from the centre of gravity of the cylinder in a vertical direction, represent the whole weight of the cylinder. This force may be resolved into two others, *ce* perpendicular to the plane, and *cg* parallel to it (see No. 13). But *ce* is counteracted by the resistance of the plane, and can produce no effect; therefore *cg* or *ef* represents the force with which the cylinder is urged in the direction of BA; *fe* will therefore represent the force of P which keeps W in equilibrium. Now, it can be shewn that the triangle *cfe* is similar to the triangle ABD; therefore *fc* is to *ef* as AB to BD—that is, *W is to P as the length of the plane to its height.* If AB is twice the length of BD, one hundredweight at P will sustain two hundredweight at W; and if AB is six times the length of BD, W will be six times P.

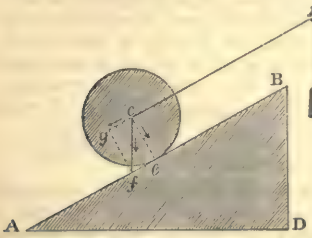

Fig. 24.

The proportion of P to W now stated is true only when the direction of the force P is parallel to the plane; in any other direction, part of the effect of P is lost.

In speaking of sloping roads, they are said to have an inclination or rise of one foot in ten, one in thirty, one in a hundred, and so on. The degree of slope in a railway is called the *gradient*, and seldom exceeds one in 50 or 60. The annexed cut represents a cart drawn by a horse up a common road with a rise of one in ten. On a perfectly level road, a certain force of draught would be required to overcome friction (see page 222); on the incline there is required, in addition to this, a constant pull to counteract the tendency of the cart to run down the slope. That tendency is, in this case, equal to a tenth of the weight of the load; and if the load is a ton, the horse has to pull with a force of one-tenth of a ton, or 224 pounds, above what would have sufficed to draw it along a level.

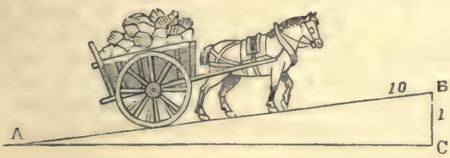

Fig. 25.

In going over ten feet of the road, the horse has raised the cart one foot perpendicularly, but he has done it by instalments; the exertion has been spread over a movement of ten feet. Intensity of exertion is saved at the expense of time.

THE WEDGE.

A common form of the wedge is represented in fig. 26. By forcing such a body below the bottom of an upright post, for instance, which can move only vertically, we may raise the post a few inches. It obviously acts on the principle of the inclined plane; it is, in fact, the inclined plane made movable.

Fig. 26.

The proportion of the power to the resistance in the wedge is calculated theoretically in the same way as in the inclined plane. But the theory is of little or no value. The power employed being percussion or blows, cannot be rightly compared with the resistance; it cannot be estimated in pounds, like other forces. The friction, too, is so great as to render any precise statement of proportion impossible. In a general way, however, the wedge is more powerful as the angle is more acute; just as the advantage of the inclined plane increases with the smallness of its height.

The wedge is used in splitting timber, stones, &c. Ships are raised in docks by driving wedges under them. In expressing oil from seeds, the seeds are placed in bags between solid pieces of wood, and these are forced together by means of wedges, till the seeds become a mass as compact as wood.

Fig. 27.

Cutting and piercing instruments all act on the principle of the wedge. The plough is also an instance.

THE SCREW.

The screw is an inclined plane wound round a cylinder. Take a cylindrical ruler AB, and cut a slip of paper in the form of a right-angled triangle *abf*, having *ab* equal to the length of the cylinder, and *bf* equal, say, to four times its circumference. If the edge *ab* is applied to the cylinder lengthwise, and the triangle is then wrapped round and round, the slanting side, *af*, will form a spiral going four times round the cylinder before it reach the bottom. In the fig. to the left of the cut, it is represented as half wrapt on.

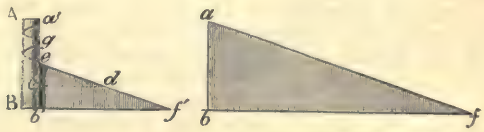

Fig. 28.

If a ridge or projection were raised on the cylinder along the spiral line, it would form a screw. The several turns or coils of the spiral are called the *threads* of the screw; *ed* represents the *length* of one thread, and *ec* the *distance between the threads.* In moving over a complete round of the spiral, a perpendicular ascent or descent is made equal to *ec*. As in the inclined plane, therefore, the mechanical advantage of the screw depends on the proportion between the length of a thread and the distance between two contiguous threads.

In using the screw as a machine, the resistance is not applied directly to the spiral surface, as in the wedge or the straight inclined plane; the screw is made to work in a hollow cylinder with spiral grooves cut out to correspond to the projecting threads. This concave screw is technically

called a *nut*, as represented at M, fig. 29. The threads and corresponding grooves are sometimes of a triangular form, as in fig. 29; and sometimes flat. To produce pressure with the screw, either the screw or the nut must be fixed. Whichever is free, is then turned, and made to press against the resistance.

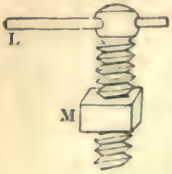

Fig. 29.

Practically, the screw is never used as a simple machine, the power being always applied by means of a lever, passing either through the head of the screw or through the nut. The screw, therefore, acts with the combined power of the lever and inclined plane; and in investigating the effects, we must take into account both these simple mechanical powers, so that the screw now becomes really a compound machine.

To arrive at the proportion of the power to the weight in this compound machine, we may apply the principle of virtual velocities. The power acts at the end of the lever L (fig. 29), and in turning the screw once round, it describes a circle, of which the lever is the radius. The circumference of this circle represents the velocity of the power. In the meantime, the weight has moved over a space equal to the distance between two threads, which is its velocity. Therefore, *in the screw, the power multiplied by the circumference it describes, is equal to the weight multiplied by the distance between two contiguous threads.*

Applications of the Screw.

The most common purpose for which the screw is applied in mechanical operations, is to produce great pressure accompanied with constancy of action, or retention of the pressure; and this quality of constancy is always procurable from the great friction which takes place in the pressure of the threads on the nut, or on any substance, such as wood, through which the screw penetrates.

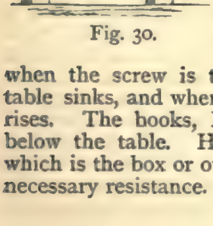

Fig. 30.

The common standing-press used by bookbinders for pressing their books, affords one of the best examples of the application of the screw to produce great pressure (fig. 30). The screw A has a thick round lower extremity B, into holes in which the lever is inserted. This extremity B is attached by a socket-joint to the pressing-table C, so that when the screw is turned in one direction, the table sinks, and when turned in another, the table rises. The books, D, lie upon a fixed sole S, below the table. H is a cross-beam above, in which is the box or overlapping screw, to give the necessary resistance.

STRENGTH OF BODIES AND OF STRUCTURES.

A knowledge of the simple principles of mechanics above considered, together with that of the general properties of matter, enable us to determine what forms of bodies and what positions are best calculated to resist forces that tend to break, crush, or overthrow them. This constitutes engineering. A few of the more important general truths thus arrived at may be here noticed.

The strains to which the parts of machines and edifices are subjected, are chiefly of four kinds: 1. Tension, as when a rope is pulled in the direction of its length; 2. Compression or crushing; 3. Transverse or Cross Strain; and 4. Torsion or twisting.

Tension.

When a rod of wood is suspended vertically, and a weight attached to it tending to tear it asunder, all its fibres act equally, and its strength evidently depends on the strength of the individual fibres and their number—that is, the area of the cross-section of the rod. If there are two rods, then, of the same material, the one having an area of one square inch in its cross-section, the other an area of three square inches, the last will sustain three times the weight that the other will sustain, and this whatever be the shapes of the sections. The same reasoning applies to a rope or a rod of iron or other metal.

The power of bodies to resist tension or tearing force, is called their Tenacity, Direct Strength, Absolute Strength, or Tensive Strength. It depends upon the force with which their atoms cohere; and differs in different substances. The following are the absolute or tensive strengths of some of the more important materials, as determined by experiments: A rod of ash, 1 square inch in section, sustains a weight of 17,000 lbs.; a similar rod of English oak, from 8000 to 12,000; of red pine, 12,000; cast-iron, 18,000; wrought-iron, 29 tons or 65,000 lbs.; iron wire, 41½ tons or 93,000 lbs.; cast-steel, 134,000 lbs.; copper, 21 tons or 47,000 lbs.; hempen rope, 6000 lbs. From these numbers the tensive strength of a rod or beam of any given dimensions may be found, by multiplying by the number of square inches in the section of the rod or beam. *Ex.* What weight will a cylindrical rod of wrought-iron, 3 inches in diameter, sustain? Here area of section is $3^2 \times \cdot 7854 = 7 \cdot 0686$ square inches; and $29 \times 7 \cdot 068 = 205$ tons, nearly.

Compression.

Numerous experiments have been made on the power of different materials to resist crushing force; but no law has been found by which we can deduce with any accuracy the strength of bodies of dimensions different from those experimented upon.

Transverse Strain.

Let *ab* be a beam fixed at one end into a wall *ag*, and loaded with a weight W at the other end. If the beam is to break (supposing it of uniform dimensions throughout), the rupture will evidently be at the wall, because there W acts with the greatest leverage. Before actual rupture, a portion of the fibres in the upper part of the section from *a* to *c* are drawn out or stretched, and a portion in the lower part, from *c* to *f*, compressed; and there must therefore be a line of fibres somewhere, as at *c*, which are neither stretched nor compressed. This line is called the *neutral axis of rupture;* and as W tends to bring the beam into the position marked by the dotted lines, we may conceive *c* to be the fulcrum of a bent lever with three

arms, of which W acts on the long arm *cn′*, *ce* and *cd* being two short arms at right angles to *cn′*. The fibres of the upper part of the section (which we suppose not yet ruptured, but only extended)

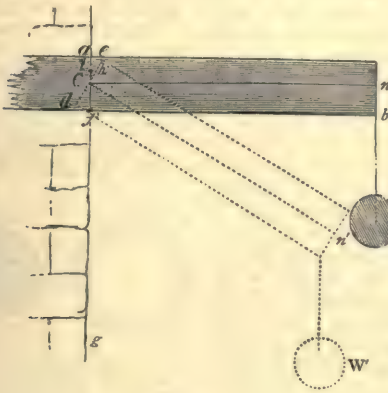

Fig. 31.

are acting all along the arm *ce*, as at *ik*, *ae*, drawing it towards the wall; while those in the lower part are resisting compression, and pushing the arm *cd* away from the wall. Both these sets of forces resist the tendency of W to turn the lever about the axis *c*, and thus together constitute the strength of the beam. The effects or moments of the two sets must evidently be equal to each other; for the neutral axis so adjusts itself that the amount of resistance on the one side balances that on the other. If the tensive strength of the fibres is equal to their compressive strength, the neutral axis will be in the middle of a rectangular beam; if the tensive strength is greater, the neutral axis will be nearer the upper side; and *vice versâ*.

But the most important point to observe in this investigation is that the fibres are not all equally well situated for offering resistance. A fibre at *a*, for instance, acts with twice the leverage of one at *i*, supposing *i* in the middle of *ca*. If we call the tensive strength of a fibre of certain area 1, its moment or efficacy at *a* will be expressed by $ca \times 1$, or simply *ca*; while the moment of a similar fibre at *i* will be $ci \times 1$, or *ci*. The sum of the moments of a row of fibres from *c* to *a* would thus be expressed by the number of such fibres multiplied by their *mean distance* from *c*, which is $\frac{1}{2}\,ca$. Since the number of fibres along the line *ca* increases with the length of the line, we may take that length to represent the number; and therefore, the sum of the moments will be $ca \times \frac{1}{2}\,ca$, or $\frac{1}{2}\,ca^2$. But the resistance to compression made on the arm *cd*, is equal to the resistance on *ca*; therefore, the whole resistance to fracture made by a line of fibres from *a* to *f*, is expressed by (2 times $\frac{1}{2}\,ca^2$ or) ca^2. And if we put *b* for the breadth of the beam, the whole strength of the beam is expressed by $b \times ca^2$.

From a variety of causes, the formula above given does not enable us to calculate at once the transverse strength of a beam from merely knowing the tensive strength of a rod of its fibres. One of these causes is that we have no means of determining where the neutral axis is situated. The formula, however, serves this valuable purpose, that when the actual transverse strength of one beam of certain dimensions has once been determined by experiment, it enables us, from this data, to calculate the strength of another beam of the same general form, but of different dimensions. For, whatever fraction *ac* is of *af*, in a beam of any material, it is the same fraction in all beams of that material, or the length of *ac* varies with the length of *af*; and, therefore, to express the relative strengths of beams, we may put *af* in the formula instead of *ac*. If, then, we put *d* for the depth, or *af*, the formula becomes $b \times d^2$, which expresses the leading proposition in the strength of materials, that THE TRANSVERSE STRENGTH OF A BEAM INCREASES AS THE BREADTH MULTIPLIED BY THE SQUARE OF THE DEPTH.

The truth of this important proposition is fully confirmed by experience, and is constantly acted upon in all kinds of constructions. Rafters, joists, &c. are never made square in the section; but as deep as possible, and no thicker than is necessary to prevent them from bending laterally, or *buckling*, as it is called. Strength is thus gained, and material saved. *Ex.* Let A (fig. 32) be the section of a square wooden beam of 10 inches in the side, and B that of another beam of the same wood, 5 inches broad by 20 deep. The areas of the two sections are equal, being 100 square inches each; but the transverse strength of A is as $10 \times 10^2 = 1000$, and that of B is as $5 \times 20^2 = 2000$. B has thus double the strength with the same amount of material. When the breadth of a beam is doubled, retaining the same depth, the strength is merely doubled; when the depth is doubled, retaining the same breadth, the strength is quadrupled.

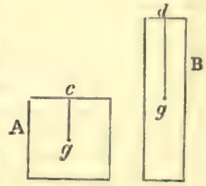

Fig. 32.

In order to make this expression available for finding the actual weight that any beam will bear, small beams or prisms are taken, of the most usual materials, having a section of one square inch, and a length of 12 inches, and loaded with weights till they break. The breaking weights of these small bars are then used as *constants* or coefficients, for calculating the breaking weights of other beams of the same materials. The following are a few of the results of experiments made on small bars fixed and loaded as in fig. 31:

Ash	2030	Oak, English	from..1200 to....2260
Elm	1030		
Fir, Scotch	1140	Cast-iron	8100
Red Pine	1340	Wrought-iron	9000

To find the weight that will just break a beam of given dimensions, we have only to multiply the constant for the material in the table by the breadth and square of the depth, and divide by the length—the dimensions being all reduced to inches; or, employing the formula, $W = \text{Constant} \times b \times d^2 \div l$. *Ex.* What weight will break a beam of Scotch fir, fixed at one end, and loaded at the other, its breadth being 3 inches, depth 11 inches, and length 9 feet? *Ans.* $W = 1140 \times 3 \times 11^2 \div 108 = 3832$ lbs. nearly.

When the beam is cylindrical, find the strength of a square beam, whose side is equal to the diameter of the cylinder, and take two-thirds of the result. *Ex.* What is the strength of a round

beam of ash, diameter 10 inches, and length 12 feet? Here $2030 \times 10 \times 10^2 \div 144 = 14097$ lbs. the strength of a square beam of 10 inches in the side. But a cylindrical beam of 10 inches diameter has less area by about one-third, and therefore its strength will be $14097 \times \frac{2}{3} = 9398$ lbs. More exactly, the square is to the circle as 1 to ·7854; and $14097 \times{} ·7854 = 11071$ lbs.

The most frequent case of transverse strain is that of a beam resting freely on supports at the two ends, with a weight or weights pressing somewhere between. If the weight rests on the middle point, as in fig. 33, each of the supports sustains a pressure equal to $\frac{1}{2}$ W. We may therefore consider the reaction of either of the supports, B, as a force acting upwards, and tending to break the beam at C, while the two forces at A and C merely hold the end of the beam fixed, as the wall does in fig. 34. The moment of the force of rupture is thus $\frac{1}{2}$ W × CB = $\frac{1}{2}$ W × $\frac{1}{2}$ AB = $\frac{1}{4}$ W × AB. But if the beam were fixed in a wall at A, with a force W acting at B, the moment would be W × AB. That is, *a beam supported freely at both ends will support four times as much weight at its middle point, as it would if fixed at one end, with the weight resting on the other.*

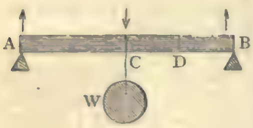

Fig. 33.

Ex. A bar of cast-iron, 2 inches square and 15 feet long, is supported at both ends, what weight applied at its middle will break it? Such a bar, if fixed and loaded as in fig. 31, would support, by the former rule, $8100 \times 2 \times 2^2 \div 180 = 360$ lbs. The breaking-weight in the present case is, therefore, $360 \times 4 = 1440$ lbs.

The strain of W is greater when applied at C, the middle point, than when applied at any other point, D.

Form of Greatest Strength.—It is evident (see fig. 31) that the fibres of a beam near the neutral axis on both sides, have little efficacy in resisting rupture, and might be removed without much affecting its strength; and this principle is largely applied in constructing metal beams or girders, in order to produce the greatest strength with the least material. For girders of cast-iron, resting on both ends, and loaded in the middle, the form of section adopted is that of an inverted T (fig. 34). Cast-iron has much less power of resisting extension than compression, and therefore the lower *flange* is made much greater than the upper, so as to throw the neutral axis as nearly as possible in the middle of the beam; for the sum of the moments of the two sets of resistances is greater when the axis is in the middle than when it is anywhere else. With wrought-iron, which resists extension better than compression, the upper flange is made the larger. The advantage of the T-form is, that the great mass of the material being collected on the two flanges, acts at the greatest possible leverage. In a series of experiments with cast-iron beams, the strongest form was found to be that represented in fig. 34, in which the lower flange, *cd*, is six times the area of the upper, *ab*. With this proportion, the strength per square inch of section of the whole beam was 4075 pounds, whereas 'in the best form of girder used before these experiments, there was never attained a strength of more than 2885 pounds. There was, therefore, by this form a gain of 1190 pounds per square inch of the section, or of $\frac{2}{5}$ the strength of the beam.'

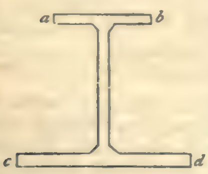

Fig. 34.

Hollow or Tubular Structure.—Another way of throwing the great body of the material at a distance from the neutral axis is, to make it into the shape of a tube or hollow cylinder. Let B be the section of a hollow cylinder, the thickness of whose walls is represented by the shaded ring; and A be the section of a solid cylinder of the same material. If the area of A is equal to that of the ring in B, the two cylinders will contain the same quantity of matter, but B will be stronger than A, in proportion as *cg* is longer than *dg*.

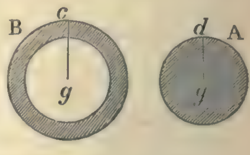

Fig. 35.

The principle of hollow structure prevails both in nature and art, wherever strength and lightness have to be combined. It is seen in the stems of plants, especially of the grasses; the bones of animals are also hollow, and those of birds, where great lightness is required, are most so. A feather, with its hollow stem, is perhaps the best instance of the union of strength and lightness that could be given. In art, again, we have hollow metal pillars; and sheet-iron for roofing and other purposes is *corrugated*, or bent into ridges and furrows, to give it depth. Each ridge or furrow is, as it were, half a tube, and resists bending with twice or thrice the energy it would if flat.

The most striking application of the principle of hollow structure is seen in Tubular Bridges. Fig. 36 represents a section of the tube of the Conway Bridge. The object being to resist a vertical strain, the form is made rectangular, and the chief mass of the material is thrown into the top and bottom. The tube may, in fact, be considered as an immense beam or girder constructed on the principle of fig. 34, the top and bottom being the two flanges, and the two sides serving to connect them, instead of the one rib in the middle. As it is constructed of plate-iron, the top requires more metal than the bottom, in order to resist the compression; but instead of putting the metal into one thick plate, or into several plates laid the one on the other, it is made to form a set of minor tubes or cells, which gives additional stiffness and strength to the whole tube. The floor, in like manner, contains cells. Each of the tubes over the Conway is 24 feet high, 14 feet wide (outside), and 420 feet long, and weighs 1300 tons; yet these enormous hollow beams sustain not only their own weight,

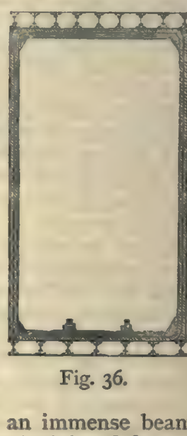

Fig. 36.

but the heaviest railway-trains without sensible deflection.

In beams supported at both ends, the strain is greatest in the middle; girders are therefore made strongest in the middle, and taper towards the ends.

Torsion.

If one end of the axle or shaft of a wheel is immovably fixed, and a power acts at the circumference of the wheel (or at the end of a lever or winch), the power may be so increased as to twist the shaft asunder at its weakest point. If a shaft A has twice the diameter of another shaft B, there will be four times as many fibres in the section of fracture of A, to resist the twist, as in that of B. But as the separation takes place by the one end of the fracture turning round upon the axis of the shaft, making the ends of the separating fibres describe circles, those fibres that are furthest from the centre will have the greatest power of resistance, and the sum of their moments, or their united effect, will be in proportion to their mean distance from the centre. This mean distance in A is twice that in B; therefore, the resistance in A is 2×4 or 8 times the resistance in B. Generally, ***the strength of shafts to resist torsion is as the cubes of their diameters.*** On the other hand, the twisting force that may be applied to the wheel or lever will be less as that lever is longer. The torsive strengths of shafts 1 inch diameter, and with weights acting at 1 foot leverage, being found by experiment for different materials; the strength of shafts of other dimensions are found from these 'constants' by multiplying by the cube of the diameter, and dividing by the length of the lever. It is evident that the torsive strength of a hollow shaft will be greater than that of a solid one of the same quantity of material, on the same principle that its transverse strength is greater.

MACHINERY.

The object of all machinery is to transmit and modify motive-power. It is not, as already explained, to create or multiply power; for no machine can give off more working-power at one part than has been applied to it at another. The most usual and convenient form of motive-power is rotary or circular motion; having once a motion of this kind, we can transmit it to any point where it is required, and can alter its velocity, and change it into another kind of motion, at pleasure. The more important elements of machinery by which these purposes are effected, we now proceed to notice.

COMPONENT PARTS OF MACHINERY.

Shafts.—A rigid bar of metal or wood made to revolve on its axis by any motive-power applied at one part, is capable of conveying and giving off that power at any part of its length to machinery connected with it. A large bar or beam of this kind is called a *shaft;* a smaller one, a *spindle.*

The part of a shaft on which it rests while turning is called the *journal* or *gudgeon.* The *bearings* of a shaft are the rests in which its journals or ends turn. The lower bearing of a vertical shaft is called a *step.*

Bands or Straps.—Bands or straps are used to convey motion from one shaft to another parallel and distant shaft. In fig. 37, A is a *drum* or *pulley* with a flat surface, supposed to be fixed on a shaft put in motion by the source of power; B is another pulley fixed on the shaft S; and over the surfaces of the two a broad leather belt, L, is stretched tight. As A turns, the friction between its surface and that of the belt carries the latter along with it, and thus B is also made to revolve. The shaft S thus set in motion may be made to communicate rotation to any number of pulleys and spindles, C, E, each of which may drive a separate apparatus. The main stream of driving-power is thus distributed into a number of small rills.

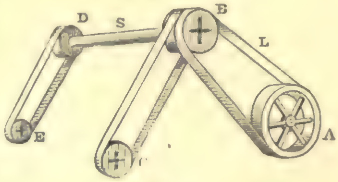

Fig. 37.

In order to economise the power, the band should have no more tightness than is just sufficient to prevent its slipping; for it is evident that the greater its tension, it will cause the axes of the pulleys to press the more against their bearings, and thus increase the friction of the machine. When the two parts of the band are made to cross each other, as in fig. 38, it works with less tension, owing to its embracing a larger arc of each drum. There is thus some economy of power in this arrangement; besides that, it serves another purpose—namely, that of reversing the direction of the rotation.

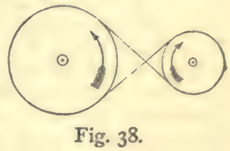

Fig. 38.

Toothed-wheels.—If the two pulleys or drums in fig. 38 were near enough to touch each other, by making the one revolve, the other would be made to revolve with it. This method of communicating motion serves only when the resistance to the driven pulley is very slight. The usual and sure method is to raise projections or *teeth* on the pulleys; this contrivance is called *toothed-gearing.*

Let C and C′ (fig. 39) be the centres of two toothed-wheels in gearing with each other (the centres are not represented in their actual positions, in order to save space). The line CC′ is called *the line of centres;* and the two circles, *gg, hh,* which touch each other in T, midway between the extreme projections of the teeth, are the *pitch circles.* The *pitch* of the teeth of a wheel is the distance, AB, from the centre of one tooth to the centre of the next, measured upon the pitch circle; and it is evident that for two wheels to work together, the pitch must be the same in both—that is, AB must be equal to TD. The breadth of the teeth is made a little less than the intervals between them, that they may have room to engage and separate without becoming locked in consequence of any slight irregularity.

The actual size of the wheels is not indicated by their solid rims or bosses, *ee, ff,* but by the pitch circles, *gg, hh;* and we shall best understand what is necessary to the true working of

toothed-wheels, if we conceive these circles to be, in the first instance, two drums touching at T,

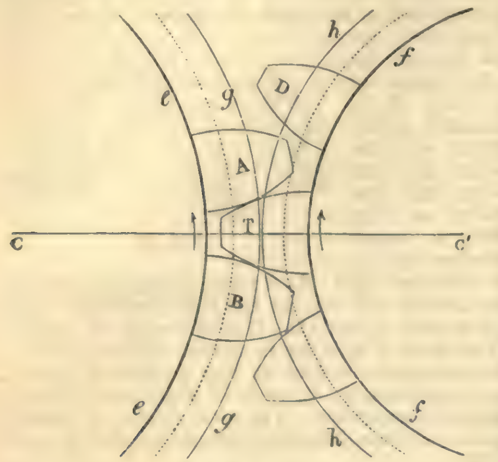

Fig. 39.

and the one driving the other by friction. It is obvious that while any portion, as a foot, of the drum *hk*—supposing it to be the driver—passes through the point of contact T, it causes an equal portion of the driven drum, *gg*, to pass through the same point; in other words, the driven circumference moves with the same velocity at every instant as the driving one. Now, when a part of the width of each wheel is removed, and projecting teeth substituted, these teeth must be so contrived that the primitive or pitch circles shall still move exactly as if they were in contact. Mere straight pegs or blades, like the paddle-boards of a steam-boat, would not answer the purpose. In the first place, the corners of one tooth would have to slide along the face of another, thus grinding away the teeth, and wasting the driving-power. Secondly, the motion would not be equal; during the first portion of the time that two teeth were in contact the driven wheel would move slower than the driver, and during the last portion, faster. The faces or edges of the teeth must, therefore, be curved, so that they shall roll on one another rather than slide; and the curves must be such that the driven wheel shall move at all times uniformly with the driver.

Mathematicians have discovered a great variety of ways of satisfying this condition. One way, frequently adopted, is to give the teeth of one wheel the form of the curve called the epicycloid, and those of the other that of the hypocycloid. But the form of teeth that possesses the greatest number of advantages for most purposes is that of the curve called the *involute*.

CHANGES IN THE PLANE AND IN THE DIRECTION OF ROTATION.

When the two shafts to be connected are not parallel to each other, conical or *bevel* wheels are employed. Fig. 40 represents a horizontal shaft driving a vertical one (or the converse), by means of bevel gearing. The two shafts may have any inclination to each other and to the horizon. When the two wheels are equal and the axes at right angles, they are called *mitre*-wheels. A *crown-wheel*, A, and *trundle*, B, as represented

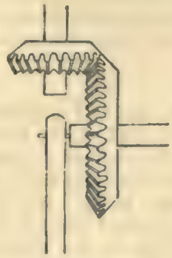

Fig. 40.

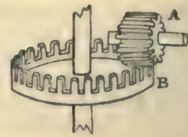

Fig. 41.

in fig. 41, is another contrivance for effecting the same purpose.

In the case of two toothed - wheels, the direction of the rotation is always reversed, as shewn by the arrows in fig. 39. In order to preserve the same direction in both, wheels are sometimes geared internally, fig. 42. By interposing a third wheel between the driving and driven wheels, the original direction is also retained; thus, the pinion F, fig. 43, revolves in the same direction as the wheel C. A crossed band (see fig. 38) reverses the direction.

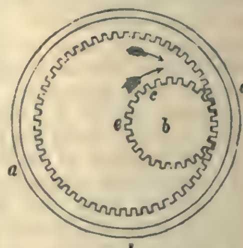

Fig. 42.

CHANGES IN SPEED.

If the wheel C, fig. 43, had three times as many teeth as the pinion G, one revolution of C would evidently cause three revolutions of G. If, instead of being an exact multiple, the teeth of C were, say 210, and those of G 90, which is in the proportion of 7 to 3, then 3 revolutions of C would cause 7 of G. Suppose, again, that C with 101 teeth were driving B with 100 teeth. These numbers being prime to one another, the proportion is not expressible in any smaller numbers than the numbers of the teeth themselves; in other words, if we note the two teeth that are at any instant in contact, C must make 100 revolutions, causing B to make 101, before the same two teeth will be again in contact—that is, before the two will finish together, each an exact number of revolutions.

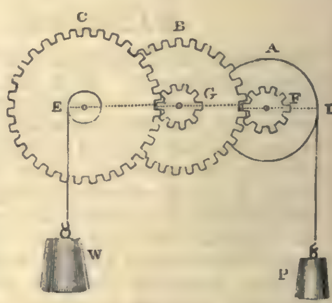

Fig. 43.

In a train of wheels connected, as in fig. 43, the velocity of the last wheel is found by the following rule: Multiply the velocity (or number of revolutions in a given time) of the first driver by the

product of the numbers of teeth in all the drivers, and divide the result by the product of the numbers of teeth in all the followers. In this rule, the diameters, or the radii, or the circumferences, of the wheels may be substituted for the numbers of the teeth.

Sometimes it is desirable to vary the speed of a part of a machine at different parts of a process, while the driving-power continues the same. One way of effecting this is by conical pulleys or drums, as in the fig. 44. According as the band is shifted along from one end to the other—and this the machine is made to do itself—the relative speed of the two pulleys will vary to the desired degree.

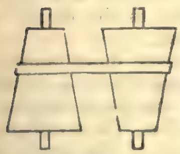

Fig. 44.

CHANGE OF ONE KIND OF MOTION INTO ANOTHER.

By means of a rack, *b*, and pinion, *a* (fig. 45), a rotary motion is converted into motion in a straight line. Both motions in this arrangement are necessarily alternating.

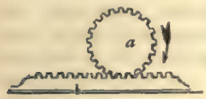

Fig. 45.

Fig. 46 represents a continuous rotary motion converted into an alternate rising and falling. The projections, called *cams* or *wipers*, of the wheel W, depress the end of the lever bearing the hammer, H, so that it is made to rise and descend on the anvil A thrice during each revolution of the wheel. The stampers of fulling-mills, and those used for crushing oil-seeds and other substances, are in a similar way lifted and dropped by the wipers of a wheel coming in contact with a pin projecting from the stamper.

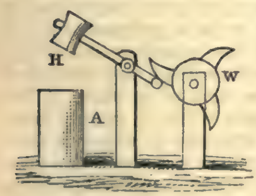

Fig. 46.

For converting an alternating straight motion into a continuous revolution, the most common means is the *crank*. A crank is an arm or bend on an axle or shaft. In the figure, the shaft extends on both sides of the bend, so that two wheels could be turned, and the motion is communicated by a connecting rod, S. If the portion to the left of the rod were removed, the arrangement would be what is called a winch, and might be driven by the hand.

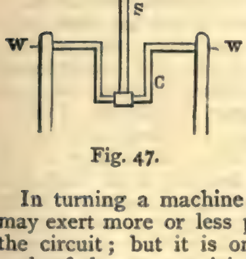

Fig. 47.

In turning a machine with a winch, the hand may exert more or less pressure at every point of the circuit; but it is only about the middle of each of the two semicircles, while the handle is being pulled towards the body, and again while it is being pushed away, that the full strength of the arms is effective. In a crank worked by a rod, there are two positions in which the effect of the pressure of the rod is reduced to nothing—namely, when the crank-arm C is in the same straight line, upwards or downwards, with the rod S. A push or pull of the rod in these positions can only press the shaft against its bearings. The effect is greatest when the rod and crank-arm are at right angles, and it decreases gradually on both sides of that position, until at the top and bottom it is reduced to nothing. In order to carry the crank over these *dead points*, as they are called, a heavy wheel, called a *fly-wheel*, is fixed on the shaft; this receives part of the force of the rod while at its best, acts as a reservoir, and by its stored-up energy carries the shaft round when the rod is powerless.

In marine-engines and in locomotives, a fly-wheel is unnecessary, and would be objectionable, owing to its weight and the room it requires. In these cases, the power is generally applied to the shaft at two points by two connecting rods, each proceeding from a separate cylinder; and the two cranks or bends of the shaft are made at right angles to one another, so that while the one is at one of its dead points, the other is at one of its best positions.

The crank can effect the converse of the change now described—that is, the conversion of a rotary motion into an alternating rectilinear one. But it is more usual, when an alternating motion of only small power is required, to take it from a revolving shaft by means of an *eccentric*. One of the most simple and elegant contrivances for converting motion in a curve into motion in a straight line is the *Parallel Motion*, invented by Watt.

FRICTION.

When one body rubs against another as it moves, a certain force is felt to resist the motion. This resistance is called *friction*. As a considerable proportion of the motive-power in all operations is spent in overcoming the friction of the parts of the machine upon one another, and is thus lost for the useful work, it is of great importance to understand the nature of this obstructive force, with a view to reduce it to the least possible amount. Accordingly, a great many careful experiments have been made on this subject, and the result is a number of precise and valuable facts or laws regarding friction, which are now considered certain and reliable. The more important may be thus stated and illustrated.

When a block of oak—say, a cubic foot, which weighs about 60 lbs.—is placed on a horizontal table of cast-iron, the two surfaces being flat and smooth, it requires a force of nearly ⅖ the weight of the block, or 24 lbs. pulling horizontally, to make it slide along the table. This measures the friction between the two surfaces. Another block of the same size and shape laid on the same table, would require the same force to draw it; and if the two were laid side by side, and fastened together so as to become one block, it would evidently require double the force, or 48 lbs. to draw the double block; the amount of the friction being thus still ⅖ of the weight, or of the pressure between the two surfaces. But suppose that, instead of being laid side by side, the second block were laid on the top of the first, what is to be expected?

Here the weight is doubled as before, but the extent of rubbing surface remains unaltered; it would be natural, therefore, to expect that this would make a difference, and that, though the friction would, of course, be increased, the increase would be less than in the former case. Experiment, however, shews that there is no difference, and that the friction is just double in both cases. In short, the unexpected and important fact is established, that, *within certain limits, the friction of any two surfaces increases in proportion to the force with which they are pressed together, and is wholly independent of the extent of the surfaces in contact.*

The amount of friction between two bodies is thus a constant fraction or proportion of the force with which they are pressed against each other. This fraction differs for the different kinds of surfaces. Thus between oak and cast-iron, it is, as already stated, about $\frac{3}{8}$, or more exactly, ·38; for wrought-iron on wrought-iron (we speak at present of dry surfaces, without grease or unguent of any kind), it is ·44; for brass upon cast-iron, ·22. This constant fraction (expressing the proportion between the pressure of two surfaces and their friction) is called the *coefficient of friction* for these two surfaces.

Friction is very much diminished by the use of grease or unguents. The coefficient of wrought-iron upon oak, which, in the dry state, is ·49, is reduced by the application of water to ·26, and by dry soap to ·21. The result of experiments on this subject is stated to be, 'that with the unguents, hog's-lard and olive-oil, interposed in a continuous stratum between them, surfaces of wood on metal, wood on wood, metal on wood, and metal on metal (when in motion), have all of them very nearly the same coefficient of friction, the value of that coefficient being in all cases included between ·07 and ·08.' Tallow gives the same coefficient as the other unguents, except in the case of metals upon metals, in which the coefficient rises to ·10.

The most important fact, perhaps, and one that could hardly have been anticipated before experiment, is, *that the friction of motion is wholly independent of the velocity of the motion.*

The resistance to the motion of a wheeled carriage proceeds from two sources: the friction of the axle, and the inequalities of the road. The resistance of friction to the turning of a shaft in its bearings, or of an axle in its box, has evidently the greater leverage, the thicker the journal or the axle is; the axles of wheels are accordingly made as small as is consistent with the required strength. The resistance that occurs between the circumference of the wheel and the road, constitutes what is called *rolling* friction. There are on all roads, to a greater or less extent, visible rigid prominences, such as small stones, in passing over which the wheel and the load resting on it have to be lifted up against gravity. But even were these wanting, the hardest road yields, and allows the wheel to sink to a certain depth below its surface; so that in front of the wheel there is always an eminence or obstacle, which it is at every instant surmounting and crushing down. This is the case even on iron rails, though of course to a much less extent than on any other road. Now, for overcoming this resistance, it can be shewn on the principle of the lever that a large wheel has the advantage over a small one; and by numerous experiments, the fact has been fully established, that on horizontal roads of uniform quality and material, *the traction varies directly as the load, and inversely as the radius of the wheel.*

The best direction of traction in a two-wheeled carriage, is not parallel to the road, but at a slight inclination upward, in proportion to the depth to which the wheel sinks in the road.

On a perfectly good and level macadamised road, the traction of a cart is found to be $\frac{1}{30}$ of the load; that is, to draw a ton, the horse requires to pull with a force equal to 75 lbs. On a railway, the traction is reduced to $\frac{1}{280}$ of the load, or to 8 lbs. per ton. For the addition to traction occasioned by an incline on the road, see page 215.

The force of friction is often directly employed in mechanics. It is used, for instance, to communicate motion by means of belts, chains, &c. It is the force that holds a knot. It is specially useful when a machine, with great momentum, has to be checked or arrested in its motion. The best example of this is the ***brake*** used on railways. By means of a system of levers, blocks of wood are made to press against the circumferences of a number of the carriage-wheels; and thus the momentum of a train weighing hundreds of tons, and moving with a velocity of perhaps 50 miles an hour, is gradually destroyed in a wonderfully short space of time.

WORK.

Work, in the mechanical sense, implies two things; it implies that something is moved, and that force or pressure is required to move it. In other words, all mechanical work involves the exertion of a continuous pressure over more or less space. To bear or resist a pressure without motion is not work. A man standing still with a burden on his back is not working, any more than a post that sustains the end of a beam. The hand, fig. 1, does no work while it merely holds the weight suspended, although it requires force to do so; for a fixed catch or pin above the lever would do the same. But when the upward pressure of the lever is overcome by the hand through the space PP′, a certain amount of work is done. Nor does motion, where there is no resistance, constitute work. While a cannon-ball is flying through the air, it is doing no work (if we neglect the resistance of the air that is overcome); it only works when it forces its way through an obstacle, as the planks of a ship's side.

The Unit of Work.—When one man lifts six gallons of water from a well twenty feet deep, while another lifts eighteen gallons from the same well; it is easy to see that the one has done three times as much work as the other. But in order that we may compare exactly the quantities of work in operations of different kinds, we must have some common standard to refer to. Just as, in comparing the height of a mountain with a distance on a road, we take a standard or unit of length, say a foot, and, applying it to both, find that the height of the mountain contains 800 of the unit, and the length of the road 900, and thus get a precise knowledge of their relative magnitudes; so it is necessary to have a *unit of work*, and thus be able to say of different operations, that they contain each so many of such units.

The unit of work adopted in this country is the amount of exertion necessary to overcome a pressure of one pound through a space of a foot. Thus, a hand does a unit of work when it lifts a pound-weight a foot high; or when it pulls in a foot of the cord of a pulley, the tension of which is equal to a pound-weight; or when it pushes with the force of a pound against the lever of a capstan, while the point against which it presses moves through a foot. It follows that the amount of units of work expended in any exertion of lifting, pushing, or pulling, is found by multiplying the number of pounds in the pressure by the number of feet through which it is exerted. 10 lbs. of coal lifted 10 feet high is the same amount of work, namely, 100 units, whether it is done in five seconds or in fifty. But when we consider the capacity of the agent for work, we require to take the time into account. An agent or worker that does 100 units of work in one second, has four times the working-power of an agent that requires four seconds to do 100 units. As a standard of capacity for work, the power of a horse is taken. From a number of experiments, Watt, the improver of the steam-engine, estimated that a horse, on an average, could do 33,000 units of work in one minute; that is, could lift 33,000 lbs. 1 foot high in 1 minute; and this has been generally assumed as the standard of working-power in all mechanical agents. When a steam-engine, for example, is said to be of 60 horse-power, the meaning is, that it is capable of lifting 60 times 33,000 lbs. or 1,980,000 lbs. 1 foot high in 1 minute; or, which is the same thing, 19,800 lbs. 100 feet high in 1 minute.

Ex. How many horse-power does it require to lift 1 ton of coals every five minutes from a pit 1000 feet deep? $2240 \times 1000 = 2,240,000$, the work to be done in 5 minutes. $2,240,000 \div 5 = 448,000$, the work to be done in 1 minute. $\therefore 448,000 \div 33,000$ (the work in one H. P.) $= 13{\cdot}6$, the number of H. P. required.

Work Accumulated in Moving Bodies.

A heavy body in motion is capable of moving other bodies. The force exerted to put it in motion is all treasured up in it, and ready to be exerted on any obstacle that may oppose it. In other words, a moving body has accumulated in it a power of doing the same amount of work as was done upon it, abating what may have been lost by friction or other obstacles; and if we know the velocity of a moving body and its weight, we are able to calculate how many units of work have been done upon it, and, therefore, how much work it is capable of doing.

The velocity being given in feet per second, and the weight in pounds, the rule of calculation is as follows: *Square the velocity, multiply by the weight, and divide by* $2 \times 32\frac{1}{6}$, *or* $64\frac{1}{3}$.

The reason of the rule may be thus shewn: When a body begins to fall from a state of rest, it descends $16\frac{1}{12}$ feet in the first second, and it has then acquired a velocity which, were gravity to cease, would carry it on uniformly over $2 \times 16\frac{1}{12}$, or $32\frac{1}{6}$ feet per second. The spaces descended increase as the squares of the times—that is, in 2 seconds the fall is 4 times $16\frac{1}{12}$ feet; in 3 seconds, 9 times $16\frac{1}{12}$. The velocities, again, increase simply as the times—that is, at the end of 2 seconds the velocity is 2 times $32\frac{1}{6}$ feet; of 3 seconds, 3 times $32\frac{1}{6}$. Putting h for the height or space fallen through in any number of seconds, v for the velocity at the end of that time, t the number of seconds, and g for $32\frac{1}{6}$, the velocity caused by gravity in one second, the relations of these quantities are expressed in the following formulas, which enable us to calculate any one of them from the others.

$h = 16\frac{1}{12} \times t^2$, or (1.) $h = \frac{1}{2}g \times t^2$; (2.) $v = g \times t$, and $\therefore\ t = \frac{v}{g}$, and (3.) $t^2 = \frac{v^2}{g^2}$.

If, in formula (1.), we substitute for t^2 its value in (3.)—namely, $\frac{v^2}{g^2}$, we get $h = \frac{1}{2}g \times \frac{v^2}{g^2}$, or (4.) $h = \frac{v^2}{2g}$.

Knowing the velocity of a falling body, then, we can find the space through which it must have fallen in order to acquire it, by squaring the velocity and dividing by $2 \times 32\frac{1}{6}$. The height thus found is said to be the height *due* to that velocity.

A falling body is urged by a pressure equal to its own weight; and, during a second, that pressure acts upon it over $16\frac{1}{12}$ feet. Therefore, if the body is a pound in weight, gravity has done upon it in that time $16\frac{1}{12}$ units of work; and if it is 10 lbs., the work done is $160\frac{10}{12}$ units. In other words, the work done upon a falling body, and therefore the work accumulated in it, is equal to the space through which it has fallen multiplied by its weight. We may not know that space, but if we know the velocity, we can substitute for it its value, $\frac{v^2}{2g}$.

Now, a cannon-ball, moving with a given velocity, has the same force, whether it acquired that velocity by falling from a certain height, or by being shot from a cannon; and the same rule that enables us to calculate the units of work in it in the former case, applies also in the latter. Calling e the accumulated work, and w the weight of the body, the rule given above may be expressed in a formula, thus: $e = \frac{v^2 \times w}{2g}$.

The expression $\frac{v^2 \times w}{2g}$, or $\frac{w}{2} \times \frac{v^2}{g}$, is what was formerly called the *vis viva* (living force) of a moving body, but is now spoken of as its *energy*.

Ex. 1.—A ram, weighing 5 cwt. or 560 lbs. as it strikes the top of a pile, has a velocity of 70 feet; what is the work accumulated in it?

$$\frac{70^2 \times 560}{2 \times 32\frac{1}{6}} = 42,653 \text{ units of work.}$$

Or we might proceed thus: The height from which the ram must have fallen to acquire the velocity of 70 feet, is $\frac{70^2}{2 \times 32\frac{1}{6}} = 76{\cdot}166$ feet. To raise the ram to this height required $76{\cdot}166 \times 560 = 42,653$ units of work done upon it, and this work it is capable of reproducing by its fall.

Ex. 2.—A train weighing 100 tons has a velocity of 50 feet a second, how far will it run before stopping after the steam is shut off, supposing the friction to be 8 lbs. per ton, and that the train is ascending an incline of 1 in 100?

$\frac{50^2 \times 224,000}{2 \times 32\frac{1}{6}} = 8,704,663$, the work accumulated in the train. Now, the resistance of friction is $8 \times 100 = 800$ lbs. and the resistance of the incline is $\frac{1}{100}$ of the whole weight, or 2240 lbs. making together 3040 lbs. To overcome this resistance over 1 foot makes 3040 units of work,

which is to be taken out of the store accumulated in the train; for how many feet, then, will that store last? Evidently for $\frac{8,704,663}{3040} = 2863$ feet.

Of the moving-power applied to a machine, only part goes to do useful work; another part is expended uselessly in overcoming the friction of the machine, and other resistances to its transmission. For every 100 units of work applied to the handle of a crane, possibly only 70 are done upon the load. In this case, the fraction $\frac{70}{100}$, or ·7, expresses the *efficiency* of the machine, and is sometimes called its *modulus*. The working values of different machines may thus be exactly compared. Of machines, for instance, for raising water, the modulus of the bucket-wheel is ·6, and that of the Archimedean screw, ·7.

SOURCES OF POWER.

The principal moving forces are, the muscular power of men and animals; the weight of bodies, or gravity; wind, and the flow of streams; the expansive force of steam; electricity; and magnetism. Water, steam, and electricity, as sources of moving power, are treated of in other parts of the work. The labouring-power of animals varies greatly with the way or position in which they exert their muscular strength. In turning a handle or winch, the pressure exerted at different parts of the circuit is very different; but it has been found that a man can exert for a considerable time a mean pressure of 30 lbs. while moving the handle through 120 feet per minute. This would give 3600 units of work a minute, or about $\frac{1}{9}$ of a horse-power. Another estimate of labour of this kind, when continued for eight hours a day, makes the work per minute only 2600, or $\frac{1}{13}$ of a horse-power. Rowing is one of the most advantageous ways of exerting muscular strength, the effective work being 4000. In working at the tread-mill the man exerts his strength to raise his own body, and the weight of the body in descending turns the wheel. The work got in this manner is 3900.

ENERGY.

A moving body, as we have seen, has in it a store of force called Energy, and the exact amount of this store can be stated in the number of foot-pounds of work it can do before being brought to a stand. But this is not the only form in which energy exists. A ram suspended ten feet above the head of a pile has in it, while yet at rest, a store of working power in virtue of its position; and it requires only to be let go in order to bring that power into action. While resting on the head of the pile after the impact, it has no working power, if we except the pressure of its own weight. It must be again raised so as to have a free space to fall, and then it is invested anew with energy equal in amount to what has been spent in raising it. A store of force thus quiescent, but capable of being called into action, is called *potential* energy; while that which exists in a body in motion is called *actual* or *kinetic* (from a Greek word signifying to move) energy. A ram descending upon a pile, a cannon-ball flying towards its mark, a running stream driving an undershot wheel, the wind pressing a sail, all are examples of actual or kinetic energy. As examples of potential energy that can be directly used for mechanical purposes, we may cite a coiled watch-spring, a drawn bow, the charged receiver of an air-gun, a store of water with a fall or head. In a common clock we see the potential energy of the wound-up weights gradually converted into actual energy in the motions of the parts. The very sound of the bell is a vibratory motion derived from the energy of the driving weight.

Correlation of Physical Forces.—In treating of HEAT (see No. 13), it was shewn that mechanical motion could be converted into heat, which is itself a motion among the molecules of bodies, and therefore a form of energy. The latent heat of steam is a store of potential energy, which, in the steam-engine, is converted into mechanical power. If that power is made to drive a shaft, and a brake is applied, heat to any amount may be reproduced; or if it is made to turn a common electric machine, or a magneto-electric one, electric currents will result, attended with attractions causing sensible motions, and with heat and light. Light, again, causes chemical combinations and decompositions, as in photography; and chemical action in the voltaic battery gives rise in its turn to electricity, heat, light, and magnetism. It is facts like these, shewing the convertibility of one force into another or into others, that constitute what is called the Correlation of Physical Forces.

Conservation of Energy.—But there is something more than mere convertibility in the different forms of energy; there is constant equivalence. If, in rubbing two pieces of wood against each other, energy has been expended equal to that of lifting a pound-weight 722 feet high, the heat produced is sufficient to raise a pound of water one degree of F. This relation is constant, and 722 foot-pounds is thus the mechanical equivalent of one unit of heat. The equivalents of the other physical forces have not been determined, although an approximation has been made in the case of light. But everything tends to prove that whatever transformations energy may undergo, none of it is ever lost. In every machine it is only a portion, greater or less, of the motive power that is effective for the work intended. But the residue, though said to be lost, so far as useful work is concerned, is not annihilated; it is mostly expended in overcoming the friction of the machinery, and in doing so it is transformed into heat. A part of it is spent in noise, but this also, in the end, results in heat, which is still energy. Energy, in the shape of heat, has a constant tendency to uniform diffusion; but although it thus becomes dissipated, it does not cease to exist. This truth has become the cardinal principle of natural philosophy in recent times under the name of the *conservation of energy;* and nearly all the ordinary physical laws can be shewn to be involved in it. Thus a planet has a certain amount of potential energy in virtue of its distance from the sun, just as a stone has when suspended above the surface of the earth. That energy must therefore become less as the planet moves from its aphelion towards its perihelion; what then becomes of it? The difference appears in the increased velocity of the planet, being thus transformed from potential energy into actual. Numerous illustrations of this important doctrine will occur in the treatises on ELECTRICITY and the STEAM-ENGINE.

HYDROSTATICS—HYDRODYNAMICS—PNEUMATICS.

THE properties of matter treated of under MECHANICS are such as arise chiefly from the *solid* state of bodies. But consequences scarcely less important arise from the other two states in which matter presents itself—from the *liquid* condition, as in the case of water, and the *gaseous* or aëriform condition, as in the case of air; and these form the subjects of the present treatise. The nature of the difference between these three states of matter is considered in the number on NATURAL PHILOSOPHY.

Liquids and gases agree in this, that their particles seem at liberty to glide about among one another, seemingly without resistance; they *flow*, and hence both classes of bodies are called *fluids*. There are very different degrees of fluidity. Some fluids are thick and viscid; such as tar, honey, and some metals in a state of fusion. Viscid fluids are, in general, not homogeneous; they consist of solid granules floating in a real fluid. Alcohol and ether are more fluid than even water. The most perfect fluidity belongs to the gases.

But what chiefly distinguishes gases from liquids is elasticity. A cubic foot of any gas may readily be compressed into half a foot; double the pressure will reduce it to a quarter of a foot; and when the pressure is removed, the gas returns to its original bulk. But no ordinary pressure produces any sensible compression on water or any other liquid. Hence gases have been denominated *elastic fluids*, and liquids, *non-elastic*. It is on account of this difference that the mechanical properties of the two classes of fluids are treated of apart.

We have said that liquids cannot be sensibly compressed by any ordinary force; and this is so far true, that both in the theory of hydrostatics and in practice they are assumed to be perfectly incompressible. But the assumption is not absolutely correct. They are slightly compressible under great pressure. By sinking a vessel in the ocean to the depth of 6000 feet, where every square inch supports a weight of 2648 pounds, it is found that twenty cubic inches of water contained in the vessel are reduced to nineteen cubic inches, or the volume of water is diminished by one-twentieth. A pressure equal to that of the atmosphere, or fifteen pounds on the square inch, reduces a million cubic inches of water to forty-five or fifty inches less.

The phenomena of liquids are considered under two heads, according as the pressures to which the liquids are subjected produce rest or motion. The laws of liquids at rest or in equilibrium form the subject of *Hydrostatics* (from two Greek words signifying *water* and to *stand*); those of liquids in motion form the subject of *Hydrodynamics* (from the Greek words for *water* and *power*). *Hydraulics* is sometimes used in the same sense as Hydrodynamics, but has more especial reference to the flow of water in *pipes* (Gr. *aulos*).

HYDROSTATICS.

In treating of the mechanical properties of liquids, water, as the most common and important, is taken to represent the whole class.

It is the perfect *mobility* of the particles of liquids that gives them the mechanical properties considered in Hydrostatics. The fundamental property may be thus stated: WHEN A PRESSURE IS EXERTED ON ANY PART OF THE SURFACE OF A LIQUID, THAT PRESSURE IS TRANSMITTED UNDIMINISHED TO ALL PARTS OF THE MASS, AND IN ALL DIRECTIONS. Most of the other propositions of Hydrostatics are only different forms or direct consequences of this truth.

The proposition may be experimentally proved in a variety of ways. If, for instance, a bladder is filled with water, and tied, and then pressed down with one hand; the other hand, if applied to the bladder, will be pushed out with corresponding force, and that whether resting on the top, the sides, or under. Suppose, again, a close box, B, filled with water, and having a tube, *a*, inserted into the upper cover, of an inch in area, and with a plug or piston fitting into it. If the piston *a* is now pressed down upon the water with a force equal to a poundweight, the water, being unable to escape, will react upon the piston with the same force; but it obviously will not press more against *a* than against any other part of the box, therefore every square inch of the interior surface of the box is pressed outward with the force of a pound. If, then, there is another tube inserted in any part of the box with a plug of the same area, as at *b*, it will require a force of a pound to keep this plug in its place. (We leave out of account at present the pressure upon *b* arising from the *weight* of the water in the box above it, and consider only the pressure propagated by the forcing down of the plug *a*.) However many plugs of the same size there were, each would be pressed out with the same force of a pound; and if there were a large plug of four times the area, as at *c*, it would be pressed out with a force of four pounds.

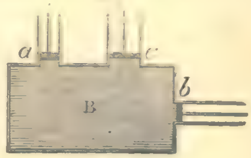

Fig. 1.

We have only, then, to enlarge the area of the piston *c* to obtain any multiplication of the force exerted at *a*. If the area of *c* is 1000 inches, that of *a* being one inch, a pressure of one pound on *a* becomes a pressure of 1000 pounds on *c*; and if we make the pressure on *a* one ton, that on *c* will be 1000 tons. This seemingly wonderful multiplication of power has received the name of the *hydrostatic paradox*. It is, however, nothing more than what takes place in the lever, when one pound on the long arm is

made to balance one hundred pounds on the short arm. When we think of the machine in motion, we see that what is gained in power is lost in time. If the piston in *a* descend one inch, it will raise the piston *c* only the one-thousandth part of an inch; for a descent of one inch in *a* dislodges a cubic inch of water, forcing it into the box; this causes a cubic inch of water to rise into *c*, where it is spread out over a thousand times as much surface, and therefore has only the thousandth part of the depth.

If the pressure we have supposed exerted on the piston *a* arose from a pound of water poured into the tube above it, it would continue the same though the piston were removed. The pound of water in the tube is then pressing with its whole weight on every square inch of the inner surface of the box—downwards, sidewise, and upwards—and, if the box is twenty inches each way, so as to have upwards of 2000 inches of surface, this one pound of water is tending to burst it with a force of about half a ton. That this is no mere theory, may be proved without much difficulty, by fitting a long small tube, *b*, into the top of a cask, *a*, as represented in fig. 2. If the tube is only the twentieth of an inch in area, and is made long enough to contain a pound of water, it gives a bursting force of twenty pounds on every square

Fig. 2.

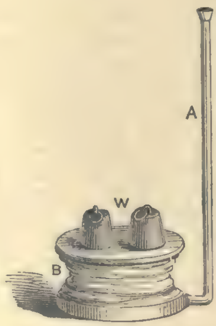

Fig. 3.

inch of the inner surface—a strain which no ordinary cask could resist.

The apparatus called the *hydrostatic bellows* acts on the same principle (see fig. 3). It consists of two stout circular boards connected together by leather in the manner of a bellows, B. The tube A is connected with the interior; and a person standing on the upper board, and pouring water into the tube, may lift himself up. If the area of the upper board is 1000 times that of the tube, an ounce of water in the tube will support 1000 ounces at W.

It is on the principle explained with regard to the two pistons, *a* and *c*, in fig. 1, that the very useful machine called the *Hydraulic Press*, invented by Bramah, is constructed. Fig. 4 represents the essential parts of the machine, the details of construction being omitted. F is the cavity of a strong metal cylinder, E, into which the piston D passes water-tight through the top. A tube, G, leads from the cylinder to a force-pump, H; and by means of this, water is driven from the tank T into the cavity F, so as to force the piston D upwards. The piston supports a table on which are placed the bales, books, or other articles to be pressed; and the rising of the table presses them against the entablature AA, which is fastened to the pillars B, B.

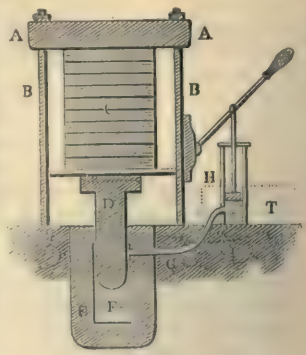

Fig. 4.

The power of the hydraulic press is readily calculated. Suppose that the pump has only one-thousandth of the area of F, and that, by means of its lever handle, the piston of the pump is pressed down with a force of 500 pounds, the piston of the barrel will rise with a force of one thousand times 500 pounds, or more than 200 tons. The rise, however, will be slow in proportion to the gain of power.

PRESSURE OF WATER ON SURFACES IN VARIOUS POSITIONS.

Water has weight like solids, and this weight produces pressure; but the quality by which it transmits pressure in all directions, makes its weight be felt in many respects differently from that of solids. Thus, suppose a cylindrical vessel filled with a piece of ice exactly fitting it; the whole weight of the ice will rest on the bottom, the sides being unaffected. But if the ice is now melted, the bottom will sustain the same weight as before, and the sides will at the same time be pressed outwards with a certain force. Any object immersed in water is also pressed on all parts of its surface in contact with the water. We have now to determine the amount of this pressure caused by the weight of water in various circumstances.

The pressure of water increases in intensity with the depth, without regard to the shape or size of the cavity or vessel containing it.

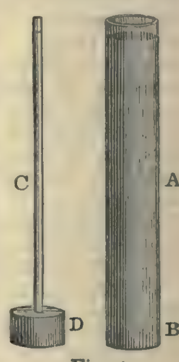

Fig. 5.

Suppose the water in the two vessels represented in fig. 5 to be divided into layers of an inch deep. If the area of the tube C is one square inch, and that of the larger cylinder, A, ten inches, the top layer in the tube will contain a cubic inch of water, and that in the cylinder ten cubic inches. Now, these layers rest on the surfaces of the layers below them; the second layer in the tube sustains the weight of a cubic inch of water; that in the cylinder, ten cubic inches. But in the last case the weight is equally distributed over ten square inches of surface; in both cases, then, the pressure on a square inch of the upper surface of the second layer is the weight of a cubic inch of water, or about 252 grains. In like manner, each

square inch of the surface of the third layer, in either vessel, has to bear the weight of two cubic inches of water, and the particles at that depth push upwards and laterally with corresponding intensity. The pressure thus increases with the depth equally in the narrow vessel and in the wide.

If we suppose the vessels to be each a foot deep, it is evident that on every square inch of the bottom of the cylinder there will rest a pile of twelve cubic inches (weighing about half a pound troy), and therefore the pressure on the whole bottom will be the weight of ten such columns. But from the shape of the other vessel, the lower part of which is enlarged, it is not so evident what the pressure on the bottom is. One thing is clear, that, on the square inch in the middle of the bottom immediately under the tube, there rests a column of twelve cubic inches. Now, there must be the same pressure among the particles of the water lying around the bottom of this column as among its own particles, otherwise there would be a flow towards the part where the pressure was less. Throughout the whole of the enlarged space D, there is the same pressure as there is at the same level immediately under the tube. Therefore, if the enlarged part of the vessel is of the same width as the cylinder, having an area of ten square inches, the pressure on the whole bottom is equal to the weight of ten times twelve cubic inches of water, exactly as in the cylinder at B.

It thus appears that *the pressure on the horizontal bottom of a vessel is as the area of the bottom and the perpendicular height of the liquid*, and that without regard to the shape of the vessel.

Take the case of two vessels of equal capacity, and shaped as in figs. 6 and 7. In fig. 6, the

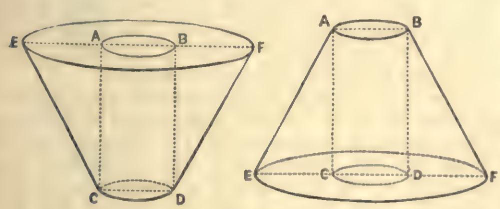

Fig. 6. Fig. 7.

bottom is pressed with the weight of the column of water ACDB. In fig. 7, the portion CD, equal to the whole base of the other, sustains an equal column; but from the law of liquids the same pressure is extended over the whole bottom. Now, if the diameter EF is three times the diameter CD, the larger bottom is nine times the area of the smaller. Therefore, the pressure on the bottom of fig. 7 is nine times the pressure on that of fig. 6, although both vessels contain the same quantity of water. If the bottoms of the vessels were separate from the sides, and kept in their places by springs or weights, it could be shewn experimentally that such is the case.

A strange consequence would seem to follow from this. If the two vessels in fig. 5 were placed on the opposite scales of a beam, the bottoms of both being equally pressed, it would seem as if they must balance each other. Similarly, we might expect fig. 7 to weigh nine times as much as fig. 6. But that such cannot be the case appears from the following considerations: In the upright cylinder in fig. 5, the lateral pressure being directly horizontal, neither presses the sides down upon the bottom nor lifts them up; but with the irregular vessel it is different. Where the small tube C enters the wide part D—say two inches from the bottom—the pressure of the column is equal to ten cubic inches of water on the square inch; and as this pressure acts upwards as well as downwards, the horizontal cover of the wide part is pressed *upwards* with a force of ten cubic inches on the square inch. Its area, the tube being one inch, is nine inches, so that the whole upward pressure is 9×10 cubic inches. The cover being attached to the sides, and the sides to the bottom, a part of the pressure on the bottom is thus counteracted, and only the difference—the difference between 10×12 and 9×10—or thirty cubic inches of water—remains to weigh down the scale. The confined water is in this case like a person in a covered box who should place his shoulders against the top and press against the bottom with his feet; he would thus add nothing to the weight of the box beyond his own dead weight. With regard to figs. 6 and 7, the pressure on the sides EC and ED of the former being at right angles to those sides, is partly downwards, and thus adds to the direct pressure on the bottom; while in fig. 7 the pressure on the sides is partly upwards, so as to relieve a part of the bottom pressure. The result is, that the pressure or weight on the scale is the same in both.

Pressure of Liquids on the Sides of Vessels.—We begin with the case of an upright side as the simplest. Let AB represent a vessel with upright rectangular sides filled with water, and suppose the perpendicular depth, AC, of the water to be six inches. A square inch of the bottom at C*d* is evidently pressed with the weight of a column of six cubic inches of water. Now, as water presses equally in all directions, the square inch from C to 5 of the side adjacent, will also be pressed; but evidently not to the same extent, owing to the gradual diminution of the weight of the water, as we advance upwards. The particle of water in the corner at C presses equally downwards and outwards, and as its pressure

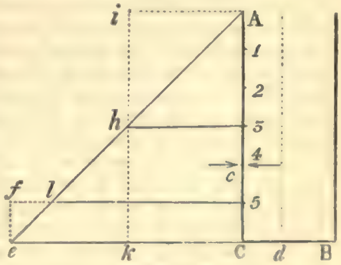

Fig. 8.

downwards arises from the weight of the column of particles above it from C to A, we may represent its outward pressure by the line C*e*, made equal to CA. At 5, the downward pressure, and therefore also the outward pressure, is one-sixth less, and will therefore be represented by 5*l*, made equal to 5A. If *el* is joined, the figure C*el*5 represents the sum of the outward pressures of all the particles from C to 5, and also the mode of their gradual diminution. Had the pressure continued constant, the sum would have been expressed by the parallelogram C*f*, which is equal to A*d*, the weight on the bottom. From this it

appears that the pressure on a square inch of the side next to the bottom is less than that on a square inch of the bottom itself, by the weight of half a cubic inch of water.

By similar reasoning, the pressure at any point on the side is represented by a horizontal line equal to the depth of the point from the surface, or the *head of water* of the point, as it is called. Thus, at 3, the pressure is $3h$, equal to 3A. Now, by the property of similar triangles, the extremities of all such lines, e, l, h, are in the same straight line with A; and by joining them, we have a triangle, CeA, representing the amount and mode of distribution of the lateral pressure on the side CA.

What is true of one vertical row of square inches in the side, is true of all the vertical rows of which it is composed; and therefore the pressure on the whole rectangular side is equal to the weight of a wedge-shaped mass of liquid, ACe, whose base is equal in area to that side. But the content of ACe is evidently equal to that of a uniform rectangular column of mean depth, $3h$. If, then, we suppose the length of the side to be 10 inches, its depth being 6 inches, the area will be 60 square inches; and this multiplied by 3, the mean depth, gives 180 cubic inches of water, the weight of which is equivalent to the lateral pressure. The truth thus arrived at may be expressed in the following general proposition: *The lateral pressure of a liquid, perpendicular to the side of a vessel, is equal to the weight of a column of the liquid whose base is the side and height equal to the depth of the middle point, or centre of gravity of the side.*

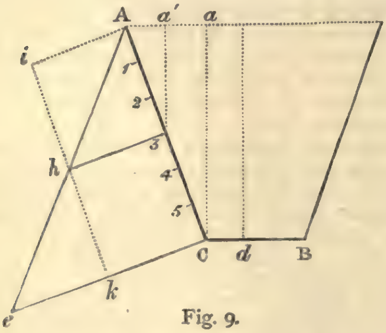

Fig. 9.

In the case of a vessel with a sloping side, AC (fig. 9), the pressure perpendicular to AC is still represented by a wedge-shaped mass, ACe; but here Ce is not equal to CA, but to Ca, the perpendicular depth of the water; and $3h$ to $3a'$, the mean perpendicular depth. In all cases, when speaking of depth or head of water, it is perpendicular depth that is meant.

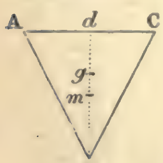

Fig. 10.

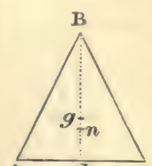

Fig. 11.

We have as yet considered only rectangular sides, in which the middle point, or point of mean pressure, lies midway between the surface and the bottom, or at half the depth. But in the case of a vessel with a triangular end or side, like ABC (fig. 10 or 11), it is evident that the middle point of the figure is not at m, the middle of the vertical line Bd. For in fig. 10 the number of points or units of surface that lie below m, and are therefore pressed with greater force, is far less than of those that lie above m, and sustain less pressure. The real middle point of any surface is its centre of gravity; and the centre of gravity of a triangular surface is found by drawing a line from any angle, B, to the middle of the opposite side, d, and taking the point g at one-third of the distance from d to B. The mean depth, then, or mean head of water, in fig. 10, is dg; and in fig. 11, Bg.

The pressure of a liquid on a surface is the same whether the surface forms part of the bottom or sides of the vessel containing the liquid, or belongs to a body immersed in the liquid. If an empty box, having for one of its sides a triangle like ABC, fig. 10, is sunk in water to any depth, the water will exert a pressure tending to force in the side, whether it be uppermost or undermost, vertical or oblique; and the amount of the pressure could be shewn, as in the cases already examined, to depend on the area of the surface and the depth of its centre of gravity from the surface of the water.

A cubic foot of pure water weighs very nearly 1000 oz. avoirdupois, or 62·5 lbs. More exactly, a cubic inch of distilled water, at the temperature of 62° F. and barometric pressure of 30 inches, weighs 252·46 grains; and a cubic foot weighs 62·32 lbs. or 997 oz. The cubic foot of sea-water may be taken on an average at 1026 oz. By means of these data, we can solve such a question as the following:

Required the pressure on a lock-gate 12 feet wide, the depth of the water being 10 feet? The area of the surface pressed is $12 \times 10 = 120$ square feet; 120 multiplied by 5 (the depth of the middle point of the surface) gives 600 cubic feet of water as the pressing column; and $600 \times 62{\cdot}5 = 37{,}500$ lbs. is the pressure in weight.

The circumstance of pressure increasing in proportion to depth, makes it necessary to increase the breadth of embankments for dams and canals from the top downwards; also to increase the strength of the lower hoops of large vats, to prevent their bursting. It likewise teaches the propriety of making dams, ponds, canals, and vessels for liquids generally, as shallow as is consistent with convenience or their required purpose. In every case, it is important to recollect that the degree of pressure on the sides is irrespective of shape or size of the contents, and depends exclusively on the perpendicular depth of the liquid.

When the poet speaks of 'the *broad* ocean leaning against the land,' we are apt to think of the broadness as adding to the weight that the land has to sustain. But the pressure against a square foot of the shore of the broad Atlantic is no greater than against a foot of the shore opposite Dover, or a foot of the side of a canal, at the same depth. The pressure against the gates of a canal is the same whether the next lock is a mile or whether it is 50 yards off. It might be brought within a foot, or even a fraction of an inch, and the weight on the gate would remain unchanged so long as the depth was the same. This being the case, it is really no more difficult to embank the calm ocean than a small lake of the same

depth; except for the violence of the waves, the same strength of dike would resist the weight in both cases.

At the depth of a foot, the pressure on a square inch of surface is a column of 12 cubic inches, weighing, in the case of fresh water, very nearly 7 oz.; and in the case of salt water, slightly more than 7 oz. This gives, at the depth of 7 feet, a pressure of 49 oz. or about 3 lbs. As water is so very slightly compressible, we may assume, without any great error, that its density is uniform at all depths, and, therefore, that the pressure will go on increasing regularly at the rate of 3 lbs. on the square inch for every 7 feet in depth. It is thus easy to calculate the pressure at any given depth. At a thousand feet, for instance, it will be $\frac{1000}{7} \times 3 = 428\cdot6$ lbs. or about 29 atmospheres. At the depth of a mile, or 5280 feet, it will be $\frac{5280}{7} \times 3 = 2263$ lbs. or 150 atmospheres.

Centre of Pressure.—We have seen that a vertical line or section AC (fig. 8) of a vessel containing a liquid, is pressed outwards by a set of forces increasing in intensity at every point from A to C. Now, there is evidently a point somewhere in AC at which, if a single pressure of sufficient strength is applied on the outside in the opposite direction, it will counteract the effect of all the outward pressures at the several points on the inside, and hold the line in its place. This point is called the *Centre of Pressure;* it is the point of application of the resultant of all the elementary pressures exerted at the different points.

As the pressures on the opposite sides of the centre of pressure must balance as on a fulcrum, it is clear that it cannot be on the middle of AC, but nearer the bottom, where the pressures are the greatest. And since the distribution of the pressure is represented by the triangular area AC*e* (fig. 8), the centre of pressure will be determined by that of the centre of gravity of the triangle; in other words, it will be at the point 4, which is ⅓ of the height of the triangle (see NATURAL PHILOSOPHY).

For surfaces of other forms than rectangular, the investigation of the centre of pressure is too difficult for introduction here. On a triangular side in the position of ABC (fig. 10), it is determined to be at *m*, ½ the depth; in the position of fig. 11, it is at *n*, ¼ from the bottom.

Each stave of a vat or cask may be considered as a rectangular side; the position, therefore, where a single hoop has the greatest effect in resisting the pressure, is at ⅓ from the bottom.

THE SURFACE OF LIQUIDS.

The surface of a mass of liquid at rest is a perfect level. Two or more points are on the same level when they are equally distant from the earth's centre. Let EAPBS represent a portion of the earth's circumference, C its centre, and L, T, two points above the surface equally distant from C; then L and T are on the same level; and if an arc of a circle is described from C through these two points, any other points, as Q, R, in that arc are on the same level with L and T. In like manner, the points A, P, B, in the earth's circumference, are on the same level; and so are *m* and *n*, below it. A level line, then, is, strictly speaking, not a straight line, but a portion of a circle; and similarly, a level surface is not a plane, but a portion of a spherical surface.

The direction of gravity—that is, the direction of a plumb-line—is always towards the earth's centre. Thus, at T or at B, the direction of

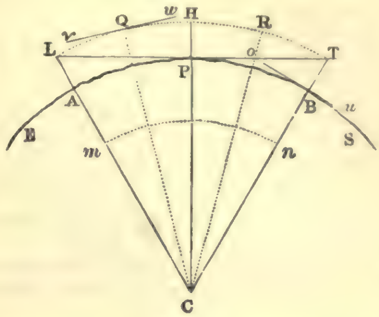

Fig. 12.

gravity is the line TBC; at Q, it is the line QC; and so of the other points in the figure. These lines marking the direction of gravity are perpendicular to the earth's surface, or to any other level surface, as LHT. A straight line, as TB, is perpendicular to a curve when it is perpendicular to the line B*u* drawn touching the curve at the point B. The lines TB, HP, LA, that mark the direction of gravity, are called *vertical* lines; and lines at right angles to them, such as *o*B*u*, LPT, *v*Q*w*, are *horizontal* lines.

When we confine our attention to a small arc of a very large circle, it does not differ sensibly from a straight line. Owing to this, 'horizontal' and 'level' are used, in common language, to signify the same thing. It is only when we take in a considerable space that the difference becomes appreciable. When considering a mass of water in a vessel or pond, then, the surface may be assumed to be straight or plane, and all vertical lines, or lines shewing the direction of gravity, as parallel to one another.

The familiar fact, that the surface of a liquid at rest is always level or horizontal—in the popular sense—admits of explanation; it can be shewn to be a consequence of the primary property of 'pressing equally in all directions.' For let *da* and *cb* be vertical lines, or lines in the direction of gravity; and *ab* a plane at right angles to that direction, or horizontal. A particle of the liquid at *a* is pressed by the column of particles above it from *a* to *d;* and the like is the case at *b*. Now, since the liquid is at rest, these pressures must be equal; for if the pressure at *b*, for instance, were greater than at *a*, there would be a flow of the water from *a* towards *b*. It follows that the line *ad* is equal to *bc*, and hence that *dc* is parallel to *ab*, and therefore horizontal. The same might be proved of any two points in the surface; therefore the whole is in the same horizontal plane. Or we might prove the same thing by the

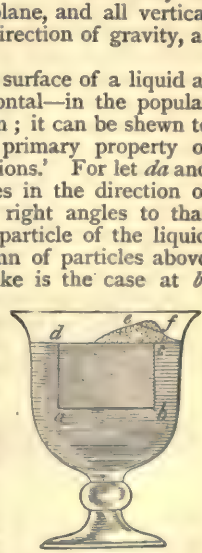

Fig. 13.

following consideration: if we could conceive a portion of the surface heaped up, as at *ef*; besides causing unequal pressure, and therefore disturbance in the mass below, the particles on the summit would have a tendency to flow down as on an inclined plane. Particles of sand so heaped up have this tendency; and are only prevented from spreading out into a perfectly level surface by their imperfect mobility.

It seems so natural that the surface of an unbroken mass of liquid should be all of one height, that we seldom think of it as requiring explanation. But when the surface of a liquid is not continuous, being contained in separate vessels, with communication between them, it requires consideration, and experience to convince us that the several parts of the surface must in all cases stand at the same level. A common tea-pot affords the most familiar illustration of this truth.

Fig. 14 represents six vessels communicating with one another, or rather one vessel consisting

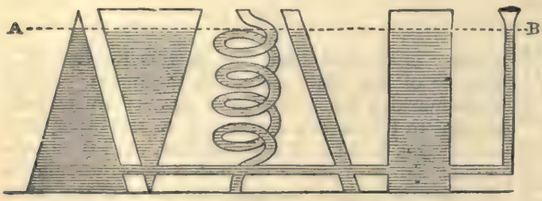

Fig. 14.

of six compartments of different shapes and sizes; and it can be shewn in the same way as with a continuous mass of water, that the surface in all the compartments must form part of the same horizontal line AB.

It is only when a sheet of water is stretched out to an extent of several miles that the convexity becomes conspicuous. It is very perceptible on the ocean when a ship is approaching on the horizon; first, the masts and sails of the ship are seen, and lastly, the hull. The convexity of the land is not so conspicuous, in consequence of the many risings and fallings in the surface. It is only in extensive plains that the roundness can be perceived in the same manner as at sea.

The amount of the earth's convexity can be calculated exactly. It is very nearly eight inches in each mile; that is, if PL (fig. 12) is a mile long, the point L will be eight inches above the surface.

In constructing canals and railways, allowance must be made for the convexity of the earth; for the channel of a canal, or a line of level railway, does not form a straight line, but a curve; it is not a part of the tangent or PL, but of the curve PA.

Levelling.—The most common instrument for determining levels is the *spirit-level.* It consists of a glass cylinder, *ac*, slightly convex on the upper side, and filled with spirits, all except a small space. It is placed for protection in a wooden or brass case, the bottom of which is exactly parallel with the tube. If the instrument is laid on the upper surface of a stone slab or a beam, and if one end of the slab or beam is higher than the other, the liquid in the tube will seek the lowest position, and the air-bubble will move towards the

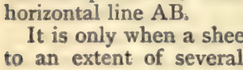

Fig. 15.

higher end; when the bubble rests in the middle, as at *b*, the surface is horizontal or level. To ascertain levels at a distance, the spirit-level is fixed below a small telescope, the tube of the telescope and the glass tube being made exactly parallel. The telescope being fixed on a stand, is adjusted by screws until the air-bubble of the spirit-level stands exactly in the middle, and is thus made perfectly horizontal. A pole being now set up at the spot where the level is to be found, the telescope is directed to it, and the point of the pole which appears in the centre of view is in a horizontal line with the eye. If the distance is short, this point may be considered as the level; but if the pole is as far as a mile off, the natural level at which water would stand, if there were a sheet of it all the way, will be eight inches below. The difference between the *apparent level* and the *true level*, as they are sometimes called, varies for different distances, and may either be calculated or taken from a table.

BUOYANCY AND FLOTATION.

When a solid is immersed in a liquid, it displaces exactly its own bulk of the liquid. This requires no demonstration; as soon as we conceive clearly what is meant, the truth of the proposition is self-evident. Of course, it is only of solids that are neither melted nor penetrated by the liquid that the proposition holds good.

If a cubic inch of wood or of a metal is wholly immersed in a vessel previously full of water, the liquid that occupied the space where the solid now is, must overflow; or, if the vessel was not full, the level of the liquid must rise. This affords a ready means of measuring solids, even the most irregular in shape. To ascertain what bulk of solid metal there is in a gold chain: have a cylindrical vessel with a base of known area—say a square inch—filled to a certain height with water; drop in the chain, and note the rise of the liquid. If it rise an inch, the chain contains a solid inch of gold, and so for any fraction of an inch. Archimedes is said to have been the first to think of measuring solid bodies in this way, and to have applied it in detecting the adulteration of a gold crown.

Every one must have experienced that a heavy body, held in the hand, becomes lighter when it is immersed in a liquid. We have now to consider how this loss of weight arises, and what is its amount.

Conceive, first, that a body of water, AB, forming part of the contents of a vessel, is separated from the rest by an imaginary film; this water will clearly remain suspended like any other portion of the mass. Now, as its weight is pressing it downwards, there must be an equal force acting upon it upwards. That force arises from the pressure of the surrounding liquid, which is acting upon it in all directions, upwards, downwards, and laterally. The horizontal pressures have each an opposite and equal resultant, and thus mutually destroy one another; but the under surface being at a greater depth than the upper, there remains a

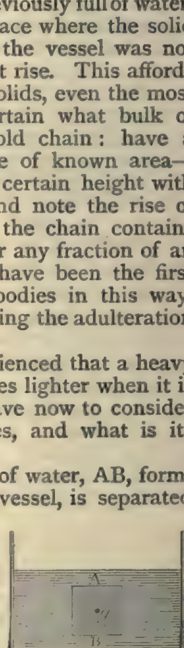

Fig. 16.

balance of upward pressure. This balance or result must be exactly equal to the weight of the conceived isolated body, otherwise it could not keep it at rest. The upward pressure, then, on any separate portion AB, say a cubic foot, within a mass of liquid, is equal to the weight of that portion. This is true, whatever be the shape of the isolated body. If we now suppose the mass of water, AB, to become solid ice without change of bulk, the same pressure will act upon it as before; and if we further conceive the cubic foot of ice to become a cubic foot of gold, the upward pressure upon it will remain the same—namely, the weight of a cubic foot of water, or the weight of the water it displaces. To this extent the water supports it, and renders it lighter.

It appears, then, that *a solid body in a liquid loses as much weight as an equal bulk of the liquid weighs.*

If a cubic foot of the liquid and of the solid have equal weights, the solid will lose all its weight, or will remain in the liquid wherever it is put; if a cubic foot of the liquid weigh more than one of the solid, the solid will not only lose all its weight, but will rise up, and that with a force equal to the difference; if a cubic foot of the liquid weigh less than one of the solid, the solid will lose weight, but will still sink.

It follows that, when two liquids, or, generally, when two fluids (for the principle is true of gases as well as of liquids) of different specific gravity are put together into the same vessel, the lighter will float on the top of the heavier, provided they are of a kind that do not intermix. For if we suppose AB (fig. 16) to be a mass of oil surrounded by water, being lighter than the same bulk of water, it must rise up; and as it cannot remain in a heap at the top, it diffuses itself in a horizontal stratum.

A body of alcohol or spirits in similar circumstances would take the same position for an instant; but the attraction existing between alcohol and water, soon causes a mutual and equal diffusion of the one through the other.

When a solid swims, or rises and *floats* on the surface of a liquid, the next problem of hydrostatics is to determine how much of it will be below the surface. We have already seen that any solid in a liquid is pressed upward with a force equal to the weight of the water whose room it occupies. Now, a floating body must be pressed up with a force equal to its own weight, otherwise it would sink lower; hence, *a floating body displaces its own weight of the liquid.*

By measuring how many cubic feet of water a floating body, such as a ship, displaces, we can thus know its weight, by allowing 1000 ounces, or 62·5 lbs. for every cubic foot.

As the buoyancy of a body thus depends on the relation between its weight and the weight of an equal bulk of the liquid, the same body will be more or less buoyant, according to the density of the liquid in which it is immersed. A piece of wood that sinks a foot in water, will sink barely an inch in mercury. Mercury buoys up even iron. Sea-water is denser than fresh water, in the proportion of 1026 to 1000. A ship, then, that carries 1026 tons on the sea, would carry only 1000 tons on a fresh-water lake.

The human body has almost the same weight as an equal bulk of water. When the lungs are full of air, it is slightly lighter, and will float with a bulk of about half the head above water. A person, then, that cannot swim, but has presence of mind to lie flat on the back, with the back part of the head submerged, may, by keeping the lungs full, continue to float with the face above water; but if any other part of the body, as a hand, is raised above the surface, the whole head goes immediately under. Swimmers, by the action of hands and feet against the water, keep the whole head, and often more, above the surface.

A body which would sink of itself, is buoyed up by attaching to it a lighter body; the bulk is thus increased without proportionally increasing the weight. This is the principle of life-preservers of all kinds. The most common are those which consist of pieces of cork, or other very light material, attached to the upper part of the body. But air-tight bags are preferable, as they may be said scarcely to encumber the body when empty, and, as danger approaches, they can be inflated with ease by being blown into. Life-boats have large quantities of cork in their structure, and also air-tight vessels made of thin metallic plates; so that, even when the boat is filled with water, a considerable portion of it still floats above the general surface. The bodies of some animals, as sea-fowl, and many other species of birds, are considerably lighter than water. The feathers with which they are covered add very much to their buoyancy. Fishes are enabled to alter their buoyancy by means of an air-bag, which they can inflate at pleasure by an apparatus for generating gases.

The buoyant property of liquids is independent of their depth or expanse, if there be only enough to surround the object. A few pounds of water might be made to bear up a body of a ton-weight; a ship floats as high in a small dock as in the ocean.

Stability of Floating Bodies.—Conceive *abd* (fig. 17) to be a portion of a liquid turned solid, but unchanged in bulk; it will evidently remain at rest, as if it were still liquid. Its weight may be represented by the force *cg*, acting on its centre of gravity *c*; but that force is balanced by the

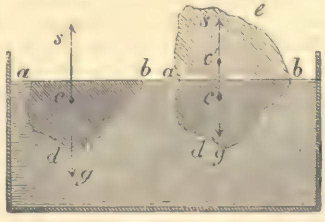

Fig. 17.

Fig. 18.

upward pressure of the water on the different parts of the under surface; therefore, the resultant of all these elementary pressures must be a force, *cs*, exactly equal and opposite to *cg*, and acting on the same point *c*, for if it acted on any other point, the body would not be at rest. Now, whatever other body of the same size and shape we suppose substituted for the mass of solid water *abd*, the supporting pressure or buoyancy of the water around it must be the same; hence we conclude, that *when a body is immersed in a liquid, the buoyant pressure is a force equal to the weight of the liquid displaced, and having its point of*

application in the centre of gravity of the space from which the liquid is displaced. This point may be called the *centre of buoyancy.*

We may suppose that the space *abd* is occupied by the immersed part of a floating body *aebd* (fig. 17). The supporting force, *cb*, is still the same as in the former case, and acts at *c*, the centre of gravity of the displaced water; the weight of the body must also be the same; but its point of application is now *c'*, the centre of gravity of the whole body. When the body is floating at rest or in a state of equilibrium, this point must evidently be in the same vertical line with *c*; for if the two forces were in the position of *cs*, *c'g* (fig. 18), they would tend to make the body roll over. The line passing through the centre of gravity of a floating body and the centre of gravity of the displaced water is called the *axis of flotation.*

The equilibrium of a floating body is said to be *stable*, when, on suffering a slight displacement, it tends to regain its original position. The conditions of stability will be understood from the accompanying figures. Fig. 19 represents a body

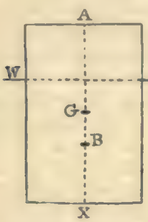

Fig. 19.

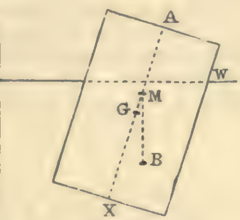

Fig. 20.

floating in equilibrium, G being its centre of gravity, B its centre of buoyancy, and AGB the axis of flotation, which is of course vertical. In fig. 20 the same body is represented as pushed or drawn slightly from the perpendicular. The shape of the immersed portion being now altered, the centre of buoyancy is no longer in the axis of the figure, but to one side, as at B. Now, it is evident, that if the line of direction of the upward pressure—that is, a vertical line through B—meets the axis above the centre of gravity, as at M, the tendency of the two forces is to bring the axis into its original position, and in that case the equilibrium of the body is stable. But if BM meet the axis below G, the tendency is to bring the axis farther and farther from the vertical, until the body get into some new position of equilibrium. There is still another case; the line of support or buoyancy may meet the axis in G, and then the two forces counteract one another, and the body remains in any position in which it is put; this is called *indifferent* equilibrium. In a floating cylinder of wood, for instance, B is always right under G, in whatever way the cylinder is turned.

When the angles through which a floating body is made to roll are small, the point M is nearly constant. It is called the *metacentre;* and its position may be calculated for a body of given weight and dimensions. In the construction and lading of ships, it is an object to have the centre of gravity as low as possible, in order that it may be always below the metacentre. With this view, heavy materials, in the shape of ballast, are placed in the bottom, and the heaviest portions of the cargo are stowed low in the hold.

SPECIFIC GRAVITIES OF BODIES.

If a lump of sulphur is weighed in air, and found to be two ounces, when weighed in water it will be found to weigh only one ounce. Now, as we know that the weight which a body loses in water is exactly the weight of an equal bulk of water, we infer that a body of water equal in size to the lump of sulphur weighs an ounce. Bulk for bulk, then, sulphur is twice as heavy as water, or their weights are as 2 to 1. *The specific gravity of a body, then, is its weight compared with that of water.* In tables of specific gravities, that of water is generally expressed by 1, but sometimes also by 1000. Thus, with water as 1, the specific gravity of sulphur is 2; of iron, 7; with water as 1000, these substances would be 2000 and 7000 respectively (see No. 13). The process of determining specific gravity varies with the nature of the substance; it requires delicate apparatus and delicate handling.

Instruments for readily indicating the specific gravities of liquids are called *hydrometers*, from two Greek words signifying *water* and *measure.* The name *areometer* (Gr. measurer of *rarity*) is also applied. Hydrometers are of various kinds; but the general principle on which they act will be understood from the accompanying figure. *b* is a glass ball, with a smaller ball, *c*, below it, containing shot, in order to make the instrument float upright; the fine stem, *ed*, being uniform and graduated. Suppose the hydrometer first immersed in water, it sinks until the water displaced equals the weight of the whole instrument; if placed next in a liquid rarer than water, it must sink farther, so as to displace more of the liquid, before it is in equilibrium. By knowing what part of the volume of the whole instrument each division of the stem is, we get the comparative volumes of water and of the liquid that sustain the same weight; and then the specific gravities are inversely as the volumes. It is evident that the thinner the stem, the more delicate will the instrument be. Hydrometers are made to indicate a difference in specific gravity of 1 part in 40,000.

Fig. 21.

The heaviest substance known is platinum, whose specific gravity (when rolled) is **22**; the lightest is hydrogen gas. The standard of comparison for gases is atmospheric air, which, at 60°, is 800 times lighter than water. Its specific gravity is taken at 1000. Hydrogen is fourteen times lighter than air, while carbonic acid and chlorine are more than twice as heavy as air. The vapour of iodine is eight times the weight of atmospheric air.

Spirits, such as brandy, whisky, gin, &c. consist of alcohol and water in varying proportions; and as the excise-duty is charged according to the amount of the alcohol, it is important to be able to tell at once what proportion or percentage of alcohol is present in any spirit. Alcohol, or spirit of wine, without any water—absolute alcohol, as

it is called—has a specific gravity of ·796, water being 1. The stronger any spirit is, then—that is, the less the proportion of water it contains—the lighter it is; and in this way the hydrometer becomes the means of measuring the strength of spirits. The hydrometer used by the officers of excise is of the kind known as Sikes's Hydrometer. What is called 'proof-spirit' consists of equal weights of alcohol and water, and has a specific gravity of ·92. When placed in this liquor, the exciseman's hydrometer sinks to a point on the scale marked *proof*. In a stronger, and, therefore, lighter spirit, it will sink farther, and the spirit will be so many degrees 'above proof.' The contrary takes place with a weaker spirit. The degrees are so contrived that a spirit that is, we shall say, 11° overproof, would require 11 measures of water added to every 100 measures of the spirit, in order to reduce it to proof.

As heat expands liquids, rendering them specifically lighter, great attention must be paid to the temperature of those experimented upon, as otherwise wrong results will be obtained. The standard temperature is 60°, and observations taken at any other temperature have to be reduced to the standard by certain rules.

HYDRODYNAMICS.

Hydrodynamics treats of the laws of the motion of liquids; the flow of water from orifices and in pipes, canals, and rivers; its oscillations or waves; and its resistance to bodies moving through it. The term Hydraulics is sometimes applied to this part of the subject, from the Greek word *aulos*, a pipe. The application of water as a moving power forms the practical part of the subject.

Efflux.—If three apertures, A, B, C, are made at different heights in the side of a vessel (fig. 22) filled with water, the liquid will pour out with greater impetuosity from B than from A, and from C than from B. The velocity does not increase in the simple ratio of the depth. The exact law of dependence is known as the theorem of Torricelli; the demonstration is too abstruse for introduction here, but the law itself is as follows:

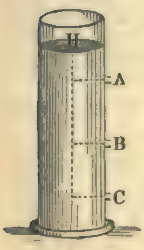

Fig. 22.

'*Particles of fluid, on issuing from an aperture, possess the same degree of velocity as if they had fallen freely, in vacuo, from a height equal to the distance of the surface of the fluid above the centre of the aperture.*' The jet from B, for instance, has the same velocity as if the particles composing it had fallen in vacuo from H to B. Now, the velocity acquired by a body in falling is as the time of the fall; but the space fallen through being as the *square* of the time, it follows that the velocity acquired is as the square root of the space fallen through. In the first second, a body falls sixteen feet, and acquires a velocity of thirty-two feet. If C, then, is sixteen feet below H, a jet from C flows at the rate of thirty-two feet; and if A is at a depth of four feet, or one-fourth that of C, the velocity of the jet at A will be half the velocity of that at C, or sixteen feet. In general, to find the velocity for any given height, multiply the height by 2×32, and extract the square root of the product.

The area of the orifice and the velocity of the flow being known, it is easy to calculate the quantity of water discharged in a given time. Thus, suppose the area to be one square inch, and the velocity twenty feet a second, it is evident that there issues in a second a cylinder or a prism of water one square inch in section and twenty feet long, the content of which is $1 \times 240 = 240$ cubic inches. This is true only on the supposition that the water in the vessel or reservoir is kept constantly at the same height.

The 'Contraction of the Vein.'—When, by means of the area of the opening and the velocity thus determined, we calculate the number of cubic feet or of gallons that *ought* to flow out in a given time, and then measure the quantity that actually does flow, we find that the actual flow falls short of the theoretical by at least a third. In fact, it is only the central part of the jet, which approaches the opening directly, that has the velocity above stated. The outer particles approach from all sides with less velocity; they jostle one another, as it were, and thus the flow is retarded. In consequence of this want of uniformity in velocity and direction among the component layers of the jet, as they enter the orifice, there takes place what is called a 'contraction of the vein' (*vena contracta*); that is, the jet, after leaving the orifice, tapers, and becomes narrower. The greatest contraction is at a distance from the orifice equal to half its diameter; and there the section of the stream is about two-thirds the area of the opening. It is, in fact, the section of the contracted vein that is to be taken as the real area of the orifice, in calculating by the theory the quantity of water discharged.

Adjutages.—It has as yet been supposed that the issue is by means of a simple opening or hole in the side or bottom of the vessel; but if the flow takes place through a short tube, the rate of discharge is remarkably affected. Through a simple opening, in a thin plate, the actual discharge is only about 64 per cent. of the theoretical; through a cylindrical conducting-tube, or *adjutage*, as it is called, of like diameter, and whose length is four times its diameter, the discharge is 84 per cent. The effect is still greater if the discharge-tube is made conical both ways, first contracting like the contracted vein, and then widening. The effect of a conducting-tube in increasing the discharge is accounted for by the adhesion of the water to its sides, which widens out the column to a greater area than it would naturally have. It has thus a tendency to form a vacuum in the tube, which acts like suction on the water in the reservoir, and increases the quantity discharged.

Pipes.—When a conduit-pipe is of any considerable length, the water issues from it at a velocity less than that due to the head of water in the reservoir, owing to the resistance of friction. With a pipe, for instance, of one and a third inch in diameter, and thirty feet long, the discharge is only one half what it would be from a simple orifice of the same diameter. The rate of reduction depends upon the diameter of the tube, its length, the bendings it undergoes, &c. The resistance increases greatly with the narrowness of the pipes.

Rivers.—The natural tendency in the water

of a river to descend at a certain speed is checked by friction, by bends in the course of the stream, and by projections on the banks and bottom. It also flows at a slower rate of speed at and near the bottom than at the surface, and also slower at the sides than in the middle. The place at which the velocity is greatest is called the *line of current;* it is generally at the deepest part of the channel. The surface of a river is not quite level; it is slightly convex, the highest part of the convexity being at the line of current. This arises from the fact, that flowing water does not press so much laterally as if it were at rest; the more slowly flowing side particles thus press in upon the central portions that are flowing fast, and heap them up until there is equilibrium of lateral pressure.

To get the mean velocity of a river or other stream, find first the surface velocity in the line of current by observing the rate in feet per minute at which a floating body is carried down. As an approximation to the truth, the mean velocity may be taken at four-fifths of the greatest surface velocity; and if this is multiplied by the area in feet of the cross-section of the stream, the product is the discharge in cubic feet per minute.

Resistance of Water to Bodies moving through it.—This is greatly affected by the shape of the body, which ought to have all its surfaces oblique to the direction of the motion. When a cylinder terminates in front in a hemisphere, the resistance is only one-half what it is when the cylinder terminates in a plane surface at right angles to the axis; and if, instead of a hemisphere, the termination is an equilateral cone, the resistance is only one-fourth. If a globe is cut in halves, and a cylinder, whose length and the diameter of whose base are each equal to the diameter of the globe, is fixed between them, this cylinder with hemispherical ends experiences less resistance than the globe alone, the diminution being about one-fifth of the resistance of the globe. Ship-builders have become, in recent times, more alive than formerly to the importance of length and of sharp angles both at bows and stern, in order that vessels may sail well. The best form in all respects for ships is still a disputed point, though it seems to be agreed that swift-swimming fish present the nearest approach to the true model

The resistance offered to a body moving in water increases in a higher ratio than the simple one of the velocity. One part of the resistance arises from the momentum that the body has to give to the water it displaces. Moving at a certain rate, it displaces a certain quantity; moving at twice that rate, it displaces twice the quantity in the same time. But not only does it displace twice the number of particles of water; it also has to displace them with twice the velocity; the pressure of the resistance is thus not merely doubled, but quadrupled or squared. Similarly, when the velocity is tripled, the resistance arising from the simple displacement of water becomes nine times as great.

Another part of the resistance of liquids to bodies moving in them is owing to the cohesion of the particles, which have not to be thrown aside merely as separate grains, but to be torn asunder. In addition to this, when the velocity is considerable, the water becomes heaped up in front, and depressed at the other end, from not having time to close in behind, thus causing an excess of hydrostatic pressure against the direction of the motion. Owing to the combination of these causes, the real law of the increase of resistance is difficult to investigate, and the results of experiments are not a little discordant.

The law, however, established with regard to that part of the resistance arising from the displacement of the water, has an important practical application. We have seen that when the speed of a vessel is doubled, the pressure against her bows must be at least four times as great as before. Now, this fourfold pressure has to be overcome over twice the space in the same time; and this amounts to doing eight times the amount of work in one hour or in one minute that was done before, implying, of course, an eightfold working or impelling power. We thus arrive at the important conclusion, that *the impelling power required for a vessel increases as the cube of the velocity.* If an engine of twenty horse-power is sufficient to impel a steamer six miles an hour, then, to impel the same vessel twelve miles, or at twice the velocity, would require $2^3 \times 20$, or $8 \times 20 = 160$ horse-power. It thus appears that to do twelve miles in one hour requires eight times as much expenditure of coal as to do six miles in one hour; or it may be put thus: to do six miles in half an hour costs four times as much coal as to do the same distance in a whole hour.

WATER-POWER.

Water is used as a moving power, either by taking advantage of the impulse of its velocity acquired in falling or descending, or by applying its mere weight to bear down one side of a wheel. The impulse of water is used when the fall of the water is low, and is applied to an *undershot wheel,* that is, to a wheel with float-boards dipping into the stream, which sweeps under the wheel. It is evident that an undershot wheel can never receive but a fraction of the effect due to the head of water, for the water leaves the float-boards retaining at least half its velocity.

The more economical mode is to make the

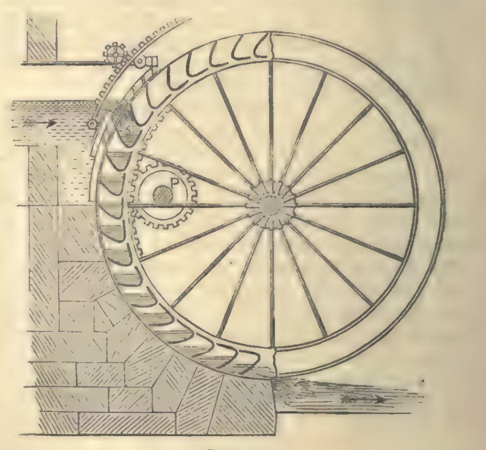

Fig. 23.

water act by its gravity, and this is done wherever

the height of fall is sufficient to allow the water to be let on above the centre of the wheel. When the channel or trough is carried over the top, the wheel is called an *overshot* wheel. This arrangement is now seldom followed. It is found preferable to make the diameter of the wheel a foot or two greater than the fall, and to deliver the water a little below the summit, as at the upper channel in fig. 23. The water may enter the bucket with greater impulse by the former arrangement, but the dash makes the bucket overflow before it is full, which more than counterbalances the advantage. When sufficient fall is not available, the water is sometimes laid on as low as the level of the axis. The term *breast*-wheel is generally applied where the water is delivered anywhere above the level of the axis without being carried over.

The absolute working-power possessed by water descending from a height depends upon the quantity and the height of the fall. If the descent is twelve feet, one pound of water is urged over twelve feet by a pressure of a pound, which makes twelve units of work, and is equivalent to the work of lifting one pound to the height of twelve feet. Therefore, the absolute work inherent in a ton of water having a descent of twenty feet, is $2240 \times 20 = 44{,}800$ units. If the stream deliver ten tons per minute, $44{,}800 \times 10 = 448{,}000$ is its work per minute; and as a rate of 33,000 units of work in a minute is what is meant by a horse-power, the power of such a stream is equal to $\frac{448{,}000}{33{,}000} = 13\frac{1}{2}$ horse-power.

But water acts fully on a bucket-wheel only from the point where the bucket is filled to the point where it begins to flow out, or for about two-thirds of the fall. Owing to this and other causes of loss, the proportion of the absolute power of the fall rendered available seldom exceeds from 55 to 65 per cent. It is advantageous, with a view to economising the power, to give a small velocity to the circumference of the wheel, not exceeding three or four feet per second.

There are a great many kinds of horizontal water-wheels. In the class known as *turbines* (Ital. *turbino*, a whirlwind), the water is made to escape horizontally from a column under pressure, inside the wheel; and, receiving a spiral direction from curved blades, strikes on the oblique palettes of the wheel, and makes it revolve. There is another class called *reaction wheels*, the principle of which is seen in the machines known as Barker's or Segner's mills. A drawing of a Barker's mill, in its simplest or typical form, is annexed (fig. 24). A is a wide metal pipe resting at its lower end by the spindle T, on a metal block B, and kept in a vertical position by the spindle S, at its upper end, which passes through the frame of the machine, so that it can easily revolve round its axis. Near its lower end, two smaller pipes or arms, C, C, are inserted, which project horizontally from it; and these have, near their outer extremities, holes cut in them, opening towards opposite sides. The water is supplied by the pipe P. The reaction caused by the water gushing from the arms, forces them backwards, and gives to the whole machine a rotatory motion. The action is similar to the recoil of a musket. More closely analysed, it may be thus explained. When an opening is made in a vessel containing water, as at C in fig. 24, the pressure is less on that side of the vessel than on the other, and if it were standing on a piece of wood floating on water, it would move in a direction opposite to the jet.

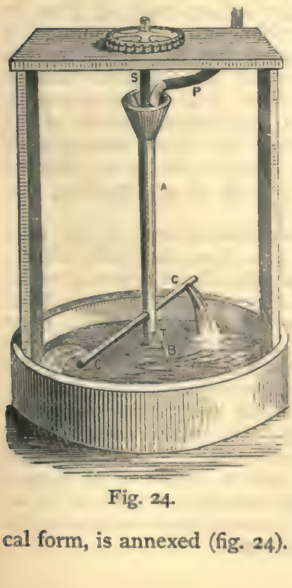

Fig. 24.

Water-column Machines.—We shall understand the nature of those machines, if we conceive that in a steam-engine, instead of steam, water, under the pressure of a high column, were admitted alternately above and below the piston.

The Hydraulic-ram is a simple and conveniently applied mechanism, by which the momentum or weight of falling water can be made available for raising a portion of itself to a considerable height. In the annexed figure (fig. 25), which represents a section of Montgolfier's hydraulic-ram, R is the reservoir from which the water falls; RS, the height of the fall; and ST, the horizontal tube which conducts the water to the engine, ABHTC. E and D are two valves, the former of which closes its cavity by ascending, the latter by descending; and FG is a pipe reaching within a very little of the bottom CB. The valves are such that the water at its normal pressure cannot support their weight; the valve E is prevented from falling below a certain point by a knob above *mn*. When the water is allowed to descend from the reservoir, after filling the tube BHS, it rushes out at the aperture *mn*, till its velocity in descending RST becomes so great as to force up the valve E, and close the means of escape. The water being thus suddenly checked, and unable to find a passage at *mn*, will produce a great action on every part of the containing vessels, and by its impact raise the valve D. A portion of water being admitted into the vessel ABC, the impulse of the column of fluid is expended, the valves D and E fall; the opening at D being thus closed, and that at *mn* opened. The water now rushes out at *mn* as before, till its motion is again stopped by its carrying up the valve E, when the operation is repeated, the fluid impulse opening the valve at D, through which a portion of the water passes into ABC. The valves at E and D thus alternately closing and opening, and water at every opening of D making its way

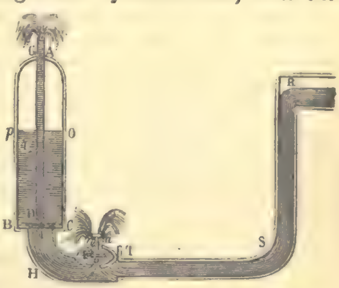

Fig. 25.

into ABC, the air therein is condensed, for it has no communication with the atmosphere after the water is higher than the bottom of the pipe FG. This condensed air, then, exercises great force on the surface, *op*, of the water, and raises it in the tube, FG, to a height proportioned to the elasticity of the imprisoned air.

The principles of the hydraulic-ram are susceptible of a very extensive application. In well-constructed rams, the mechanical effect obtained should be from 65 to 75 per cent. of the force supplied. For raising comparatively small quantities of water, such as for single houses, farmyards, &c. the ram is the best mechanism yet introduced. But the concussion, and consequent deterioration of the valves, places a limit to the use of the mechanism when applied to raise large quantities.

PNEUMATICS.

Pneumatics, from the Greek word *pneuma*, 'breath,' or 'air,' is a general term for the science of aëriform fluids, embracing both Aërostatics and Aërodynamics. What follows relates chiefly to the weight, pressure, and elasticity of gases; in other words, to the statical part of the subject. The most interesting motions of air fall under METEOROLOGY.

Modern science has made us acquainted with a number of distinct *airs*, besides common air; these are now usually called *gases*, and the name *air* is confined to the fluid composing our atmosphere. Aëriform fluids differ from one another in weight as well as liquids do; the other properties treated of in pneumatics are common to them all. Whatever, therefore, is established regarding air, is to be understood as applying to gases in general.

WEIGHT OF AIR.

The idea of air as a material fluid possessing weight and exerting pressure on everything immersed in it, is modern. The ancients thought of it as essentially *light*, or without weight, and as wanting generally the characteristics of matter. Yet it really possesses all the properties of matter, as surely as water does. A portion of it may be much compressed, indeed, but cannot be squeezed to nothing; it still occupies space, and is therefore *impenetrable* (see MATTER AND MOTION). It also resists sensibly a flat body, such as a fan moving through it; and when itself in motion, as in a strong wind, it is felt to have a powerful momentum or moving force.

With regard to the *weight* of air, nothing in the history of science is more remarkable than that men should have lived so long subject to the great pressure which this weight occasions, without discovering it. The fact is, that air acts so little on the senses, that it does not make us aware directly of its existence. The effects produced by its weight were therefore attributed to other causes. The facts, for instance, that go by the name of *suction*, are all owing to the pressure of the atmosphere. But when water was seen to rush up a pipe from which the air was withdrawn, it was explained by saying that 'nature abhors a vacuum'—that is, an empty space. This explanation continued to satisfy philosophers till the middle of the seventeenth century. Some mechanicians near Florence, having to construct a pump of unusual length, found, to their surprise, that the water refused to rise higher than thirty-four feet. This led to the conjecture, that the weight of the atmosphere was the cause of water rising in the pump; and Torricelli, the pupil of Galileo, confirmed the conjecture by a happy experiment.

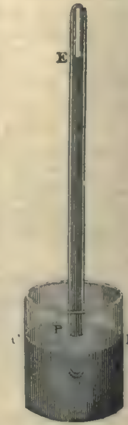

Fig. 26.

Mercury weighs nearly 14 times as much as water. If, now, he argued, the atmospheric air can support a column of 34 feet of water, it must also be able to sustain a column of mercury of about 1-14th that height. The experiment is easily made. A glass tube of upwards of 30 inches in length, and closed at one end, is filled with mercury; and the finger being firmly pressed on the open upper end, the tube is inverted, and the end closed by the finger is plunged into a vessel containing mercury, CD. The finger being now withdrawn, the liquid in the tube descends, however long the tube may be, till it stands at the height of about 30 inches above the level of that in the vessel.

All doubt on the subject was shortly after put an end to by the celebrated Pascal, who caused the Torricellian tube, as it was called, to be carried up the Puy-de-Dôme, a mountain in France. By ascending a mountain, a part of the atmosphere is left below; if it is the pressure of the superincumbent atmosphere, then, that sustains the column, the mercury must sink farther and farther as the elevation is greater. Such was found to be the case, and the question was set at rest for ever.

That air is ponderable, or has weight, can be put to direct proof. By means of an air-pump, to be afterwards described, vessels of a certain construction can be emptied of air, which, in ordinary circumstances, fills every space not occupied by other matter. When a hollow globe of glass or of copper, holding a cubic foot, is thus emptied of air, and weighed, on admitting the air again, it is found to be about an ounce and a quarter heavier than before. As a cubic foot of water weighs 1000 ounces, water, at the ordinary height of the barometer, is thus about 800 times heavier than air. It is sufficiently accurate for most purposes to consider a cubic foot of air as weighing one ounce.

Weight of the whole Atmosphere.—If the tube (fig. 26) is an inch in area, the column of mercury, PE, 30 inches high, weighs about fifteen pounds. Now, as this weight is sustained by the pressure of the atmosphere, that pressure must be equal to a weight of fifteen pounds on every square inch of surface. By multiplying the number of inches on the surface of the globe by fifteen, the product is the weight of the whole atmosphere in pounds. It is the same as the weight of an ocean of mercury spread over the whole globe to the uniform height of 30 inches, or of one of water 34 feet deep, or of one of oil 37 feet deep. It has been calculated to amount to 77,670,000,000,000,000 tons.

THE BAROMETER.

In the Torricellian tube above described, we have the well-known instrument called a *barometer* (from two Greek words signifying 'weight' and 'measure'). The weight of the atmosphere is liable to fluctuations, and these are marked by the rising and sinking of the top of the column at E. The height of the column varies, at the level of the sea, from 28 to 31 inches, the average height being 29·7. A scale is attached to the tube to mark the rise and fall. It is important to observe, that the height of the column is counted from the level of the mercury in the open vessel, and that this level is not steady. If the column sink, for instance, part of the mercury in the tube descends into the basin, and raises the level of the surface. When the basin is comparatively wide, the rise is insignificant, and is seldom attended to; but where great accuracy is required, either the scale is so constructed as to allow for the alteration of level, or the bottom of the basin is made flexible, and can be raised up and down by a screw, so as to bring the surface of the mercury always to the same point on the outside of the tube.

Barometers are of various constructions, according to the uses they are intended for. The common *weather-glass* consists of a glass tube, upwards of thirty inches in length, closed at one end A, and bent upwards at the open end C, as represented in fig. 27. The height of the column sustained is here to be counted from E down to a point on the tube on a level with F, the surface of the fluid in the open end. On the surface of F there floats a small ball, from which a thread is passed over a pulley G, and kept stretched by a lighter ball W. When the column at E sinks, the surface at F rises, and carries up the float, and the friction of the string turns the pulley, and with it the index H, whose motions are marked by a graduated circle. Such instruments are not capable of any great accuracy in ascertaining the actual height of the column; they indicate, however, generally whether it is high or low, and whether it is rising or falling, and these are the chief points in prognosticating the weather. (See METEOROLOGY.)

Fig. 27.

ELASTICITY OF GASES.

The laws which regulate the pressure of gases are essentially the same as those already established with regard to liquids. The fundamental fact of *transmitting pressure equally in all directions*, is as true of the one class of substances as of the other. But the effects in the case of gases are much modified by their peculiar property of *elasticity*, which requires careful consideration. The elasticity of gases involves two things—compressibility and expansibility, and in the case of common air, both properties are without any known limit.

Air unlimitedly Compressible.—The compressibility of air follows a remarkable law. Let *ab* (fig. 28) be a cylinder 12 inches long, closed at *b*, and open at *a*, having an air-tight piston, *d*, moved up and down by the rod *c*. Before the piston is inserted, the air in the cylinder sustains the usual pressure of the atmosphere, which is resting upon it at the open end *a*; and if the area is an inch, the amount of the pressure is 15 pounds. When the piston is placed on the open end, and about to enter, the direct action of the outer air is cut off, but it continues to act on the upper side of the piston, so that the column inside still sustains 15 pounds. Let the rod be then loaded with weights till the piston descend through half the cylinder, so as to squeeze the confined air into half its original bulk; it will be found that 15 pounds have been laid on. The piston is now forced down with a weight of 15 pounds, in addition to the weight of the outer atmosphere; the pressure on the confined air is thus exactly *doubled*, and the effect is to compress it into *half* the space.

If the weight is *tripled* by adding 15 pounds more, the piston descends two inches farther to *e*, and the air is reduced to *one-third* of its original bulk. An additional 15 pounds, making in all *four* atmospheres, sinks it to *f*, *one-fourth* from the bottom; and *twelve* atmospheres leave the air confined between *b* and *g*, *one-twelfth* of the whole space. This regular progression holds good, without variation, for atmospheric air up to at least twenty-seven atmospheres.

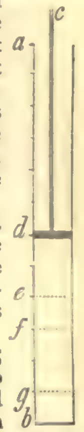

Fig. 28.

It follows from this that *the elastic force or tension of compressed air—that is, the force with which it seeks to expand—is exactly equal to the compressing force, and inversely, as the space it occupies.* At *f*, the air in the cylinder reacts upon the piston with a force of four atmospheres; at *d*, where it occupies twice the space, it presses up the piston with a force of only two atmospheres; at *a*, the under side of the piston is pressed with a force of one atmosphere, so as exactly to balance the weight of the external air. The law now explained was discovered independently by the two philosophers Boyle and Mariotte, and is known as *Boyle's Law*, or *Mariotte's Law.*

Air expansible without Limit.—The spring of air is not like that of a compressed feather or of a piece of india-rubber, which loses its tension as soon as it regains its original condition; air cannot be said to have any original volume, for it is always striving to occupy a larger space. Suppose an opening at the bottom of the cylinder (fig. 28), and let the piston be at *f*; its upper and under sides sustain each 15 pounds, for the external atmosphere is admitted to both; and air, like water, presses equally in all directions, up as well as down. If the opening is now closed by a plug or a stop-cock, cutting off the external air from acting on the under side, the piston does not move, because the confined air presses on the under side, not by its weight, but by its expansive force, as much as the external air on the upper.

Let the piston be next drawn upwards, and the air not only follows it, but continues to press upon the under side of it, though with a diminishing force. When the piston has risen to *d*, the air occupies twice its original bulk, and its tension or pressure against the under side of the piston is reduced to one-half, or 7½ pounds; and if its

volume is again doubled by drawing the piston to *a*, its elastic force falls to one-fourth, or 3¾ pounds. Thus the law of Mariotte holds for rarefied air as well as for condensed air.

HEIGHT OF THE ATMOSPHERE.

Air at the level of the sea being, in round numbers, 11,000 times lighter than mercury, it would require a column of air of that density to be 11,000 times 30 inches, or nearly five miles, high, to balance the mercury in the barometer; and this would actually be the height of our atmosphere if air were like water, of uniform density throughout its whole depth. But we could conclude even without trial, that the air must become rarer and rarer as we ascend, there being at every stage a diminished mass pressing it down; and experience verifies the conclusion. At the height of about three miles, the barometer shews that one half the mass of the air is below, so that the density at that point is reduced to one half. While, therefore, an ascent of 500 feet above sea-level makes the barometer fall half an inch, an ascent of 500 feet above three miles produces only half that fall. That the air does not extend indefinitely into the planetary spaces, we infer from the consideration that its elastic force diminishes as it becomes rarer, and is further weakened by the increasing cold of the upper regions. There must thus be a limit at which the tendency of a molecule to recede from the rest is balanced by the action of gravity drawing it towards the earth. From various appearances, it is inferred that the atmosphere extends to the height of at least 100 miles, if not much farther.

The regular decrease in density which would follow from Boyle's law, is interfered with by the decrease of temperature, which is subject to much irregularity and uncertainty. Were it not for this, the barometer would furnish a ready means of measuring heights. As it is, the rule is too complex for explanation here.

THE AIR-PUMP.

The air-pump, by which air is removed from vessels, acts by means of the expansibility of the fluid. There are various forms of the instrument; fig. 29 represents one of the simplest. R is the glass-receiver, or vessel to be exhausted, standing on a smooth plate P, and fitting so exactly, that no air can penetrate between them. From an opening in the middle of the plate, a tube passes down to the sole of the frame, and then along to the end, where it opens into the bottoms of the two pumps or syringes, as is seen in fig. 30, which represents the syringes A, A′, in section. The piston-rods, R, R′, are alternately raised and depressed by turning the pinion *o* backwards and forwards by the handle H (which, for facility in working, is often made double, as represented in fig. 29). As the piston, P, descends, the valve, V, is closed, and that in the piston opens and allows the inclosed air to escape. When the piston has reached the bottom, and begins to ascend, the valve in P closes, and a vacuum would be formed, were it not that the air in the receiver, R, and the connecting tube being relieved of the pressure of the outward atmosphere, expands, and opening the valve at V, fills the barrel below the piston. Thus, when the piston reaches the top of the barrel, the air that was at the outset confined in the receiver and tube, now fills a larger space, and is therefore so much rarer. The action of the other syringe is exactly the same; and the two do not interfere with each other, as the valve at V′ is always shut when that at V is open. Some air-pumps have only one syringe; and the chief use of two is for rapidity of exhaustion. Although every stroke of each piston removes a barrelful of the inclosed air, it must be remembered that that air is continually becoming rarer, so that the absolute quantity removed becomes less and less for every stroke. The whole of the air could never thus be removed, even in theory; and in practice, a limit is put to the degree of rarefaction by the elasticity of the remaining air becoming too feeble to raise the valves. The syphon-gauge at G shews to the eye how far the exhaustion has proceeded. It is constructed on the principle of the bent-tube barometer, fig. 27. When the process of rarefaction has reached a certain point, the mercury begins to descend in the closed leg of the tube; and if the exhaustion could be made complete, the two surfaces would be on the same level.

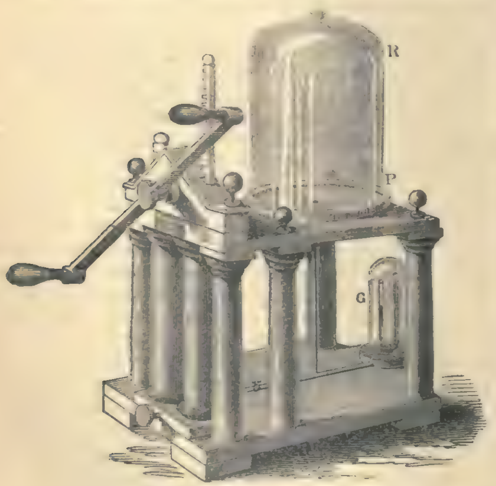

Fig. 29.

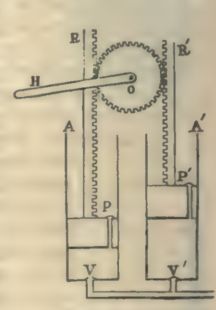

Fig. 30.

The *condensing pump*, or syringe, is the counterpart of the exhausting air-pump. By means of it, a receiver can be charged with an amount of air that would fill it many times at the ordinary density, and experiments can thus be tried on bodies inclosed in the receiver, under the pressure of many atmospheres.

A condensing syringe is used for charging the chamber of air-guns, which consists of a strong hollow copper ball. The valve of this chamber being then suddenly opened by the trigger, a portion of the highly compressed air is allowed to escape into the barrel behind the ball, which it propels with great velocity.

WATER-PUMPS.

The effect of atmospheric pressure on water affords a convenient method of raising it above its ordinary level; this is effected by pumps, which may be termed both hydraulic and pneumatic machines. Fig. 31 represents the outline of a common suction-pump. It consists of a cylinder, furnished with a piston, A, made to fit air-tight. In this piston there is a valve opening upwards, but here indicated as closed. At the bottom of the cylinder or barrel there is another valve, B, opening upwards; and from the bottom proceeds a feeding-pipe, and dips more or less into the water. When the piston is raised, the air under it is rarefied more and more at each stroke, and the pressure of the air upon the surface of the water on the outside of the pipe causes the water to rise inside where the pressure is lessened. The valve B is at the same time opened upwards, and the water, after several strokes, rushes in above it. When the upward stroke of the piston is complete, it is again depressed—the water passes through the valve in the piston, and on the next stroke it is discharged at the spout.

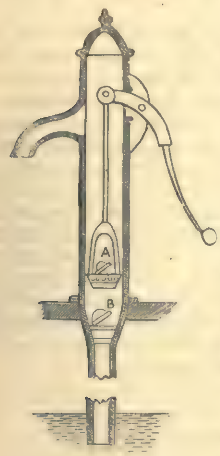

Fig. 31.

In this form of pump, the greatest height to which the water can be raised, counting from the level of the water in the well to the bottom valve, B, is, in theory, 34 feet. In practice, however, owing to the imperfect vacuum, the limit is usually from 20 to 28 feet. But with the *forcing-pump*, fig. 32, there is no such limit. The mode of its action will be understood from the accompanying outline. A feeding-pipe connects the water and the barrel, as in the suction-pump; but the piston, P, is solid, or without a valve, and a pipe, called the ascension-pipe, provided with a valve opening from the barrel, enters near the bottom. When the piston is lifted, the valve, S, closes, and the water rises through the feeding-pipe and suction-valve, on the same principle as in the suction-pump. The piston being raised to the top of the barrel, and the space below it being filled with water, it is now pressed down; the valve V closes, that at S opens, and the water is forced up the pipe to the required height.

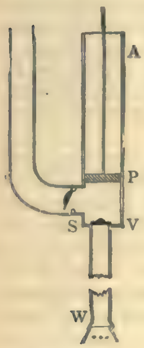

Fig. 32.

The Fire-engine.—The fire-engine is an application of the force-pump. The principle of its action, and its connection with the pumps, &c. will be easily understood by the aid of the annexed diagram (fig. 33), where *a* represents in section a piston ascending, *d* the other piston descending, *f* the pipe or hose communicating with the water-supply, *g* the hose that conveys the issuing stream to the fire, *bc* the level of the water in the air-chamber, *e* the space above filled with compressed air. The rising piston raises the water from *f* to fill its cylinder; the descending piston forces the water contained in its cylinder into the bottom of the air-chamber, and thereby compresses the air in *e*. The pistons rise and descend alternately. The compressed air reacts by its elasticity, and pressing upon the surface *bc*, forces the water through the hose *g*. In the space *e*, above *bc*, the whole of the air that formerly filled the chamber is supposed to be compressed. Assuming this to be one-third of its original bulk, its pressure will be about 45 lbs. to the square inch, and this pressure will be continuous and nearly steady, if the pumps act with sufficient force and rapidity to keep the water at that level.

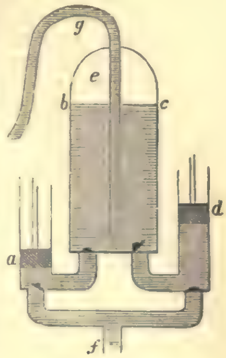

Fig. 33.

The Syphon.—The action of the syphon will be readily understood from the principles already illustrated. It is simply a bent tube, with one end inserted in a liquid, as shewn in fig. 34. To begin the action, the air is withdrawn from the tube by means of the mouth or a syringe, when the liquid enters and fills it, as in other cases of suction. When the suction is stopped, there are two forces acting on the liquid in the tube—the pressure of the atmosphere on the liquid in the vessel, forcing it in the direction from C towards B and A, and the pressure at A forcing it in the opposite direction. These two pressures are of themselves equal, and when the lengths of the columns of liquid in the two legs are equal, there is no flow; but when one column, as AB, is longer than the other, its weight destroys the balance, and produces a flow towards itself.

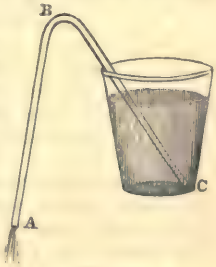

Fig. 34.

Pressure of the Atmosphere on the Human Body.—The body of a man has, on an average, a surface of about 2000 square inches. At the rate, then, of fifteen pounds to the square inch, the whole pressure which a person of an ordinary size sustains on the surface of his body is 30,000 pounds, or nearly fourteen tons. It gives a wrong notion of this pressure to speak of it as a load. It has, on the contrary, a buoyant effect, and makes a man lighter, or press less on the earth, than he would without it.

The reason why this compression is not felt, and does not in effect squeeze the body into less bulk, is, that there is an equal pressure *outwards* at all parts. In fig. 1, a force of a pound pressing in the plug *a*, is felt as an equal force pressing out the plug *b*. Now, the blood and other liquids in

the body, though contained in tubes, transmit pressure through all their ramifications, as the water in the box B does through its mass; and the direct pressure of the atmosphere on any spot of the outer surface, tending to squeeze in the sides of the tubes containing the fluids, is met by an equal pressure on the part of the fluids, tending to force them out; which outward pressure itself is caused by the atmosphere pressing on other parts of the system.

We are as little sensible, in ordinary circumstances, of this outward pressure of the fluids on the vessels of the body, as we are of the compressing force of the atmosphere. But it makes itself felt whenever the external pressure is removed from any part, as in the familiar act of sucking the finger, or more strikingly in the operation of *cupping*. A small bell-shaped glass, in which the air has been rarefied by burning a slip of paper, or by other means, is suddenly applied to a flat surface of the body. The small portion of air under the glass, as it cools, presses with diminished force on the surface of the skin; and the fluids within, released from the usual check, swell out the vessels and skin, and if a wound has been made with a lancet, the blood is forced out.

When the usual pressure of the atmosphere is much diminished over the whole body by ascending great heights, uneasy sensations are often felt, occasioned most likely by air contained in the liquids and in cavities of the solid parts of the body, seeking to expand.

A boy's sucker lifting a stone affords a good illustration of the operation of atmospheric pressure. Correctly speaking, the sucker does not lift the stone; it only lifts the weight of a column of the atmosphere from off the stone, and thus allows the remaining atmospheric pressure to push it up.

The bird-cage fountain and the ink-bottle of the same make, are other illustrations. The same cause sustains the liquid in such a vessel that sustains the column of mercury in fig. 26, and keeps it from flowing out at C—the atmospheric pressure, namely, on the surface at C, while the top at A is close, like the top of the tube in fig. 26.

Fig. 35.

The ink is introduced into a bottle of this kind by inclining it over, and pouring in gradually at C. When the ink in the tube CB sinks down by use to the level of the horizontal communication, a bubble of air gets in, and rising to the top at A, fills part of the space, and forces down a portion of ink into C.

On the principle now explained, if the lid of a tea-pot were quite close, so as to exclude the pressure of the atmosphere from the top of the liquid within, the liquid could not be poured out. It is for this reason that in drawing liquor from an opening in the lower part of a cask, there must be a vent-peg at the top to admit air.

BUOYANCY IN AĒRIFORM FLUIDS.

The fundamental law in this is exactly the same as in liquids. A body in air displaces its own bulk of the air, and is borne up with a force equal to the weight of the air so displaced. If the body's own weight is less than this, it must rise up, as a piece of cork does in water; if greater, the body only loses a portion of its weight, as a stone in water.

In weighing bodies in air, the fact that the air deprives them of part of their weight, does not interfere with the accuracy of the process so long as the substance is nearly of the same density as the weight against which it is balanced, because then both are equally affected. But where there is great difference of density, it leads to sensible error. A pound of feathers—as it is sometimes paradoxically stated—is heavier than a pound of lead—that is, it contains more matter. If a quantity of feathers occupying a cubic foot of space, were balanced in a vacuum against a piece of metal, the balance would be destroyed on taking them into the air. The feathers would lose above an ounce—the weight of a cubic foot of air—the metal would lose only a few grains.

BALLOONS.

Solid bodies cannot of themselves float in air, being all heavier than an equal bulk of it; but by inclosing air rarefied by heat, or a light gas, such as hydrogen, in a bag, it may be made to buoy up more or less solid matter along with it. Such a contrivance is a balloon. A soap-bubble blown from hot water with warm air, is the simplest form of balloon, but soon loses its buoyancy by cooling; if blown with hydrogen, it continues ascending till it bursts. A body floating in air rises till it arrives at a stratum of the atmosphere whose density is the same as its own.

A balloon is a bag made of varnished silk, and surrounded by a net-work, from which a car is suspended. Balloons were originally filled with heated air, and had a fire suspended in the opening below, to keep up the temperature. So far as lightness is concerned, hydrogen would be the best gas for the purpose; but, from its cheapness, common coal-gas is generally employed, whose density is about half that of air.

The air contained in a room fifty feet long, thirty wide, and twenty high, weighs upwards of a ton. A balloon of this capacity (30,000 cubic feet) would thus displace a ton of air, while the gas contained in it weighed only half a ton; it would therefore ascend with a force equal to the difference, or half a ton, after deducting, of course, the weight of the silk, the car, and other parts of the apparatus.

The most remarkable recent balloon ascents have been made by Mr Glaisher for the purpose of meteorological observations. On one occasion he ascended to a height of about 40,000 feet (7½ miles), the barometer standing at 7 inches. The balloon contained 90,000 cubic feet of gas, and carried a load of 600 lbs. As it is impossible to direct the horizontal motion of balloons, they are almost useless as a mode of conveyance. During the siege of Paris in 1870, a few persons made their escape in balloons from the city to the provinces, but there could, of course, be no return.

LIGHT AND SOUND.

LIGHT.

LIGHT (German, *licht;* Latin, *lux*, *lumen;* French, *lumière*).—That branch of physical science which treats of light and vision is termed Optics, from a Greek word meaning *to see.* To explain the production of light, let us first state two suppositions, which are now all but universally admitted to be true. *First*, all matter is built up of small particles, which are in a constant state of vibration. There are many ways of increasing the rapidity of these vibrations, of which it is sufficient to mention friction, chemical action, heat. When the vibrations become sufficiently rapid, the body becomes luminous. *Second*, pervading all space, and even the interstices between the component particles of matter, there is a subtle, highly elastic medium called ether, which can be agitated by the vibrations of these particles, thus forming ethereal waves. We see objects by these waves entering our eyes, and acting on the nerves of the retina. This theory has been successful in explaining all the facts of vision, and some even that at their discovery seemed opposed to it. Besides, consequences have been deduced from the theory that have been afterwards verified by experiments, so that its truth is in the highest degree probable. The only other theory at all deserving of consideration was that devised by the illustrious Newton, who supposed that luminous bodies throw off streams of particles in all directions, some of which entering the eye, produce vision. There are now so many facts that are utterly inconsistent with this hypothesis, that it has been generally abandoned; though, owing to the influence of Newton's name, it long reigned supreme. This is called the *emission* theory, as the former is called the *wave* or *undulatory* theory of light. In what follows, we shall adhere to the wave theory.

With regard to their power of exciting the sense of vision, bodies may be divided into luminous and non-luminous, or those whose vibrating particles can, and those whose vibrating particles cannot, produce those ethereal waves fitted to act on the retina. The sun, the fixed stars, a fire, the flame of a candle, a piece of glowing metal, are instances of the first class, or luminous bodies, which can be seen in the absence of other bodies; while the second class cannot be seen, except in the presence of one of the first, in a way to be presently explained.

Light proceeds from a luminous body in all directions; thus the flame of a candle is seen on whichever side of it we stand. Also each small part of a luminous surface gives out its own share of the whole light; so that, when we wish to have a luminous point, we place a screen, with a small hole in it, in front of the luminous surface. Bodies are said to be transparent when they permit light to pass through them, as a sheet of glass; and opaque, when they stop it completely, as a thick sheet of metal. No body is so transparent as to allow all the light to pass through it, for even the purest glass, if thick enough, will stop some light; and, on the other hand, if we take a thin enough sheet of any opaque body, some light will be transmitted. Gold-leaf, for example, exhibits a pale green tinge when held between a light and the eye.

In every uniform medium, such as air, water, glass, a vacuum, light is propagated in straight lines. Thus we can see through a straight tube, but not through a bent one. A shadow is a correct outline of the object which throws it, which could not be the case if light did not travel in straight lines. Any one of these lines, proceeding from a luminous point, is called a *ray* of light; and a bundle of rays is called a *pencil* of rays, which may be a parallel, diverging, or converging pencil, according as the distance between the component rays remains the same, increases, or diminishes.

Light is not transmitted instantaneously, but travels at the rate of 186,000 miles per second. This fact was first established in 1675 by a Danish astronomer, Römer, whose reasoning may be illustrated by the following diagram.

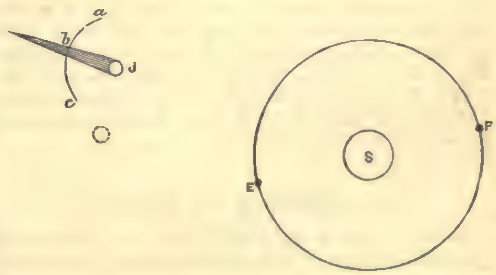

Fig. 1.

Let S represent the sun; E, F, the earth in two positions in its orbit, at considerably different distances from J, the planet Jupiter; and *abc*, a portion of the orbit of Jupiter's first satellite. At *b*, the satellite is just plunging into Jupiter's shadow, and a spectator at *e* sees it suddenly disappear. Six months afterwards, the earth is about F, while Jupiter has not materially altered his place (the small circle below J indicates his real place); and as the satellite revolves in a little over forty-two hours, the spectator at F again sees the eclipses, but they are now about a quarter of an hour later than the times calculated from those at E. Römer simply and rightly explained this fact by saying that the eclipses really happened at the calculated times, but that light took the additional time to travel the extra distance to F. By careful calculations he thus deduced the velocity of light to be 195,000 miles per second; but as the sun's distance from the earth is now known to be less

than it was supposed to be in his time, this estimate is too large.

As light advances from its source, it becomes weaker, though not in the ratio of the distance. If we take a board, *a*, a foot square, and place it at any distance from a candle, it will be found to

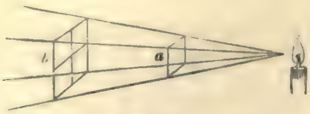

Fig. 2.

hide the light from another board, *b*, two feet square, at double the distance. Now, the latter board having four times the surface of the first, the light spread over it, when *a* is removed, must be four times weaker. Thus we say, when the distance is doubled, the intensity is one-fourth; similarly, when the distance is increased three times, the intensity is diminished nine times; and generally, in whatever ratio the distance is increased, the intensity is diminished in the square of that ratio.

This law is made use of in the construction of photometers, or instruments to measure the intensity of light. There are many varieties of the instrument, but the most convenient and extensively used is Bunsen's. A screen of white opaque paper, which can be moved backwards and forwards on a divided scale, has a round grease-spot in its centre. If a light is on the same side of the screen as the eye, the central spot appears dark on a white ground; but if the light is on the opposite side, then the spot is light on a dark ground. If, now, we have a light on each side of the screen, and if we shift the screen until the whole of it appears of one uniform tint, it is clear that the intensity of each light is as the square of its distance from the screen.

REFLECTION OF LIGHT.

When a ray of light, CD, falls on a plane and polished surface, as AB, it is bent back or reflected

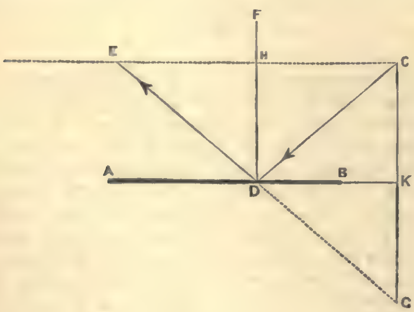

Fig. 3.

in DE, making the angle EDA equal to the angle CDB. If the surface is not plane, it is more convenient to draw the perpendicular DF, and then the angle CDF is equal to EDF, or the angle of incidence is equal to that of reflection. The truth of this law may be experimentally shewn by laying a plane looking-glass, AB, on a table, with its front all covered except a small patch at D, over which a plummet, FD, hangs. A candle-flame, C, is now placed just as high above the table as the eye of the observer is, and it will be found on trial that the only point where the flame is visible is a point, E, whose distance from the plumb-line is the same as C's.

If we draw the line ED backwards, and measure off DG equal to DC, then an eye anywhere in the line ED will see the light as if coming from G, which is therefore called the image of C. If we connect C and G by a straight line, meeting the direction of the mirror in K, it will be found that CG is perpendicular to AK, and that CK is equal to KG. Hence the following rule to find the position of the image of a luminous point formed by a plane mirror. Draw a perpendicular from the point to the mirror, and continue the line backwards its own length beyond the mirror; the extremity of the line is the image of the luminous point.

To trace the course of the pencil of rays by which any point of an object is seen after reflection. Let A be any point of the object; B, the image of A, determined as before. From B draw the diverging pencil of all the rays which can enter the eye at E, and let these rays meet the mirror in C. Join all the points of intersection of the rays at C with A; then the pencil ACE is that by which the point A is seen.

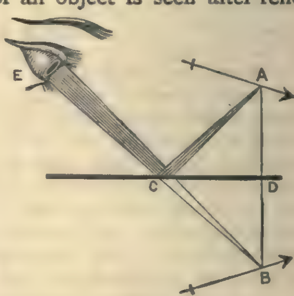

Fig. 4.

Since every point of an object has its own image just as far behind the mirror as the object is in front, the whole image must be of the same size as the object, and its position independent of the position of the eye. Suppose, again, AB to be a mirror, with an object, CD, of twice the length,

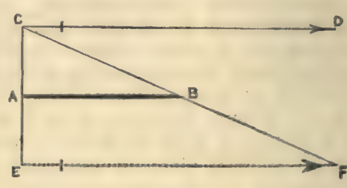

Fig. 5.

placed in front of it, and parallel to it, CA being perpendicular to AB; EF is the image; and being twice the length of AB, the direction, FC, in which an eye at C would see the point F, just passes through B. The whole of the image would therefore be seen from C. And this explains the fact, which puzzles many people, that a person can see himself full length in a mirror of just half his height.

Reflection at a Concave Spherical Surface.—The shape of such a spherical mirror resembles that of a watch-glass, silvered on the convex side, and

looked into from the other side. Let ACB be a section of such a surface through its centre, O. AB is called the aperture of the mirror; C, the

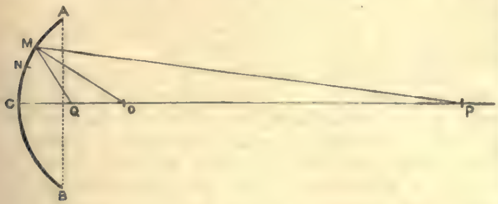

Fig. 6.

centre of the aperture; O, the centre of curvature; CO, the radius; and the line COP the axis. If PM be a ray coming from the luminous point, P, since MO is perpendicular to the surface at M, it will be reflected in MQ, making the angle OMQ equal to the angle PMO. Another ray coming from P, and striking the mirror at a different point, as N, will not be reflected exactly to Q, so that there is no exact image formed of the point P. The image is drawn out into a line, in which, however, one point is brighter than the rest: that point, namely, which is formed by rays striking near C. The farther the luminous point, P, is from the mirror, the nearer is this bright point to the middle of CO; and when P is so far off that the rays coming from it may be considered to have lost their diverging character, the bright point is exactly half-way between C and O. This point is therefore called the principal focus of the mirror, and the distance, CQ, is then called the focal length. It is clearly equal to half the radius. The indistinctness of the image, caused by all the rays not being brought accurately to one focus, is called the aberration of the mirror.

To explain the formation of images by such a mirror, let PQR be the object, AB the mirror, and O its centre. The brightest point on the image of

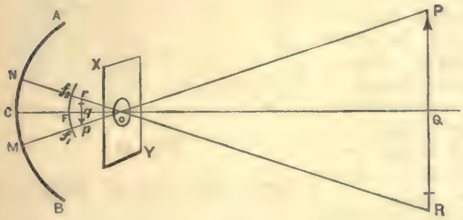

Fig. 7.

Q is *q*, rather nearer the centre, O, than F is, the middle of CO. Also for P, its principal image is in the line POM, at *p*, between O and f_1, the middle of OM. Proceeding in this way for all points of the object, PQR, we find the image, *pqr*, which we thus see is diminished and inverted.

It is to be observed also that the reflected rays actually pass through the image, which is called a real one; whereas, with a plane mirror, the reflected rays do not pass through the image, which is consequently called a virtual one. If the points P, Q, R, are in a straight line, their images, *p*, *q*, *r*, are not, so that the image of the object is curved. Again, of all the rays coming from P, it is only those striking the mirror in the immediate neighbourhood of M that are reflected to *p*, the rays falling more obliquely being reflected to different points. This produces confusion in the image, which, however, may be obviated by interposing a *diaphragm*, XY, to cut off all the indirect pencils. If we consider *pqr* as a small object, then PQR is its image, which is real, magnified and inverted, but is affected by the aberration, curvature, and confusion, as before. If the sun is the object in front of the mirror, then a small but bright image is formed at the principal focus. This explains the use of such mirrors as burning-glasses, where a parallel beam of light is made to converge to a focus. If a light is placed in the focus, then its rays are reflected in a parallel beam, and consequently such reflectors are used for lamps of coaches and light-houses. For convex spherical mirrors, the image is always virtual and diminished.

REFRACTION OF LIGHT.

It has been already mentioned that as long as rays of light are in the same medium, they travel in straight lines. If, however, the rays suddenly change their medium—for instance, if they enter water from air—their direction is suddenly changed, or they are refracted, unless they strike the bounding surface perpendicularly. In the diagram, let AB represent the ray travelling in air, and meeting the surface, CD, of the water at B. Its direction in the water is not BE, in the same line with AB, but BF, nearer the perpendicular, GBH. If we mark off equal lengths, BA, BK, in the two directions, and draw AG, LK, at right angles to GH, then

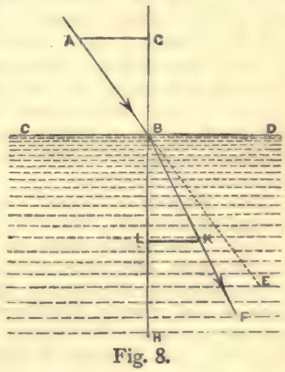

Fig. 8.

the exact law is expressed by saying that at whatever angle AB strikes the surface, the ratio of AG to KL is always the same. This constant ratio is called the index of refraction for the two media, and in the case of air and water is very nearly $\frac{4}{3}$, or LK is three-quarters of AG. If we suppose the motion of the ray reversed—that is, if it proceeds from water to air—it travels in the direction FBA, so that it is bent or refracted away from the perpendicular, GH. Thus the refraction is towards the perpendicular to the common surface if the second medium is the denser of the two, but away from it if less dense. Generally speaking, the greater the difference of density of the two media, the greater is the index of refraction. And if we take each medium with a vacuum, the index of refraction is then called the absolute refractive index. Inflammable media, if transparent, have high refractive powers; and Newton, observing the high refractive index of the diamond, conjectured that it would prove to be inflammable—a conjecture which has been subsequently verified.

The following simple experiments are well

known: Take an empty basin, and place it on a table; then lay a shilling at the bottom of the basin in such a position that the eye of the observer will just not see it. Now fill the basin with

Fig. 9.

water, and the shilling, though lying unmoved, will come completely into sight. The explanation of this phenomenon is, that the rays of light producing vision in the eye are bent on emerging from the water, and have all the effect of conveying our sight round a corner. In like manner, the refractive power of water is observable when we thrust a straight stick or instrument into it, on aiming at any object. We see that the stick seems to be bent, and fails in reaching the point which we desired it should. On this account, the aim by a person not directly over a fish must be made at a point apparently below it, otherwise the weapon will miss by flying too high. In the same way, objects at the bottom of a river appear higher up, or nearer the surface than they really are, by one-fourth of their actual, or one-third of their apparent depth. A pool which appears to be four and a half feet deep is in reality six feet deep, and fatal accidents have often happened from the ignorance of bathers on this point.

If the density of the medium changes gradually instead of suddenly, the rays are gradually bent, or curved. The rays by which we see celestial objects pass through the whole thickness of our atmosphere, which is of extreme tenuity in its highest parts, and of greatest density at the earth's surface, and consequently these rays are bent, as in the diagram. The direction in which they finally strike

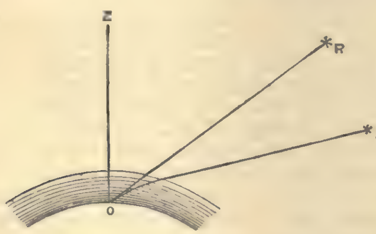

Fig. 10.

the eye of an observer at O is the line OR, and therefore a star, S, appears to be higher than it really is. If a star is right overhead, or in the zenith, as at Z, its position is not affected by refraction, as the rays by which it is seen fall at right angles on the surfaces which bound media of different density. For stars not in the zenith, the observed position must be corrected by subtracting the refraction, and this correction increases with the distance from the zenith, only much more rapidly. It is well known that when the disc of the sun or moon is seen near the horizon, it does not appear perfectly round, but seems longer from east to west than from north to south. This is because the southern limb is more raised by refraction than the northern one, while the eastern and western limbs are equally affected.

Twilight, or the gradual beginning and ending of daylight, is due partly to the refraction of the sun's rays by our atmosphere, but chiefly to their reflection in all directions by the atmospheric particles. If the atmosphere did not exist, we should have the darkness of midnight until the first streak of the sun's disc appeared above the horizon, and then suddenly this would be succeeded by broad daylight, for we learn in total eclipses of the sun that there is nearly full daylight as long as any portion of the disc is visible. But while the sun is still below the horizon, some of his rays striking the higher parts of the atmosphere are reflected downwards, and so reach the eye, and the more the nearer he is to the horizon; so that before sunrise we have all possible gradations of light, from the faintest glimmer to the full day.

It will now be evident that the directness of our vision is at all times liable to be disturbed by atmospheric conditions. So long as the atmosphere between us and the object at which we are looking is of the same density, we see as it were in a straight line to the object; but if by any cause a portion of that atmosphere is rendered more or less dense, the line of vision is not straight, or we see the object not in its true place. If the layers of air should increase in density from the earth's surface, then objects would appear lower than they really are. In the sandy plains of Africa, the intense heat of the soil at mid-day rarefies the air over it, so that the least dense layers are the lowest. Rays, then, from an elevated object, as A, are bent as in the figure, and a person at E will receive the ray as if it came from B. An inverted image of the object is thus formed, precisely as if it had been reflected from the surface of a lake. This optical illusion is called the *mirage*.

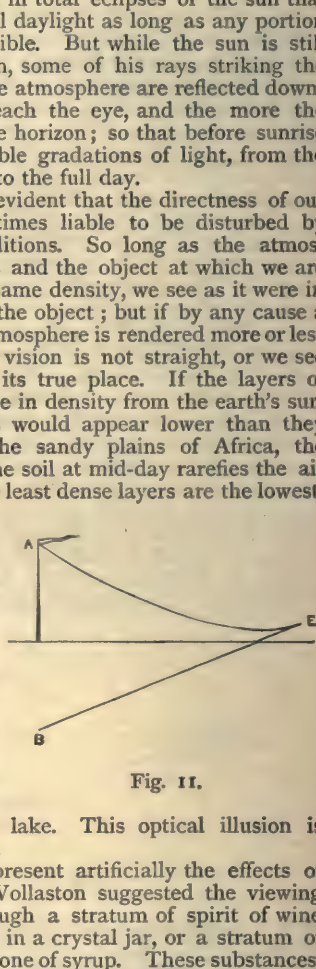

Fig. 11.

In order to represent artificially the effects of the mirage, Dr Wollaston suggested the viewing of an object through a stratum of spirit of wine lying above water in a crystal jar, or a stratum of water lying above one of syrup. These substances, by their gradual incorporation, produce a substance whose refractive power diminishes from the spirit of wine to the water, or from the syrup to the water; so that, by looking through the mixed or intermediate stratum at a word or object held behind the bottle which contains the fluids, an inverted image will be seen. The same effect, it has been shewn, may be produced by looking along the side of a red-hot poker at a word or object ten or twelve feet distant. At a distance less than three-eighths of an inch from the line of

the poker, an inverted image is seen, and within and without that, an erect image.

If the medium on which rays of light fall is bounded by two parallel faces, the rays, after passing through the plate, will be parallel to their direction before entering it, since the refraction at the one surface must be equal and opposite to that at the other. But if light falls on a refracting *prism*, it emerges in quite a different direction. Let ABC be the prism, say of glass,

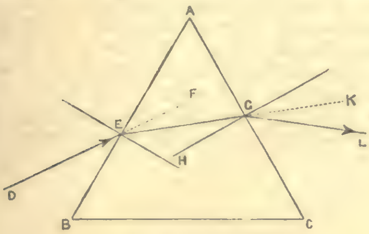

Fig. 12.

on which the ray DE falls; the direction within the prism is not EF, but EG, nearer the line EH, which is perpendicular to AB. At the second face, the ray is bent from the perpendicular GH, and takes the direction GL. By the refraction at both faces, the ray has been bent from the direction DF into GL, and the angle between these directions is called the *deviation* of the ray, which is always towards the thick part of the prism, and is proved, by a simple mathematical investigation, to be the least possible when the incident and emergent rays make equal angles with the faces of the prism.

If the refracting medium be bounded by curved faces, it is called a *lens*, and may have one or other of the following forms: A is called a double convex lens; B, convexo-plane, or plano-convex,

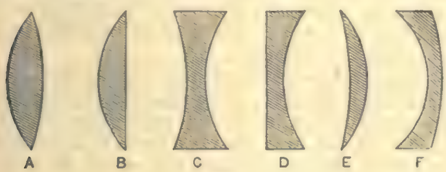

Fig. 13.

according as the light falls first on the one side or the other. C is a double concave; D, plano-concave; E, a meniscus; and F, a concavo-convex. They may be divided into two classes, according as they are thickest or thinnest in the middle; and they all, like the prism, deflect a ray of light towards the thick part. Therefore, a parallel beam of light, falling on one of these lenses, will be rendered converging or diverging, according as the lens belongs to the first or the second class. In fig. 14, the parallel rays are bent within the lens in the direction of the point A, but on emerging from the lens they are further bent, so that they converge to a nearer point, B. In the lower figure, the rays within the concave lens are bent as if they had come from C, and on leaving the lens, they seem to proceed from D. The points B and D are called the *foci* for parallel rays, or the principal foci of the lenses, and it is evident that B is a real, and D a virtual focus. The distance from the centre of the lens to the principal focus is called its focal length, and if the curvature of the two

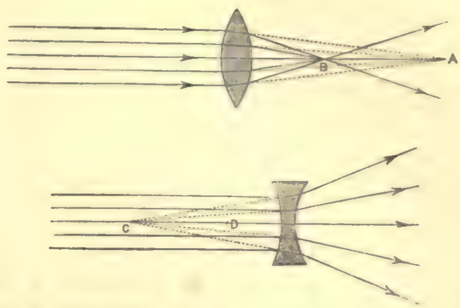

Fig. 14.

faces is the same, and both faces are spherical, this focus is at the centre of the sphere. As in reflection at a spherical surface, so likewise in refraction, rays at all distances from the axis are not brought accurately to one point, those falling on the lens near the edge being brought sooner to a focus than those near the axis. This drawing out of the focus from a point into a line is called the aberration of the lens, and might be partly remedied by covering up the parts near the edge, or those near the centre, with a stop or diaphragm. If a pencil of parallel rays falls obliquely on a lens, it is still brought very nearly to a focus, which is

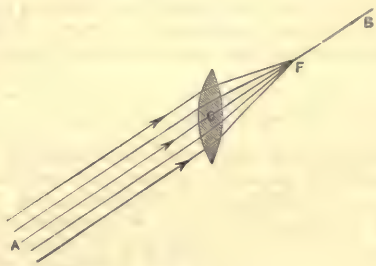

Fig. 15.

thus found. Take that ray, AB, of the oblique pencil which passes through C, the centre of the lens; the focus of the pencil lies in this line, at a distance, CF, from the centre equal to the principal focal length.

The effect of a lens thick in the middle, or convex, being to render a parallel beam convergent, it is easy to see that if a beam be already convergent, a convex lens will make it still more convergent; and if the beam be divergent, the same lens will diminish its divergency.

To understand how images are formed by lenses, let us take a double convex lens, and place an object, ABC, farther from it than F, its principal focus; all the rays coming from B, and falling on the lens, are refracted to some point, *b*, on the axis, neglecting the aberration, so that at *b* an image of the point B is formed. To find the image of A, draw a line from A through the centre of the lens, and the focus required is somewhere on this line, as at *a*, so that the rays falling on

the lens from A are all very nearly brought to a focus at this point. In this way each point of the object has its image thus formed, and

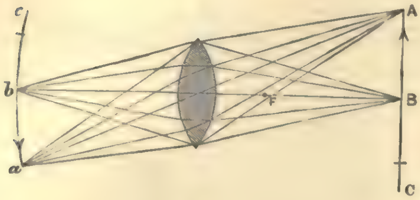

Fig. 16.

consequently an image of the object is produced, but inverted. The image is also slightly curved, as the points *a, b, c,* are not necessarily in a straight line. The relative size of the object and image will depend on the distance of the former from the lens. If this distance is twice the focal length, the size of the image is the same as that of the object; and if the distance be greater than this, the image is less than the object in the proportion of their distances from the lens. If the object ABC be the sun, the rays from it falling on the lens may be considered parallel, and therefore its image is formed in the principal focus. This gives us a method of practically finding the focal length of a lens. Receive the sun's image on a screen of ground glass, or tissue-paper, and by moving the lens or the screen backwards and forwards, with their plane always at right angles to the sun's rays, form as distinct and small a circle of light as possible: measure the distance of the lens from the screen, and this is the focal length of the lens.

THE EYE—VISION.

We can now understand the action of a lens in assisting imperfect vision. As mentioned in the article HUMAN PHYSIOLOGY, the eye, in front, consists of the *iris*, or variously coloured ring, which has the property of contracting or expanding to regulate the admission of light through the little dark spot in the centre called the *pupil*. Immediately behind the iris and pupil, there is a transparent substance resembling in shape a double convex glass, which is thence called the *crystalline lens*. The use of this lens is to collect and refract the rays of light, so that they may converge to a point beyond; in other words, cause them to fall on the back part of the eye, called the *retina*. Such are the main instruments of vision; and the sense of seeing is produced by certain nerves which convey intelligence of the image on the retina to the brain. If these nerves be injured, the image will still be pictured on the retina, but the mind will possess no power of recognising their presence.

It will be understood from these explanations that the main instrument of vision is the crystalline lens, which collects the rays, and brings them to a focus on the retina. If the lens be perfectly transparent, and of the proper convexity, the light is enabled to act with due effect on the retina, and the representation of the object looked at will be correctly pictured to the mind. But if the transparent coating of the eye be dull, or the lens be either too flat or too convex, every object will appear dim.

Two kinds of defective vision are more common than any other, and they are known by the name of *long-sightedness* and *short-sightedness*. Long-sightedness, or the power of seeing objects best at a considerable distance, is caused by too great a flatness in the crystalline lens and outer coating of the eye; and the deficiency of vision in old persons is usually from a similar cause. To remedy this defect as far as possible, artificial lenses of glass are employed. These lenses are called *spectacles*, and act in the manner we are now to describe. The following figure represents an eye in which the crystalline lens is too flat. CA is the cornea or outer covering, *b* is the crystalline lens, and *d* is the retina behind: B is the object looked at. We

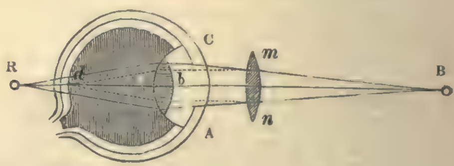

Fig. 17.

may observe, that in consequence of the flatness of the lens *b*, the rays proceeding from the object are not sufficiently refracted, but proceed to a focus as far back as R; in other words, the focus would be at R, if the retina would permit; but as the retina is in the way, the rays, from not being focalised upon it, cause imperfection in the vision. To remedy this, we interpose an artificial convex lens, or glass of a pair of spectacles, *mn*, and by its aid the rays—represented by dotted lines in the figure—are brought to a focus on the retina at *d*. Thus, by selecting spectacles of a proper focalising power in relation to the eyes, one kind of imperfect vision is very happily remedied.

Short-sightedness arises from a cause the reverse of that just alluded to, being produced by too great a degree of convexity in the crystalline lens and cornea. In this case the rays come to a focus too soon within the eye, and do not reach the retina, unless the object is brought quite close to the

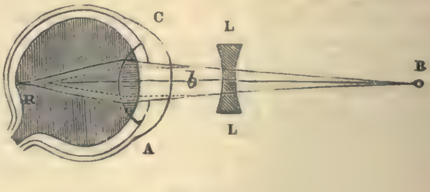

Fig. 18.

organs of vision. We here offer a representation of this condition. In consequence of the projecting globularity of the cornea, CA, and the too great refracting power of the crystalline lens, the rays from the object B fall short of the retina at R. To remedy this, we interpose a double concave lens, LL, by which the rays are rendered more

divergent before they reach the eye, and are brought to a focus, where they should be, on the retina.

We have said above, that in short-sighted persons the rays do not reach the retina unless the object is held close to the eyes. The effect produced by this is similar to that of employing concave spectacles; because the nearer we hold an object to our sight, the angle of the rays from it is the wider; the rays are more expanded before they enter the eye—that is, more divergent. Thus the extreme rays from a point to the pupil of the eye make a greater angle at *o* than those from a point of a more distant object make at *a*; that is, the rays from *o* are more divergent on entering the eye than the rays from *a*, and thus nearness of an object is equivalent to seeing it at a greater distance through a concave lens. So when the object *a* is further distant than *o*, the rays from *a* have a less divergence, which is equivalent to viewing it at a nearer distance with a convex lens. Long-sighted persons must therefore diminish the divergency of the rays falling on the crystalline lens, and this they can do either by holding the object at which they are looking at a greater distance, or by using convex spectacles. Short-sighted persons can, to some extent, remedy their defective vision by partially closing the eyes. The effect of this partial closure is to cut off those rays which would pass through the marginal parts of the lens, and which principally cause the confusion and indistinctness of their vision.

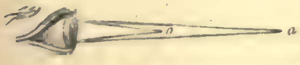

Fig. 19.

We think it unnecessary to discuss the questions why, having two eyes, we should see objects single, and why we should see objects erect, when their image on the retina is inverted, as these questions belong more to physiology and the science of mind than to optics.

DISPERSION OF LIGHT BY REFRACTION.

If the ethereal waves whose motion constitutes light were all of the same length—in other words, if light were homogeneous—refraction by prisms and lenses would be as we have described it. But when a small beam of sunlight falls on a prism, the refracted beam is not white, but is split up into a number of coloured beams. The experiment which was devised by Newton may be thus performed. In the shutter, AB, of a darkened room, a small hole, C, is made, to give entrance to a small pencil of sunlight, CD, which, if uninterrupted, would proceed in a straight line to E, and form a white spot, or image of the sun. A prism, FGH, is interposed in the path of the beam, and a screen is placed to receive the pencil emerging at K. The sun's image formed on the screen, instead of being a circular spot, is now a narrow oblong, whose width is the same as the diameter of the spot, but length many times greater. Also this stripe is coloured throughout its whole length, being red at the lowest part, R, and the colours shading imperceptibly through orange, yellow, green, blue, and indigo, to violet at V. This experiment proves that sunlight is a mixture of light of different colours and of different refrangibilities. If we make a hole in the screen at R, so as to allow only the red rays to pass through, and then place a second prism in their path, we find that they are incapable of further subdivision, and so for all the other colours. Also, if we look at the coloured stripe, or *spectrum*, as it is called, through another prism, like FGH, and placed similarly to it, all the colours are re-combined into white, and the circular image of the sun is again seen. In order that the colours of the spectrum may be pure, it is necessary, first, that the deviation should be the least possible; and secondly, that the aperture in the shutter should be small. The first condition is satisfied by turning the prism till the beam leaves the second face at the same angle as it strikes the first; or, more simply, till the spectrum occupies the lowest position on the screen possible. The necessity of the second condition will be obvious, if we consider that in a wide aperture, the highest and lowest rays will each depict its own spectrum on the screen, and that the red or orange of the lowest spectrum may overlap the orange or yellow of the highest.

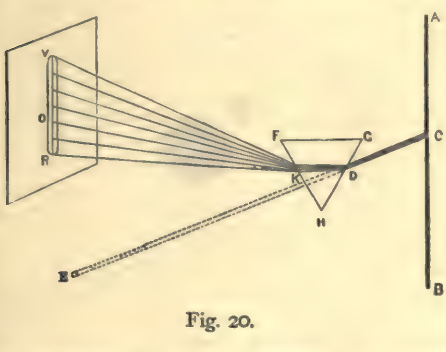

Fig. 20.

To explain the production of coloured fringes when an object is looked at through a prism or lens, let us suppose that each point of the object sends out rays of all colours. As the red rays are least refracted, there will be a red image of the object AB formed as at *ab*, and a violet one at *ef*, the other coloured images being intermediate in position. Between *e* and *b*, all the colours will be mixed in the proper proportion to form white light; and an eye at E will see the image colourless from *e* to *b*, but red predominating in *ae*, and blue in *bf*. If we vary the material of the prism, by taking, for instance, a prism of dense flint-glass, instead of one of crown-glass, we find the length of the spectrum considerably altered, and the proportions of its different parts to be no longer the same as before. Not only has flint-glass a higher dispersive power than crown-glass, but it disperses the violet end of the spectrum in a higher degree than the red end. All spectra produced by refraction are therefore said to be *irrational*. If the dispersion were always proportional to the refraction, any bending

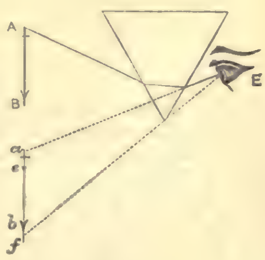

Fig. 21.

of light would always be accompanied by the production of colour, and an *achromatic* lens, or lens producing a colourless image, would be impossible. But, by opposing a glass which bends five degrees and disperses one degree to another glass which bends three degrees and disperses one, the opposing dispersions will counterbalance each other, and the refracted beam will be colourless. It is on this principle that achromatic prisms and lenses are made. The two prisms, A and B,

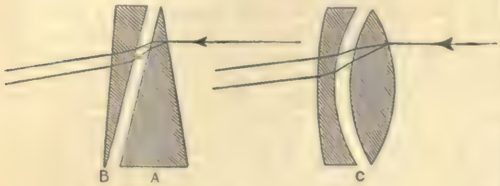

Fig. 22.

though drawn as separated from each other, are firmly fastened by a colourless cement; A is of crown-glass, and B of flint-glass, and the angle of B is so adjusted that the higher dispersive power of flint-glass is counterbalanced by the thinness of the prism, and a beam of white light passing through the combination will be deflected, but not decomposed into coloured beams. The action of the achromatic lens, C, is precisely similar; but from what has been said of the irrationality of the spectrum, no combination of prisms or lenses can be truly achromatic. The most that can be effected is to bring together any two rays of the spectrum.

When a pure spectrum of solar light is attentively examined, and especially with a magnifying eyeglass, it is seen to be crossed by many black lines; and with the same prism, these lines occupy a fixed position. Dr Wollaston, in 1802, was the first to observe and describe these lines; but Fraunhofer, an optician of Munich, rediscovered them in 1814, and published a beautiful map with the positions of many of them accurately marked. Fraunhofer discovered also that dark lines existed in the spectra of many different kinds of light, and that the lines of the spectra of the planets and of the moon were the same as those of the solar spectrum, while the spectra of the fixed stars were all different. If the source of light be a solid raised to a white heat, a spectrum is obtained without any dark lines, which is therefore continuous from end to end; if the source of light be a burning vapour, there is a remarkable change in the spectrum. Instead of being either continuous or crossed by dark lines, it consists now of one or more bright lines, which may be differently coloured. The instrument by the aid of which these phenomena may be most conveniently studied is called the spectroscope, and consists essentially of, first, an illuminated slit, from which parallel rays of light proceed: secondly, a prism or train of prisms, to separate the differently refrangible rays; and thirdly, a telescope, to view a magnified image of the spectrum produced. The following figure represents a section of the instrument in its

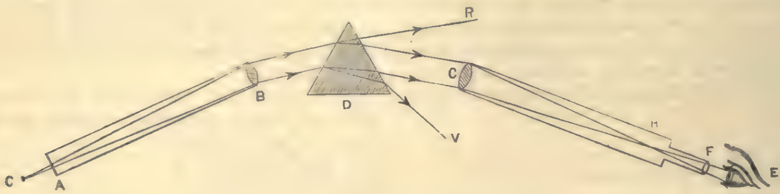

Fig. 23.

simplest form. AB is a brass tube, carrying at one end, A, a metal piece with a slit, whose width can be regulated by a fine screw, and at the other end, a convex lens, B. The source of light, C, is in the focus of the lens B, so that parallel rays fall on the prism D, by which they are scattered into the coloured beam, RGV. The telescope, FG, is movable in the plane of the figure, so as to describe part of a circle round the prism as centre, and it can therefore be directed at will to any part of the spectrum from R to V. The rays, such as G, which fall on the lens G of the telescope, are brought to a focus at H, where a distinct image of this part of the spectrum is formed. This image is in the focus of the eyeglass, F, so that an eye placed at E sees it magnified. If the part of the circle round which the telescope travels is graduated, and furnished with an index or vernier, the exact position of the telescope at any time can be read off. But a simpler plan than graduating the circle is to throw the image of an illuminated transparent scale to the focus, H, of the object-glass, G, so that the images of the scale and spectrum are seen at the same time. This is easily and ingeniously accomplished, thus: a glass circular disc, S′, has a small scale engraved in the direction of a diameter, and all the rest of the disc

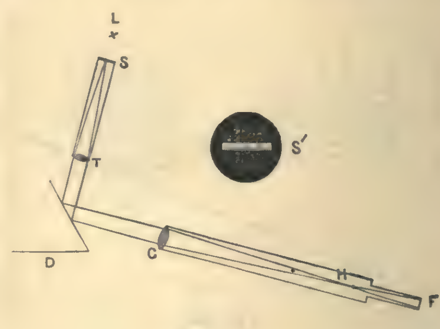

Fig. 24.

is blackened. This disc is fitted on to one end of the tube ST at S; and at the other end is a lens, T, whose focal length is just the length of

the tube. The scale, S, is illuminated by a light, L, placed behind it; and by slightly drawing out or pushing in the cap to which the scale is attached, the rays are made to emerge from the lens T, so that, after being reflected by the face of the prism, they are focused at H. Of course the direction of the scale-tube and that of the telescope must be equally inclined to the reflecting face of the prism, and therefore the former is movable round the same centre as the telescope, and in the same plane. The next figure gives a view of a complete two-prism spectroscope, and the use of its various parts will be readily understood.

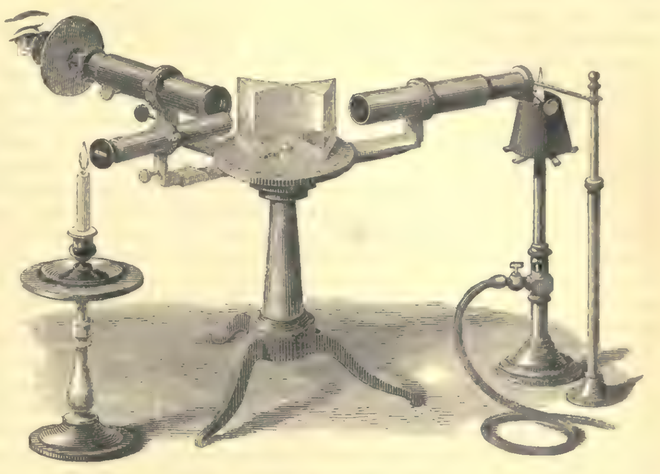

Fig. 25.

When the solar spectrum is examined with such an instrument, the positions of the dark lines are as shewn in fig. 26; but a more powerful instrument reveals the existence of several thousands. Fraunhofer mapped 576, and designated the principal ones by the letters A, B, C, D, E, F, G, H, by which designations they are still known. Their positions are determined either by stating the index of refraction for each line, or, which amounts to the same thing, the length of the ethereal wave which produces each ray. The latter method is preferable, as being independent of the nature of the prisms employed; thus the wave-lengths which would produce rays at A and the first thick line of the group H are respectively 7604 and 3968, the unit being the thousand-millionth part of a mètre. Suppose, now, our source of light to be an incandescent gas or vapour, which may be effected by exposing a substance to a heat which first volatilises it and then burns the vapour. The pale flame of a Bunsen gas-lamp will serve to volatilise and burn many substances. We find that not only do the spectra consist of isolated bright lines, but that each substance has a line or set of lines peculiar to itself. Burning sodium vapour gives two bright lines identical in wave-length, and therefore, when using the same prism, in position with the two dark lines, D, of the solar spectrum. When the electric spark is passed through a closed tube containing hydrogen, three bright lines, exactly corresponding to C, F, G, are obtained. So certain are the results, that after we have mapped the bright lines of each substance, we can tell, on looking at

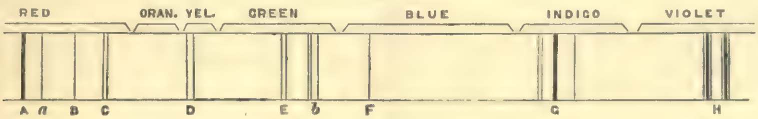

Fig. 26.

any such spectrum, what the burning substance must be. If two or more different bodies be burning together, the different sets of lines are seen at the same time, and no line of any one set interferes or coincides with a line of another. It will now be seen how readily this method lends itself to chemical analysis, for if in the spectrum of any compound substance we observe the lines of a particular element, we are certain that that element exists in the compound. And so delicate is this mode of analysis, that if a single grain of soda be dissolved in 2500 gallons of pure water, it can be infallibly detected. Again, if we find in a spectrum bright lines that have not previously been observed, they indicate the presence of a new element. In this way, Bunsen discovered the two new elements, cæsium and rubidium; Crookes, thallium; and Reich and Richter, indium. The connection between the dark lines of the solar spectrum and the bright lines of the elements was first shewn clearly by Kirchhoff in the year 1859. By allowing sunlight to enter one half of the length of the slit of his spectroscope, and the light from a sodium flame the other half, he not only shewed that the dark lines, D, of the former coincided perfectly with the bright lines of the latter—a fact which had frequently been asserted before—but he went much further. Having the continuous spectrum of the lime-light in one part of the field of view of his telescope, and the two bright lines from burning sodium immediately above it, he found that when the lime-light shone *through* the burning sodium vapour, the two bright lines were instantly converted into two dark lines in the very same place. He explained this by supposing that burning sodium vapour which could emit light waves of a certain length, could also absorb precisely those waves, when waves of all lengths were sent through it. He found the same thing to hold for many other substances which he tried, and was

led to enunciate the important law, that *all bodies which at a certain temperature can emit light rays of a certain class, can also absorb the same rays at that temperature.* The rays which are absorbed must have come from an incandescent solid or liquid at a higher temperature than the vapour. From this law it at once follows, that dark lines in a spectrum are produced by absorption, and that the position of the dark lines indicates what must have been the absorbing vapour. Now, when iron is volatilised and burned in the electric light, its spectrum is found to consist of several hundred bright lines, and Kirchhoff had mapped 460 of these. He also found that for every one of these bright lines, a dark line corresponded exactly in the solar spectrum. Hence the conclusion was inevitable, that the sun's light must have passed through vapour of iron, and that this iron must exist either in the sun's atmosphere or in that of the earth. The latter supposition cannot be correct, else the spectra of all the stars should contain the iron absorption bands, which they do not; therefore we are driven to the conclusion that iron exists in the sun's atmosphere. In the same way it is found that many of the chemical elements with which we are familiar on the earth's surface exist also in the sun. In addition to iron, there are found copper, zinc, nickel, magnesium, hydrogen, sodium, cobalt, and several others; but not gold, silver, lead, mercury, antimony, or potassium. The spectroscope has also revealed to us something of the chemistry of the stars and of the far-distant nebulæ; we have convincing evidence that the fixed stars are burning suns, somewhat like our own, but each surrounded by its own absorbing atmosphere. Thus Aldebaran, the brightest star in the constellation of Taurus, is known to contain sodium, magnesium, hydrogen, iron, and some other terrestrial elements; while Betelgeux, a bright star in the shoulder of Orion, contains sodium, magnesium, and iron, but not hydrogen.

THE TELESCOPE.

By means of a concave mirror, or a lens, the image of any object can be formed; and the size and position of the image depend on the distance of the object, and the focal length of the mirror or lens. If the object be at a great distance, the image is formed at the focus, and is of less actual size than the object, although it is seen subtending the same angle by an eye at the centre of the mirror or lens. It is thus impossible to have an enlarged image of a distant object by means of a single mirror or lens; but the image near the eye can be magnified by using a magnifying lens or eye-glass. This is the simple principle of the *telescope*, or instrument for *seeing at a distance.* The telescope is a *reflecting* or a *refracting* one, according as the image is formed by reflection from a polished surface, or refraction through a lens. Let O and *e* in the diagram be the centres of the object-glass and eye-glass, which are supposed to be mounted in cylindrical tubes, that of the eye-glass sliding within the other, so that the distance of the lenses may be slightly varied. The line joining O*e* is called the axis of the telescope. If the axis of the telescope be directed to the centre of a distant object, the parallel rays from the upper part of the object, after refraction by the lens O, are brought to a focus at the point *a*, O*a* being the focal length of the lens. An inverted image, *ab*, of the object is thus formed; and if this image be in the focus of the eye-glass, *e*, the rays from every point of it, as *a*, will, after refraction, emerge parallel to *ae*, and will be fit for vision by the eye at E, which will thus see the

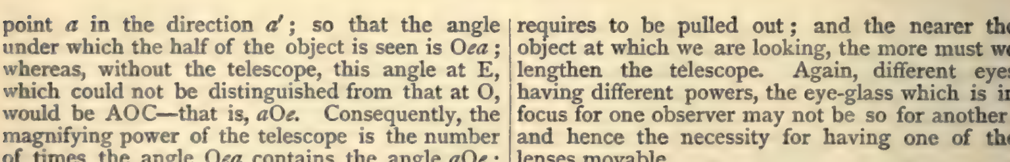

Fig. 27.

point *a* in the direction *a'*; so that the angle under which the half of the object is seen is O*ea*; whereas, without the telescope, this angle at E, which could not be distinguished from that at O, would be AOC—that is, *a*O*e*. Consequently, the magnifying power of the telescope is the number of times the angle O*ea* contains the angle *a*O*e*; that is, without sensible error, the number of times the line O*a* contains the line *ea*, or the number of times the focal length of the object-glass contains that of the eye-glass. Suppose, for instance, the object-glass had a focal length of 5 feet, and the eye-glass of 1 inch, the magnifying power would be 60; that is, a line would appear 60 times longer, a surface 3600 times greater, and a solid 216,000 times greater. If the distance of the object from the telescope be not great enough to allow us to consider the rays coming from a point in it parallel, the image is formed at a distance from O, a little greater than O*a*, and the eye-tube requires to be pulled out; and the nearer the object at which we are looking, the more must we lengthen the telescope. Again, different eyes having different powers, the eye-glass which is in focus for one observer may not be so for another; and hence the necessity for having one of the lenses movable.

To find the *field of view* of the telescope, let us draw a straight line from O to *d*, the extreme edge of the eye-glass, cutting the image in *b*. Then of all the rays falling on the object-glass, and converging to *b*, to form this point of the image, the half (namely, those passing through the lower half of the object-glass) will pass above *d*, and the eye will see the point *b* by half-pencils of light. Taking this as the boundary of the field of view, the angular diameter of the field is twice the angle *d*O*e*; that is, the angle under which the eye-glass would be seen from the centre of the object-glass. As the telescope just described

gives inverted images of objects, it is well enough adapted for celestial observations, in which this inversion is of no moment, but not at all for terrestrial observations. But by introducing a convex lens, or more frequently a combination of convex lenses, to produce an inverted image of the first image, and then magnifying this by a suitable eye-piece, the terrestrial telescope is produced, which is called an achromatic one, if the object lens be achromatic.

The reflecting telescope differs from the refracting, primarily, in having the image formed by reflection from a concave mirror; and secondarily, in requiring an arrangement for throwing the image out of the axis of the telescope, as the head of the observer, being on the same side of the mirror as the object, would obstruct the light. In the Newtonian reflector, a small plane mirror is placed in the axis of the telescope, at an angle of 45° with it, and rather nearer the mirror than its principal focus. The rays from a distant object, only a small number of which are obstructed by the plane mirror, are reflected by the large mirror, so that they would form an image in its principal focus, but striking on the small mirror, they are turned through a right angle, and the image is formed at the side of the tube. The tube is perforated at this place, and a small tube carrying the eye-glass is inserted at right angles to the large tube. As each reflection is attended by a partial loss of light, Sir William Herschel dispensed with the small mirror, by slightly tilting the large mirror, as at *mn* in the diagram,

Fig. 28.

and thus throwing the image to the side of the tube at *a*, where the eye-tube is placed. In both forms of the reflecting telescope, the magnifying power and the diameter of the field of view are calculated exactly as in the case of the refractor; but for all telescopes, they may be found experimentally, and with sufficient accuracy, as follows. Look with one eye through the telescope at an equally divided scale, placed at a distance (a brick-wall will generally suffice), and count the greatest number of divisions visible; then, with the other eye looking along the telescope, count the number of divisions in the same length: the number of times this latter number is contained in the former is the magnifying power in diameters. For the field of view, select from an atlas of the stars, or a celestial globe, a star which is on the equator, or nearly so; and directing the telescope to it, find how many seconds it takes to traverse the widest part of the field; then each second of time will correspond to 15 seconds of arc. For example, if the star remains visible for 60 seconds, the diameter of the field of view is 900 seconds of arc, or quarter of a degree.

THE MICROSCOPE.

The microscope, or instrument for viewing small objects, may be either simple or compound. The simple microscope consists of a single convex lens, of short focal length, which magnifies an object by enabling the eye to view it at a less distance than it could do without the lens; and its magnifying power is the number of times its focal length is contained in the least distance of distinct vision, which is, on the average, about ten inches. Thus, a quarter-inch lens will magnify about 40 diameters. The compound microscope consists essentially of an object lens, or combination of lenses to form a magnified image of the small object, and an eye-glass to magnify this image, as in the telescope. An additional lens, called the field-glass, is, however, always introduced between the other two, for a reason that will now be explained. Let *pq* be the minute object placed in front of the achromatic combination, A, which acts like a single lens. The pencil of rays diverging from *p* would be brought to a focus at *p'*, the line *pp'* passing through the centre of A; but the field-glass, F, being interposed, the pencil is brought more quickly

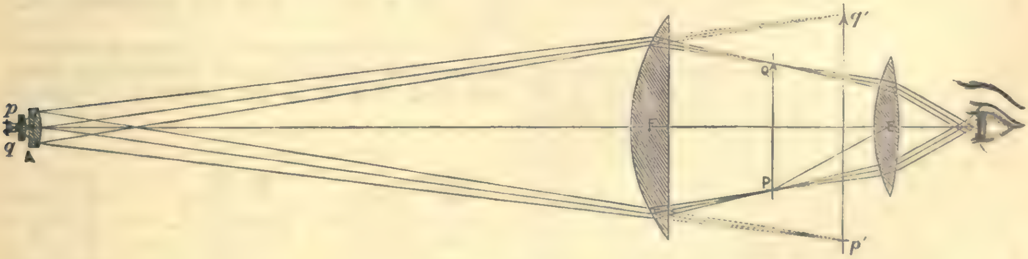

Fig. 29.

to a focus at P. Similarly, the pencil from *q* is brought to a focus at Q instead of *q'*, and an inverted image, PQ, is formed of *pq*. The image PQ being in the focus of the eye-glass E, a pencil from any point of it emerges from E parallel to the line joining the point with E, and the eye sees a highly magnified image in this last direction. The use of the field-glass is thus to cause the pencils, by which each point of the image is formed, to converge to the axis of the microscope, so that a more manageable eye-piece can be used. The magnifying power of the microscope is that of the combination, A, multiplied by that of the eye-glass, E, if we neglect the small diminution caused by the field-glass. If the distance, A*p'*, be 12 inches, and A*p* the sixth of an inch, the image *p'q'* is 72 times the size of *qp*. And if the magnifying power of E be 10, the

microscope magnifies 720 diameters. Good instruments are usually furnished with three eyepieces of different powers, and five or six object combinations, of focal lengths varying from one inch to the twelfth of an inch (or less), so that magnifying power may range from 20 to 2000 diameters.

INTERFERENCE, DOUBLE REFRACTION, AND POLARISATION OF LIGHT.

Interference.—Suppose that in consequence of a disturbance, a series of *up-and-down* waves is propagated through an elastic medium, and that, from a second disturbance, another set of the same wave-length is also propagated through it; it is easy to see that the total disturbance at any point will depend on the state or *phase* in which each wave reaches it. If the crests of both waves reach the point at the same time, it will be displaced through a distance equal to the sum of the separate displacements; and as both waves travel at the same rate, the effect is the same as if one set of larger waves were passing. But if the crest of the first wave should reach the point along with the hollow of the second, the total displacement is the difference of the two; and if these are equal, the point remains at rest. In these cases, the waves are said to *interfere* with each other; and we see that one wave will absolutely destroy an equal one, if their phases differ by half a wave-length, or a length and a half, two and a half, &c. As light consists of waves, it should be possible for two lights to produce darkness, and this strange conclusion has been established by direct experiment. Let A and B be two small holes, very close together, in the shutter of a darkened room, through which a homogeneous light is

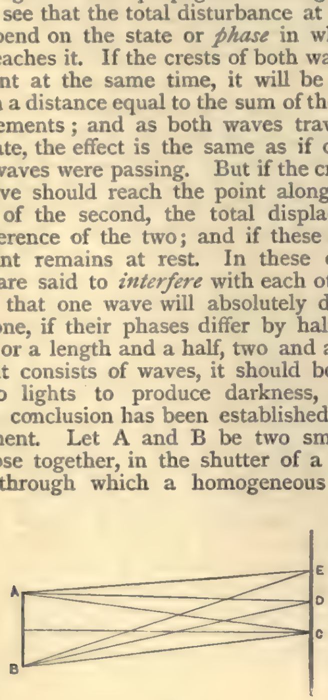

Fig. 30.

admitted. If a screen, of which EC is the section, be held at a suitable distance to receive the diverging pencils, it will be found that the intensity of the light in EC is not uniform, but that there will be a bright spot at C, which is equally distant from the two holes, a dark spot at D, a white spot at E, and so on. These spots on the section EC are of course bands on the screen; and if one of the holes, as B, be stopped, the bands suddenly disappear; if it be opened again, they reappear. Thus, the addition of more light to D has caused darkness. By careful measurement, it has been found that the difference between the paths AD and BD is half a wave-length; between AE and BE, two halves; and so on. If the compound light of the sun be used, the blue, which has the smallest wave-length, occupies a different position at E from the red, whose wave-length is greatest; and the other colours lie between. There is thus a coloured band at E, with the blue lowest; and these bands are repeated until the colours of one band are mingled with those of the next, and the screen is white.

Double Refraction.—If a ray of light be allowed to fall on a rhomb of Iceland spar, instead of being refracted as in glass, it is split up into two rays of equal intensity, one of which obeys the ordinary law of refraction, and the other does not. This property of double refraction belongs to all crystallised minerals, except those of which the cube is the fundamental form, or, more generally, to all bodies whose density differs in different directions. Thus, a cube of glass can be made to refract doubly, by compressing it strongly in one direction. The two rays into which the single one has been split up do not at first seem to differ from each other, or from common light; but if they be allowed to fall on a second rhomb, a remarkable difference is observed. If, for shortness' sake, we designate the ordinary and extraordinary rays by the letters O and E, we find that though in general both O and E are split up into two others, OO, OE, EO, EE, the two components are no longer of the same intensity, and that in certain relative positions of the crystals, one disappears altogether. If the two crystals are in similar positions, O produces only OO, OE having quite disappeared, and E produces only EE, EO having disappeared. If the second crystal be turned through 90°, OE and EO alone remain. Thus, not only have the two rays, O and E, acquired properties with respect to space (that is, got *sides* or *poles*), but these properties are the same for the two rays with respect to two planes at right angles to each other. The two rays are said to be polarised, and their planes of polarisation are perpendicular to each other.

Polarised Light.—Some crystals, after separating the two rays, absorb one of them, as tourmaline, which suppresses the ordinary ray. There are other ways of obtaining one ray without the presence of the other, but this method will be assumed for simplicity. If we wish to examine any pencil of light to ascertain whether or not it is polarised, we must use a double refracting rhomb, or such an analysing plate. If we find that in a certain position of the analyser, one ray is extinguished, the beam was wholly polarised; but if the intensity was only weakened, then the polarisation was partial.

Some of the most splendid phenomena in optics are produced when bodies are examined by polarised light. Let T be the polariser, a plate of

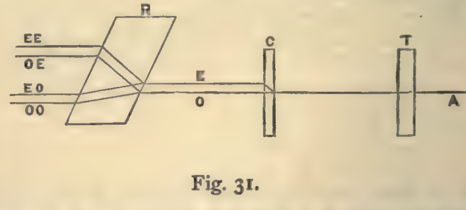

Fig. 31.

tourmaline cut parallel to its axis; R, the analysing rhomb; and C, a doubly refracting crystal, which we are examining. A ray of common light, A, after passing through T, is polarised, its companion ray having been quenched. B is split up by C into E and O, polarised at right angles to each other, and differing in phase, E being retarded more than O. If E and O were common light, they

would interfere with each other, but light polarised in one plane cannot interfere with that polarised in the plane perpendicular to it. On passing through the analyser, R, the two rays, O and E, are subdivided into four, as in the figure; the two, EE, OE, which emerge together, being polarised in the same plane, which is at right angles to the plane of the other pair, EO, OO. As the members of a pair are in different phases, they will interfere with each other, and colours will be produced by one pair which will be the same as would be produced by the other pair if their plane could be turned through 90°; or, in other words, the colours of one pair are complementary to those of the other. If the analyser be made to revolve round the line AB as an axis, all possible gradations of colour are produced. The phenomena of polarised light have proved that the waves of light are not backward and forward waves, like those of air, but transversal —that is, up and down, like waves of water, or from side to side. The polarisation of light is the resolution of the vibrations of each particle into two, at right angles to each other, which produce waves travelling in different directions. If one of these can be isolated from the other, the light is said to be polarised.

SOUND.

Sound (Latin, *sonitus;* French, *son;* German, *schall*) is the name given to the sensation produced in the organs of hearing by the vibrations of the air or other elastic medium with which they are in contact. The name is also applied to the physical cause of the sensation; and that branch of Natural Philosophy which treats of the laws of sound is called Acoustics, from a Greek word meaning *to hear*.

That the existence of an elastic medium is necessary for the production of sound, is proved by the fact, that a bell rung in the exhausted receiver of an air-pump cannot be heard. But many other substances besides air can convey sound. Divers below water can hear even a very feeble sound if it is produced under the water. And it is well known that bars of wood and metal transmit sound with great distinctness. If the ear be placed at one extremity of a long piece of wood, it will readily hear a slight tap made at the other end, much too feeble to be conveyed the same distance by the air.

Air, however, is the medium by which sound is generally conveyed to the ear, and the rate at which sound travels in air can be easily ascertained in the following manner. Let a cannon be fired at a considerable distance from an observer, who counts the number of seconds between the time of his seeing the flash and his hearing the report. The velocity of light is so inconceivably great, that we may, without appreciable error, suppose that he sees the flash at the very instant it is produced. The number of seconds is therefore the time that sound takes to travel the distance between the cannon and the observer, and if this distance be measured, the velocity of sound in air is determined. It has thus been found to be in dry air at the freezing-point about 1082·7 feet per second, or rather less than 12½ miles a minute; but the rate depends slightly on the temperature of the air, being greater as the temperature is higher. Thus, at 59° Fahrenheit the velocity is 1112·2. Again, when we know the rate at which sound travels, and the time it has taken to reach our ear, we can find the distance at which it was produced. For instance, if, after seeing a flash of lightning, we count 3½ seconds before hearing the thunder, we know, if the temperature of the air at the time is 59° F., that the discharge has taken place at a distance of 3½ times 1112·2 feet, or 3892·7 feet. It is evident that it cannot be the same particles of air that are set in motion by the sounding body which strike the ear to produce the sensation of sound, for this would require the air particles to be transported at the rate of 12½ miles a minute, or 750 miles an hour, which is six times faster than the rate of the most violent hurricane that ever blows. The motion is a vibratory one, so that the disturbed particles move backwards and forwards through a small distance, and similarly disturb the neighbouring particles. This is a wave-motion, in which the displacement of each particle is in the direction in which the wave travels, whereas in waves on the surface of water, and in the ethereal waves which constitute light, the particles move at right angles to the direction in which the waves travel. Sound-waves are therefore waves of condensation and rarefaction. And the distance between one point of greatest condensation and the next, is the wave-length. The range through which each particle moves backwards and forwards is called the amplitude of the vibration, which is quite independent of the wave-length. The extent of this range will manifestly be increased, if the exciting cause of the atmospheric disturbance be greater, and the intensity or loudness of the sound will be greater. Thus, if all other conditions remain the same, the loudness of sound is measured by the amplitude of the vibration, and is proportional to the square of this amplitude, so that a double amplitude gives a fourfold intensity. When a series of waves is propagated from any point, the amplitude diminishes in the same proportion as the distance increases, and thus the intensity of sound diminishes as the square of the distance increases.

The air-waves which produce the sensation of sound are excited by delivering a blow, or a series of blows, to the air. If a bell be struck by a hammer, its particles are thrown into a state of vibration, as we may convince ourselves by lightly applying our finger to the edge, and the vibrating particles give rapid blows to the air, and thus produce sound-waves, which are propagated in all directions. In this case, the sound is *musical;* but if a table be struck by the hammer, its vibrations cease almost immediately, and a single sound or *noise* is the result. Thus we see that a musical sound is produced when a definite noise is repeated often enough at equal intervals of time. This statement may be verified by holding the edge of a card so that it may be struck by a revolving toothed wheel. When the wheel revolves slowly, a series of noises is produced; but when it revolves so fast that the noises melt into a continuous sound, a musical note is the result. Further, the pitch of this note is higher, the faster the wheel revolves; and if the speed can be sufficiently increased, the pitch becomes too high for the ear to appreciate, and the notes become inaudible. There

is also a lower limit below which grave sounds cannot be heard, and although these limits will be different for different ears, still, for the average ear, only those sounds are audible which are made by more than 32, and less than 72,000 vibrations per second.

Like waves of light, sound-waves can be reflected by plane and curved surfaces, and also refracted by suitable lenses. When the sound-waves are reflected by a plane surface, such as a smooth wall or the flat face of a rock, an *echo* is produced, if the reflecting surface be at a sufficiently great distance. The necessity for this proviso may be thus shewn. However short a time a sound may last, the impression it produces on the ear remains a perceptible time, which is about the tenth of a second; so that, if two sounds follow each other in less than the tenth of a second, they interfere with each other. In the tenth of a second, sound will travel, at ordinary temperatures of the air, about 111 feet; and if the reflecting wall be less than 55½ feet distant from the point whence the sound proceeds, there will be less than the tenth of a second between the time of the original sound leaving the point, and the reflected sound returning to it, and a confusion of sounds is produced with no echo. It is this confusion of sounds that interferes with hearing in churches, lecture-rooms, and other large buildings that are not built on acoustical principles. A partial remedy for the defect consists in weakening the reflection by destroying the evenness of the surface, as by suspending curtains at intervals along the walls. If the wall is exactly 55½ feet distant, there is just sufficient time between the production of the sound and the arrival of the echo for the ear to discriminate them as two separate sounds, so that an echo cannot be distinctly heard unless the reflecting surface be at a distance not less than 55½ feet. The number of syllables that an echo can repeat is the number that can be pronounced in the time that sound takes to travel to and from the reflecting surface. The celebrated echo at the tomb of Metella, wife of Crassus, near Rome, was said to have repeated distinctly the first line of the *Æneid*, which contains fifteen syllables. If we allow three seconds as the time necessary to repeat this line distinctly, the reflecting surface must have been at a distance of 1668 feet. If the sound, after being once reflected, is reflected a second time, a double echo is produced; and if the reflecting surfaces be many, there is a multiple echo. One of the most interesting echoes of this kind is that which occurs on the banks of the Rhine, at the Lorlei rocks. If the weather be favourable, the report of a pistol fired on one side is repeated from crag to crag on opposite sides of the river alternately, for as many as ten or twelve times. At the château of Simonetta, in Italy, an echo between two parallel wings of the building repeats a sound thirty times. In whispering-galleries, a feeble sound made at one particular part of the building is repeatedly reflected from the smooth walls, and many of the reflected waves finally converge to another point where the sound is distinctly heard. In the dome of St Paul's Cathedral in London, a whisper at one side is heard at the other, though at all intermediate places it is quite inaudible.

That the sound-waves are refracted in passing obliquely through a medium denser than air, is clearly proved by the following experiment, first performed by M. Sondhauss. AB is a double convex bag, formed of collodion, and filled with carbonic acid gas, which is rather more than one and a half times heavier than air. A watch, W, is placed in the axis of the gas-lens, and the ear, E, of the observer is shifted backwards and forwards also in the axis of the lens, and it is found that there is one point, E, where the ticking of the watch is distinctly heard; though nearer and further from the lens, the sound is scarcely heard. E and W are therefore conjugate foci of the gas-lens, and the sound-waves have been refracted by the lens exactly as the light-waves in travelling through a glass lens.

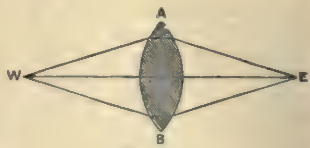

Fig. 32.

THEORY OF THE MUSICAL SCALE.

A simple musical tone, as that yielded by a tuning-fork, is produced by a continuous rapid vibration, if the number of single vibrations (the forward and the backward motions being two single, or one double vibration) fall between the limits before stated. One tone may differ from another in pitch, as the tone of one tuning-fork may be higher or lower than that of a second. The pitch, as we have seen, depends on the number of vibrations per second, or, which comes to the same thing, on the length of the wave, for as the velocity of sound is 1112 feet per second, if there are 100 vibrations per second, the wave-length is 11·12 feet. Again, the same tuning-fork may emit a weak or a loud tone; or musical tones of the same pitch may differ in intensity; and the intensity has been shewn to vary with the square of the range, or amplitude of vibration. Once more, if a pianoforte be made to yield a tone of the same pitch and intensity as the tone of the tuning-fork, we are conscious of a difference between the two tones, and this is a difference in quality, or colour, so to speak. In French, this difference is called *timbre*, and in German, *klangfarbe* (colour-tint). The cause of this difference will be explained presently.

Let us now take any note of the pianoforte, say C on the annexed scale, which is produced by 528 vibrations in a second, or 480 in the unit of time, if we make our unit $\frac{10}{11}$ of a second. If another note be yielded by 960 vibrations in the unit of time, the ear at once recognises an agreeable concordance when the two are sounded together. And similarly for any other two notes whose vibrations are as one to two. If we take two notes between these, such that their vibrations in the same time are to C's as 1½ to 1 and 1 to 1¼, we have four notes, which, when sounded together, produce a very pleasing effect, and form what is called a major chord. The lowest three of the chord have their vibrations in the proportion of 4, 5, and 6, and constitute a *harmonic triad*. Let us form two more triads from this one, by making the highest of the three the lowest of the second triad, and the lowest of

C = 528 vibrations.

the three the highest of the third triad. The numbers representing the vibrations of the second triad will be 6, 7½, 9; and of the third triad, 2⅔, 3⅓, 4; these sets of numbers having the proportion of 4, 5, and 6. In addition to our original note C, and that derived from it by doubling its vibrations, we have other six notes. And if we place the six notes between the first two, by doubling the vibrations of those below C, and halving the vibrations of the one above double C, we have the following series :

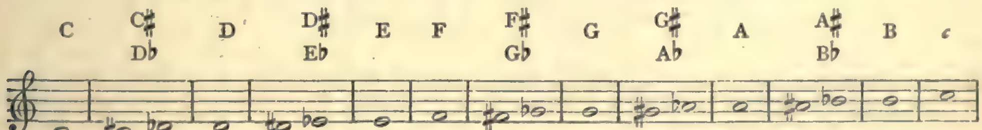
$$\begin{array}{cccccccc} 4 & 4\frac{1}{2} & 5 & 5\frac{1}{3} & 6 & 6\frac{2}{3} & 7\frac{1}{2} & 8; \\ C \end{array}$$

or, dividing each number by 4, and naming the notes by the first seven letters of the alphabet, we have :

$$\begin{array}{cccccccc} 1 & 1\frac{1}{8} & 1\frac{1}{4} & 1\frac{1}{3} & 1\frac{1}{2} & 1\frac{2}{3} & 1\frac{7}{8} & 2 \\ C & D & E & F & G & A & B & c \end{array}$$

We have now eight notes in all, forming what is called the *diatonic scale*, and *c* is called the octave above C ; G is a fifth above it, and E a third. The scale may be extended both upwards and downwards, by doubling the numbers for the right-hand extension, and halving them for that on the left, and thus a common pianoforte has a compass of seven octaves. The lowest notes of each of the three triads formed above have received special names, C being called the *tonic*, G the *dominant*, and F, the octave above the lowest of the third triad, the *subdominant*.

If, instead of making our triad consist of notes whose vibrations are as 1, 1¼, 1½, we make the ratios 1, 1⅕, 1½, the three notes form a minor triad, and when sounded with the octave of the lowest note, produce a pleasing, though somewhat melancholy effect. A scale formed from three minor triads would be a minor scale, though the minor scale in practical use is formed differently. In the ascending scale, the tonic has a minor triad, while the dominant and subdominant have major triads ; but in the descending scale, all the triads are minor. The ratio of a major to a minor third is 25 to 24, and this ratio is called an interval of a semitone. In music, it is convenient to subdivide the interval between two consecutive notes, and this is done by raising the one note, or lowering the other, by half a tone ; that is, multiplying the number of vibrations of the one, or dividing that of the other by $\frac{25}{24}$. The note formed by raising C one half-tone, or by sharpening C, is called *C sharp*, and is written C♯ ; and that by lowering or flattening D, is *D flat*, written D♭. The vibrations per second of these four notes are as the numbers $\begin{array}{cccc} 1 & \frac{25}{24} & \frac{27}{25} & \frac{9}{8} \\ C & C\sharp & D\flat & D \end{array}$; and those of C♯ and D♭ are so nearly equal that only a practised ear can recognise the difference of pitch. In the pianoforte, the same note serves for both, and the new notes introduced correspond to the black keys. As the interval between E and F, and between B and *c*, is very nearly a half-tone, it is not necessary to sharpen E or B ; and consequently the *chromatic* scale, as it is termed, is as follows :



VIBRATIONS OF STRINGS AND COLUMNS OF AIR.

If a stretched string or wire, AB, be sharply struck, or pulled aside, or agitated by a resined bow, it is thrown into to-and-fro vibrations, which give rise to a musical note. By placing the bridge, B, at different distances from A, we can vary the length of the sounding-string ; and to increase the intensity of the sound, a sounding-board, CD, which can vibrate in unison with the string, is placed below it. The blows given directly to the air by the string are too small to produce a loud sound ; but the vibrations of the sound-board being continually reinforced by those of the string, soon become appreciable, and a comparatively large mass of air is set in motion. If the bridge be successively placed at points which give vibrating lengths proportional to the numbers

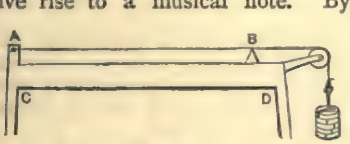


Fig. 33.

$$1,\ \tfrac{8}{9},\ \tfrac{4}{5},\ \tfrac{3}{4},\ \tfrac{2}{3},\ \tfrac{3}{5},\ \tfrac{8}{15},\ \tfrac{1}{2},$$

all the notes of the diatonic scale are produced. Therefore, we conclude that :

(1.) *When the length of the string alone varies, the number of vibrations in a given time is inversely as the length.* After a given note has been sounded, let the stretching-weight be increased four times, and it will be found that the new note is the octave above the last, or that the number of vibrations is doubled. If the two weights are as 16 to 25, the two notes form a major third, or the vibrations are as 4 to 5. The second law is therefore :

(2.) *When the stretching-weight alone varies, the number of vibrations in a given time is as the square root of the weight.* Let two strings of the same material, length, and tension, be placed side by side, but let the diameter of the second be half as much again as that of the first, or the double of it, and it will be found that the note of the second is a major fifth, or an octave below that of the first, or that the number of vibrations in a given time are as 3 to 2, and 2 to 1. So that the third law is :

(3.) *When the diameter of the string alone varies, the number of vibrations in a given time is inversely as the diameter.* And the fourth law is :

(4.) *When the density of the string alone varies, the number of vibrations per second is inversely as the square root of the density.* When the string AB is vibrating, and giving out its primary note, if it be lightly touched in the middle, it now

vibrates in two halves; and from the rapidity of the motion, the eye sees the string in its two extreme positions at one and the same time. The point C is called a *node;* and the parts AC, BC are called *loops*, or *ventral segments*. If we touch

Fig. 34.

the string at a third or a fourth of its length, it divides itself into three or four loops. The notes formed by a string vibrating in one, two, three, four, &c. loops, are respectively the primary or fundamental note, its octave, the fifth above the octave, the octave above the octave, &c.; and the whole series are called the *harmonics* of the fundamental.

The actual motion of a vibrating string is not so simple as the motion just described, but added to the primary vibration, there are a number of partial vibrations, of smaller intensity, and corresponding to the half, third, fourth, &c. parts of the string, so that a simple note is never heard, unless accompanied by several of its harmonics. The undisciplined ear cannot at first detect the complexity of a musical note, but careful attention will soon prove the fact. The existence of the harmonics may also be demonstrated by partially quenching the fundamental tone. For this purpose, after the string has been sounded, if we touch its middle point with a feather lightly for a moment, the fundamental is so much weakened that the octave is clearly heard. But the most satisfactory analysis of musical sounds has been made by Helmholtz, who, for this purpose, contrived an instrument which he called a resonance globe. This is a globe with two openings, *s* and *t*, of which one, *s*, wide and cylindrical, is turned towards the sound, and the other, *t*, has an india-rubber tube attached to it, which is applied to the ear. Like the sounding-board, the air in this cavity will respond to a certain note, so that if several other notes be sounded along with this particular one, the resonator will strengthen its own note only, and the ear will hear it distinctly to the exclusion of all the others. Consequently, by means of a series of such resonators, each one of which responds to a note of the diatonic scale, and its octaves, a given note can be analysed. And it is found that every note is mingled with many of its harmonics. By means of the same resonators, Helmholtz has succeeded in explaining the *timbre* or quality of musical notes. He has proved that the difference between the same note sounded on different instruments, say C of the violin and C of the pianoforte, depends solely on the different intensities of the harmonics which accompany the primary note.

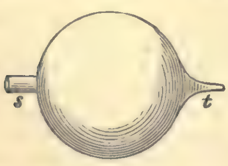

Fig. 35.

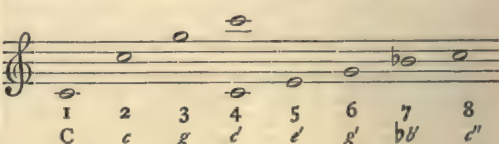
A column of air may be made to vibrate, and emit a musical sound, by taking a tube, *ab*, open at both ends, and blowing at one end, *a*, across and a little downwards. When such a tube is made to yield its lowest or fundamental note, the air particles within it vibrate, so that those at *a* and *b* are most agitated, their relative distances not being much altered; while those at the middle point, *c*, are not displaced at all, the neighbouring particles alternately approaching them, and receding from them. The distance between a point of greatest disturbance and a node, or point of rest, that is, *ac* on the figure, being quarter of a wave-length, it is clear that the wave-length of the fundamental note is twice the length of the tube. The number of vibrations in a second is found by dividing the distance which sound travels in a second by the wave-length. Supposing the note C produced by 264 vibrations in a second, and the velocity of sound at ordinary temperatures to be 1112 feet, it is easily found that the length of an open pipe, of which C is the fundamental note, is 2·1 feet. By blowing more strongly into the pipe, it is easy to produce a note whose wave-length is half of that of the fundamental note; and consequently, the new note is the octave above the former one. In this case, there is a node at *d* half-way between *a* and *c*, and another at *e*, the middle of *cb*. Again, no note between the fundamental and its octave can be obtained from the pipe, for, as the open ends, *a* and *b*, must always be points of greatest disturbance, no first node can lie between *c* and *d*. The next possible notes are produced when the first node lies at a distance from *a* of $\frac{1}{6}$, $\frac{1}{8}$, $\frac{1}{10}$, &c. of the length of the pipe; and then the wave-lengths of all the notes that can be given by such a pipe are as the numbers 1, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, &c. or the numbers of vibrations in a given time are as 1, 2, 3, 4, &c. Of these notes, which are called the harmonics of the pipe, the first eight are here represented, but the last four of the series are, for

Fig. 36.



convenience, written two octaves lower than they should be. As with vibrating strings, so likewise with vibrating columns of air, a pure note is never sounded alone, but each one is always accompanied by some of its harmonics.

If the pipe containing the column of air be closed at one end, the conditions which every vibration must fulfil are, that at the open end there must be a point of greatest disturbance and at the closed end, a node. The fundamental note of such a pipe must be one of which the quarter wave-length is that of the pipe, and is, therefore, an octave below the fundamental note of a pipe, of the same length, open at both ends. There cannot be a node in the middle of the closed pipe, for this would require *b* to be a point of greatest disturbance. There may be nodes at $\frac{1}{3}$, $\frac{1}{5}$, $\frac{1}{7}$, &c. of the length from *a*, so that all the harmonics are included in the series 1, 3, 5, 7, &c.

Fig. 37.

MAGNETISM AND ELECTRICITY.

MAGNETISM.

ANCIENTLY, there was discovered in Magnesia, in Asia Minor, a kind of iron ore which had the remarkable property of attracting other kinds of iron or steel. This ore afterwards received the name of *loadstone*, but from Magnesia we derive the terms *magnet* and *magnetism*.

Not only does the loadstone possess this power of attracting iron itself, but it can communicate its virtue to steel. A bar of well-tempered steel, if repeatedly rubbed by it, acquires exactly similar properties, and is termed an *artificial magnet*, while the other is called a *natural magnet*. In point of strength and convenience, artificial magnets are far superior to natural ones, and are therefore more commonly used.

If we take a bar of steel, which has been thus rubbed by a loadstone, and to which the name of *bar-magnet* is usually given, and scatter iron filings over it, they will adhere in tufts at both ends, but none will be found at the middle of the bar. Or we may put the magnet under a sheet of pasteboard, and sprinkle the filings over the sheet. We shall then find the small particles of iron arrange themselves in beautiful curved lines round both ends of the magnet. It appears from this that the chief power of the bar lies at the two ends, round which, as centres, the curves are formed.

These centres of magnetic force are called the *poles* of the loadstone or magnet, from another peculiar property which they are found to possess. If a magnetic bar be suspended by a thread, or be delicately poised on a pivot, it will not rest till it has settled in one position, which is in a direction nearly north and south. If moved from this position, it returns to it again, the *same end* always turning towards the north. That end which so points to the north is called the north pole of the magnet, and the other its south pole.

We can never have a magnet with only one pole. The two are always found together, and are opposite both in their properties and position. If we break a magnet in two, we do not have two pieces, one all north pole, and the other all south; but we have two complete magnets, and this however many times we break the bar. To this twin exhibition of force residing in opposite sides of a body is given the name of *polarity*. We shall find that it is not peculiar to magnetism, but is a feature of all electric phenomena. Sometimes, indeed, we have in the same bar more than *one pair* of poles; but this is owing to some irregularity of the steel temper, or of the mode in which the magnetism has been communicated. When more than one pair of poles occurs in a magnet, they are called *consecutive* points. They render a magnet practically worthless.

The action of the poles of one magnet on those of another is remarkable. If we bring two north poles together, they repel each other; or, if we bring two south poles together, they do the same. But if we bring a north near to a south pole, they attract each other powerfully, and cling together. From this simple experiment we deduce the two general laws of magnetic action: *Like poles repel each other: unlike, attract each other.* It is thus very easy to tell the north and south pole of any magnet. We have simply to try its action on a needle suspended so as to point north and south.

Magnetic Induction.—A bar of soft iron has of itself no power to attract iron filings, or another piece of iron. In presence of a magnet, however, it instantly assumes this power. When we suspend from, say, the south pole of a magnet a short rod of iron, its free end attracts filings, just as the magnet would do, and the iron has become, in every way, like a magnet. It has two poles, that end being a north pole which is next the south pole of the magnet. The same thing is seen, though in a less powerful degree when the magnet is simply brought near to the soft iron. But the magnetisation of the iron, though perfect, is merely temporary. The moment we take away the magnet, its magic power is gone, and the filings drop off.

This action of a magnet on soft iron, communicating to it a temporary magnetic polarity, is termed *induction*. All bodies, as we shall see under *diamagnetism*, are magnetic—that is, influenced by magnetism in one way or another. But induction proper, by which two magnetic poles are excited, is confined to iron and its varieties. Even here there is a remarkable contrast. The influence of a magnet on tempered steel is very different from that on soft iron. Steel will not assume the polar state at once, but only after repeated friction with a magnet. Yet, once magnetised, it retains its polarity with equal stubbornness. The cause of this is not well understood; but it is usually ascribed to the presence with the particles of steel of a *coercitive force*, as it is called, which resists equally the communication and the abstraction of the magnetic state.

Induction, or the action of a polarised body inducing a similar polarised state of another body in its vicinity, is not confined to magnetism, but appears to be manifested in every case of polarity. We shall see, under Electricity, a similar influence possessed by a body electrically excited or polarised.

Forms of Magnets.—In place of the bar shape, it is very often more convenient to give the magnet the form of a horse-shoe, so that both poles may be brought to act on the same object. When

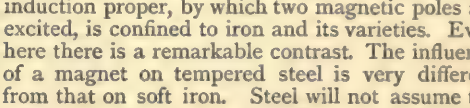


Fig. 1.

powerful magnetism is desired, it is better not to increase the mass of the magnet, but to form a *magnetic magazine*, or *compound magnet*. This

is done by magnetising separately a number of similar bar or horse-shoe shaped pieces of steel, and binding them together with the like poles lying the same way. Fig. 1 shews the mode of arrangement of a compound bar-magnet. The bars are bound by a brass screw or frame to a piece of iron at each end, in which the several poles have their magnetism concentrated. Fig. 2 represents a compound horse-shoe magnet, with its armature attached. This armature or keeper must be used with all magnets, to prevent the loss and ultimate disappearance of their magnetism. It is simply a piece of soft iron placed across the opposite poles of a horse-shoe magnet, or of a pair of bar-magnets. Any magnet, not shielded by its armature, has its polarity disturbed and even destroyed by the action of the earth, which is itself an enormous magnet. The soft iron is made, by induction, an exact counterpart of the magnet, and the power of the permanent poles is in this way even increased, for a much greater weight can be suspended from the armature than the single poles can sustain.

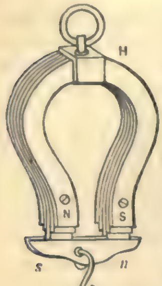

Fig. 2.

Magnetisation.—There are several processes by which a bar of steel may be magnetised. The simplest way is to pass one pole of a strong magnet from end to end of the bar several times, and always in the same direction. In this case the magnetism of the end first touched will be the same as that of the rubbing pole.

A somewhat better way is to rub the steel bar from the middle to one end with one pole, say the north, of the magnet, and then from the middle to the other end with the south pole. Each half is to be rubbed the same number of times, and the end rubbed by the *north* pole becomes a *south* pole.

Another, and a very accurate method is that shewn in fig. 3, which is employed for magnetising needles. It is called the method by *Divided Touch.* The bar, *ns*, to be magnetised, is placed

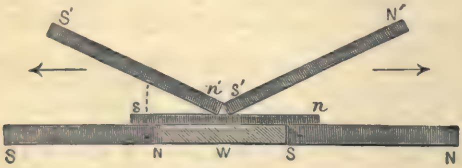

Fig. 3.

on a piece of wood, W, with its ends resting on the opposite poles of two strong bar-magnets, NS and SN. Two rubbing magnets are placed, with their opposite poles together, at the middle of *ns*, and making a small angle with it. They are then moved away from each other to the ends of *ns*, and brought back in an arch to the middle again. If this is done a few times, the bar is fully magnetised, the positions of the various poles being indicated by the letters in the figure.

For horse-shoe magnets, the usual method is to place the inducing magnet upright on the magnet to be formed, with an armature across its ends, as drawn in fig. 4. It is then moved from the ends to the bend, or in the opposite way, and

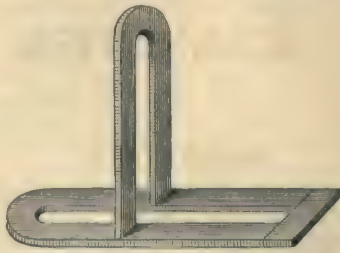

Fig. 4.

brought round again in an arch to the starting-point.

Other methods of magnetising steel, which do not require the aid of another magnet, are furnished by the magnetic power of the earth, and by the galvanic current. But these will be explained afterwards.

Magnets, when freshly magnetised, have often more magnetism than they can retain. In that case, they gradually fall off in strength until they reach a stationary point, when they are said to be *saturated.* The strength of magnetism that can be imparted permanently to any magnet, or its saturation point, depends on the quality and temper of its steel. If a magnet has got weakened, its strength may be gradually restored by hanging weights to its armature, and increasing them gradually from time to time. On the other hand, by repeatedly detaching the keeper abruptly, we weaken the power of a magnet, and in this way it is very easy to reduce one above saturation to its fixed strength. It may be remarked generally, that whatever disturbs the molecular condition, or internal state of the particles of a magnet, affects its power. A red heat will deprive it of all traces of magnetism, and a blow, or a number of blows, may do the same, or may even change the poles.

Theory of Magnetism.—The best known theory of magnetism supposes that there are two magnetic fluids existing in the substance of the magnet, and adhering to it. Each kind of fluid repels itself, but attracts the other kind. In an unmagnetised body, the two fluids are supposed to be mixed up together, and so to counteract each other's effects. Magnetisation consists, according to this view, in separating the two fluids to opposite sides of the body, or to opposite sides of each particle of the body.

Another more recent and more plausible theory regards a magnet as an assemblage of minute permanently magnetic particles, with their similar poles all lying one way. We have seen that, though a magnetic bar be broken into fragments, each piece is a perfect magnet. This fact is supposed to be a strong argument in favour of the latter theory. To magnetise a body is to throw its particles into a state of *regular* polarity, its previous want of magnetism being due to the want of this *regularity.*

Ampere's theory, which connects the phenomena of magnetism and of electricity, is another and still more novel theory, which will be explained under Electro-magnetism.

Diamagnetism.—It had been known since the beginning of this century that the metals nickel and cobalt were feebly magnetic, and could be

attracted by a strong steel magnet. But the effect of magnetism on other bodies was unknown till the discovery of an unlimited magnetic power in the galvanic current. The electro-magnet (to be afterwards described) was used in the hands of Faraday, to shew that all bodies are more or less magnetic; though, in general, the magnetism is so feeble as to be utterly insensible to the most powerful steel magnet. Faraday, in 1845, first proved that all the metals, such as gold, silver, copper, &c. as well as the liquids and gases, are influenced by the powerful magnetism of the electro-magnet. He also established, by a series of beautiful experiments, that there is a notable difference in its effects on different bodies.

If a small piece of iron wire be hung by a silk fibre between the poles of an electro-magnet (fig. 5), it will come to rest with its length in the line of the poles, *ab*, or *axially*, as Faraday termed it.

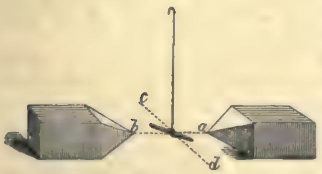

Fig. 5.

But if a small rod of bismuth be suspended in this way, it will set with its length along *cd*, that is, across the line of the poles, or *equatorially*. The reason is, that iron is attracted by both poles, while bismuth is repelled by both. Iron, and substances which behave like it, Faraday called *paramagnetic*; bismuth, and those like it, he called *diamagnetic*. Ordinary magnets are sufficient to shew the paramagnetism of iron, nickel, and cobalt; but the coercitive force of other substances is so feeble that they require a much more powerful magnetism. The following substances are found to be paramagnetic: *Iron*, *nickel*, *cobalt*, *manganese*, *paper*, *sealing-wax*, *plumbago*, *red lead*, *zinc*, *sulphate*, *shellac*, *charcoal*. These are diamagnetic: *Bismuth*, *antimony*, *zinc*, *tin*, *mercury*, *lead*, *silver*, *copper*, *gold*, *alum*, *glass*, *nitre*, *sulphur*, *resin*, *water*, *wood*, *leather*, *caoutchouc*. They are given in the order of their coercitive force. By inflating soap-bubbles with different gases, Faraday found they also were magnetic, but to a much feebler degree than any solid or liquid substances.

TERRESTRIAL MAGNETISM.

Our earth is an immense magnet, with its two magnetic poles situated *towards* the north and south ends of its axis. This is the cause that a magnetised needle, delicately poised, as shewn in fig. 6, takes up a position nearly north and south. The distances of the earth's poles are so great that their actions on the poles of the needle may be regarded as equal forces acting in opposite ways. Such forces can have no other effect than merely to turn the needle round its axis, so as to have its length in their direction. For this reason, a common steel needle, magnetised and made to swim on water, will shew no tendency to move either towards the north pole of the earth or towards the south, but will simply set in their line.

Fig. 6.

The value of the magnetic needle as a guide, in the absence of other directing marks, is obvious. To the navigator it is inestimable, and led, centuries ago, to the invention of the *mariner's compass*.

But the needle does not point *due* north and south, and the amount by which it deviates from that direction is called the *declination* of the needle. In more precise language, the *declination* is the angle between the magnetic and the geographical meridian at any place. An instrument furnished with a very delicate needle and the means of ascertaining the true meridian of a place, is called a declinometer.

It is of the utmost importance to the mariner to know the amount of this deviation of his needle, or compass, from the true north; and what makes the indications of his guide less reliable is the fact, that the declination is not the same for all places on the earth's surface. In some places, there is no declination at all—that is to say, the needle points due north. In this country, it points to the *west* of true north, while in India it is found to point to the east of it.

Charts have been drawn having these important changes accurately marked by lines traced through all places where the amount of declination is the same. These lines are called *isogonic* or *equal-angle* lines, and the charts *isogonic charts*. Looking at such a chart, we see that the needle points to the *west* of the true north in *Europe* and *Africa*, in the *Atlantic Ocean*, in the *eastern part of the two Americas*, and *the western part of Asia and Australia*. These form what may be called the western declination hemisphere, while the other parts of the earth's surface form the eastern. An irregular line of no declination separates the two hemispheres, running through the eastern continent of North America, and a corner of South America, and coming round through Australia, the west of Asia, and the east of Russia. Curiously enough, the line is slowly changing place, the Asiatic line of no declination advancing towards Europe.

Nor does the declination vary only with the place on the earth's surface, but, at the same place, it varies with the *year*, the *season of the year*, and even the *hour*. At Paris, for instance, in 1580, when observations first began to be recorded, the declination was $11\frac{1}{2}°$ E.; it gradually receded till, in 1669, it was 0°. In 1700, it had gone 8° to W. and continued its westerly sweep till, in 1814, it was as much as 22° 34′ W. Since then, it has been slowly diminishing, and it was, in 1864, down to 18° 57′ W. at Paris. In England, the greatest declination was, in 1815, 24° 27′ W.; and, in 1865, it was 21° 6′. Thus, in half a century, it has receded, in England, about $3\frac{1}{4}°$. At present, it is about 19° 45′ W.; the annual rate of decrease being about 8′.

There is also a periodical variation with the season of the year. Observations shew that, from April to July, the amount of westerly declination decreases; while, during the rest of the year, there is a slight turning to the west.

The relative position of the sun during the day also influences the needle. From three to eight o'clock in the morning, there is a gradual motion of the needle to the east of its mean position. At

eight o'clock, it begins a westerly sweep, crossing its mean position about 10 A.M. Its maximum distance to the west it reaches at 1 P.M.; when it again begins its easterly course, coming up once more to its mean position about seven o'clock in the evening.

Besides these *regular* variations of the declination, there are sudden and unforeseen disturbances, caused by what are called *magnetic storms*. Earthquakes and volcanic eruptions have a marked effect on the needle. The Aurora Borealis is invariably accompanied by its disturbance; and the appearance of solar spots, which are most numerous every ten years, has been associated with special magnetic irregularities.

Inclination or Dip.—If an unmagnetised needle be balanced about an axis, so as to remain horizontal, it will, after being magnetised, and placed in the magnetic meridian, no longer lie evenly, but will *point downwards*. This *dip* or *inclination*, as it is termed, of the needle to the horizontal is owing to the position of the earth's magnetic poles. They are deep in the interior of the globe, and by no means coincide with the poles of its axis. Now, if we take a small balanced needle, which can swing vertically up and down, and move it over a bar-magnet, we find that when it is above the middle of the bar, it remains horizontal, its ends being equally attracted by the poles of the magnet. When brought over one of the poles, it stands upright, and at any position between, it is more or less in an inclined direction. Exactly similar to the action of the bar-magnet is that of the earth. A balanced needle will be differently inclined, according to its distance from the two poles.

Over the north magnetic pole, it stands upright, with its north pole down. In 1831, Captain Ross came upon a spot in 70° 5′ N. lat. and 263° 14′ E. long. where the needle stood vertical. That spot must therefore be right over the north magnetic pole. Near the equator, again, there is no dip, and the needle lies horizontal. A line drawn through all such places of no dip is called the *magnetic equator*. It is an irregular line near to, but not identical with the earth's equator. Charts have been drawn up with lines shewing all places where the dip is the same. To these the name of *isoclinic lines* and *charts* is given.

Like the declination, the dip is subject to *periodical* as well as *irregular* variations. At the beginning of the present century, the dip was 70° 35′ from the horizontal in London, and it has since then been gradually diminishing. In London, it is at the present time about 67° 50′, and there is an annual decrease of about 2·6′. It is found that the diurnal or daily variations, as well as the disturbances of magnetic storms, affect the inclination at the same time as they affect the declination needle.

Magnetic Intensity.—If a nicely poised needle be made to swing on a pivot or axis near a magnet, it will vibrate more quickly, or more slowly, according to the strength of the magnet, and according to its distance from it. At the middle of the magnet, it will not vibrate so actively as at the ends; and the number of vibrations it will make in any time, say in one minute, will be an estimate of the *magnetic force* affecting it. Precisely in this way, then, is the strength or intensity of the earth's magnetism found at any place on its surface. At the equator, the needle, oscillating most slowly, shews the magnetic intensity to be weakest there. As we go north or south, it swings somewhat more quickly, indicating an increase of magnetic force.

These three indications, then, of the *declination*, as shewn by the compass needle, of the *inclination*, as shewn by the dipping needle, and of the *magnetic intensity*, as shewn by the vibrating needle, are termed the *magnetic elements* of a place. They are different at each place on the earth, and are always changing, so that each spot has its own magnetic history.

In recent years, much importance has been attached to these changes of the magnetic elements. An immense amount of labour has been spent in observing and registering the variations of the magnetism at different stations over the globe, but much more will doubtless have to be done before any definite results can be expected.

The variations that have been found to be regular in their occurrence, having periods either of a year, or of a month, or of a day, can evidently be traced to the influence of the sun or of the moon. These bodies are themselves, in all probability, magnetic like our earth, and they will act as huge magnets at a distance.

Some of the irregular variations can be traced, as we have said, to definite causes. But of the slow changes which take centuries to effect, no acceptable explanation has yet been given; and of the causes of other disturbances we know as yet absolutely nothing.

ELECTRICITY.

Six centuries before the Christian era, it was known to the Greeks that *amber*, when rubbed, attracted light objects, such as feathers or pieces of straw; but for twenty centuries, the fact remained an isolated and fruitless one. In the year 1600, Dr Gilbert, physician to Queen Elizabeth, recalled this curiosity of nature to the attention of the world, and shewed that many other substances, as well as amber, can acquire a similar power by friction. This attraction he ascribed to the production in the bodies of a subtle substance, for which he coined the name of *electricity*, from the Greek word *electron*, meaning *amber*.

For almost two hundred years, the term electricity was confined to the *frictional excitement*, until, by the discovery of galvanism, it received a wider application. This was but the first of a series of subsequent extensions, and what was, at one time, the whole, forms now but a mere part of the science of electricity.

The various sources of the electrical excitement, such as friction, chemical action, magnetism, and heat, naturally form the bases for the divisions of the subject. We shall accordingly begin with an account of the electricity of friction, which, if not of most practical importance, is no less interesting in itself than it is instructive.

FRICTIONAL ELECTRICITY.

Elementary Facts.—A piece of amber, sulphur, glass, or sealing-wax, when rubbed with a dry silk handkerchief, or a woollen cloth, becomes animated with a curious power of attracting small bits of paper, hairs, feathers, and such-like. When

a body manifests this attractive power, it is said to be in an *electrical state*, or to be *electrified;* and the name *electricity* is given to the strange physical cause of the power, which the rubbing has called into existence.

For experiments in this subject, it is useful to have a number of small pith-balls, formed from the pith of the elder-tree, or of the common sunflower. One of these, hung by a *silk* thread from a convenient support, is called an *electric pendulum*, and shews very readily the attraction of an electrified body.

But every substance which we rub as we did the glass or sealing-wax, will not behave in this manner. A rod of metal, held in the hand, will shew no trace of electricity, though it be rubbed ever so long. It is clear, therefore, that all bodies are not alike with regard to the electrical state.

The difference used to be explained by saying that amber, glass, and such substances are *electrics*, while the metals and others are *non-electrics*—that is to say, that the former class can be electrified by friction, while the latter cannot. This idea is now known to be erroneous. For, if the metal be held by a glass handle, and rubbed, it will at once shew its attractive power.

The true explanation lies here. In some substances, the electrical state is no sooner produced at any part than it instantly diffuses itself over the whole. In others, it is confined to the part where it is produced, or, at least, spreads over the rest of the body very slowly, and with great difficulty. According as bodies admit this instant diffusion or transmission of the electrical state or not, they are now termed *conductors* or *non-conductors*. *Non-conductors*, such as dry air, glass, shellac, &c. are also called *insulators*, because, if an electrified body is surrounded by such, its electricity is inclosed as in an island, and prevented from escaping over other conductors. The earth is a huge conductor, and any electricity, which we can artificially excite, must be carefully insulated from it, otherwise, if allowed to spread over the earth, it will be lost in its immensity, like a wave on a boundless sea.

We can now easily understand the difference between rubbing a rod of metal and one of glass held in the hand. In the former case, the electricity is dissipated as fast as it is produced, while the glass acts as the insulator of its own electricity.

There is no such thing as a perfect conductor or a perfect insulator. In other words, the very best conductors offer *some* resistance to the diffusion of electricity, and the very worst do not wholly prevent it. Nor is there any sharp line between the two; the difference is merely one of degree, and depends on a variety of causes. Temperature, for example, has a marked effect on conducting power. Thus, water is a moderate conductor, yet ice and dry steam are both insulators.

The following is a list of bodies in order, from the best conductors to the best insulators: *Silver, copper, gold, zinc, iron, lead, mercury, charcoal, acids, salt solutions, rarefied air, pure water, stone, dry ice, dry wood, porcelain, dry paper, wool, silk, glass, sealing-wax, sulphur, resin, gutta-percha, india-rubber, shellac, paraffin, ebonite, dry air*, and *gases*.

Looking more closely at the action of the rubbed glass rod on the electric pendulum, we see that the attraction is merely momentary, and is followed by as brisk repulsion. Any attempt to bring the rod near to the pith, only serves to drive it farther away. But if an excited stick of sealing-wax be brought near, the pith instantly flies to its embrace, only, however, to be in a moment cast off, as it had been by the glass before. Banished from the wax, it will now find favour with the glass for an instant again; and thus a continual exchange of sympathy for the one or the other electrified body may be kept up as long as the excitement continues.

Now, this curious behaviour of the pith can be accounted for only on the supposition that there are two opposite states of the electrical excitement, one peculiar to the glass, and the other to the sealing-wax. What the one repels, the other attracts, and the characters of the electricities must therefore be as opposite as are attraction and repulsion.

In any case, the excitement is either like that of glass or that of sealing-wax; thus, any electricity used to be defined as either *vitreous* or *resinous*. But these terms are not quite correct, as either kind may be got from the glass or from the wax, by varying the nature of the rubber. For *vitreous* and *resinous*, the terms *positive* and *negative* are now used—positive electricity being like that evoked on glass by rubbing with silk; and negative, that evoked on sealing-wax by rubbing with flannel.

Laws of Electricity.—The laws of frictional electricity are strikingly like those of magnetism. Often both may be expressed in the same language.

(1.) As with magnetism, so with electricity. *Like kinds repel: unlike, attract each other.* If we take two piths hanging together by two silk strings, and bring near a rod of glass or of sealing-wax, they will repel each other, and remain apart. But if we electrify one with the glass, and the other with the wax, they will attract.

We can thus at once tell the nature of any electricity by its repelling a pith electrified by glass or by sealing-wax. Mere attraction is no test, as a neutral body is attracted.

(2.) But as we never have one pole of a magnet without its fellow, so both kinds of electricity are always produced at the same time, and in equal amount. One kind goes to the body rubbed, and the other to the rubber. Faraday, whose name is so closely associated with this subject, shewed this fact by a very simple experiment. He made a small flannel cap to fit the end of a stout stick of sealing-wax. After rubbing the cap round the end of the wax, and presenting it to a pendulum, not the slightest effect was seen before removing the cap. But on drawing it off, by a silk string attached to it, he found the end of the rod negatively, and the cap positively, electrical.

The kind of electricity that goes to each depends on the nature of the rubbing bodies. Thus, if we rub glass with silk, the glass becomes positive, but if we rub it with cat-skin, it becomes negative. It is a curious fact that no body has yet been found which will give positive electricity when rubbed with a cat-skin.

If any two substances in the following list be rubbed together, that one which comes first in the list will be positive: Cat-skin, flannel, glass, cotton, silk, the hand, shellac, metals, sulphur, india-rubber, gutta-percha.

(3.) The electrical excitement is only found on the *surface of a conductor*. This may be shewn by a hollow brass ball with an opening of an inch diameter or so, and fixed on a glass stand. However strongly we electrify the ball, not the slightest trace of electricity will be found inside. Faraday took a cylinder of wire-gauze, and, setting it on an insulating stand, electrified it powerfully. Yet, strange as it may seem, none could pass by the meshes to the inside.

Electrical Theories.—Many theories as to the nature of electricity have been proposed, but its real character is yet beyond our reach. The two most historically important theories are the *fluid theories* of Franklin and of Symmers.

Franklin's theory is, that all bodies, when in the neutral state, contain a definite quantity of an extremely elastic, imponderable fluid which repels itself, but attracts matter. Bodies are positively electrified when they have more than their natural share of it, and negatively when they have less. Symmers' theory is, that bodies in the neutral state contain equal amounts of *two* electrical fluids, of opposite characters. By friction and other means, these can be separated, one going to each body rubbed. Each repels itself, but attracts the other, and one is peculiar to rubbed glass, and the other to rubbed sealing-wax.

These fluid theories were long exclusively adopted, and on them are based all the leading terms of the science.

The modern tendency, however, is to depart from all *material* theories of electricity, and to adopt some one more or less analogous to those of heat and light. They are based on the fact, that heat may be transformed into light and electricity, and also that electricity may be converted into light and heat. Light and heat are now ascribed to vibrations of an extremely elastic *ether*, which is so rare or fine as to pervade the densest matter as easily as air does the branches of a tree. So electricity is ascribed to some other modification of this ether, such as condensation or rarefaction of it at the surface of bodies, there being evidently some mutual influence between matter and the ethereal medium.

One thing is certain—electricity is not known to exist apart from matter, and it is very probable that it is but some particular *state* of the particles of matter. Faraday and Grove ascribed all electrical phenomena to a polarisation of the molecules of bodies, acting by attraction or repulsion, according to very definite laws. Faraday, by a series of testing experiments, went far to establish this theory, which would overturn all the fluid theories.

Induction.—An electrified body has the power of inducing, or of affecting a neutral one in much the same way as a magnet does a piece of soft iron. This may be shewn very simply in the following way. A brass cylinder with rounded ends, and fixed on a glass support, has pairs of piths hung at each end (fig. 7). If, now, an insulated conductor, such as a brass ball, be charged positively, and brought *near* one end of the cylinder, *both* pairs of piths will instantly diverge, and as quickly collapse when it is taken away. It is easily shewn that the two ends of the cylinder are in opposite electrical states, and separated by a neutral line of no electricity. Next the positive ball there is negative electricity induced, and so it is always. A charged body induces an opposite kind of electricity on the side of another next it, and the same kind on the farther side. If we had a series of cylinders like that in the figure, placed end to end in a line, without contact, we should find that the positive end of the first cylinder would act on the next just as the ball did on itself. Thus the induction might be transmitted through the whole of them; and, on our removing the inducing ball, they would all return to the neutral state instantly.

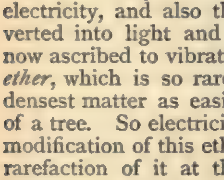

Fig. 7.

Opposite forces are here, as in a magnet, resident in opposite sides of the conductors. They are therefore said to be *polarised*, and the facts of electric induction are all in accordance with the laws of polarity. Indeed, there seems every reason to infer that all electric action is of a polar nature. When a rubbed glass attracts a pith, it is an attraction between the positive of the glass and the negative it has induced on the face of the pith next it. This is quite analogous to the action of a magnet on a piece of soft iron. There is, however, an apparent contradiction of this polar doctrine, for we may give to a body by induction only *one* kind of electricity, and this it retains permanently. If, while the cylinder is near the positively charged ball, we touch it for a moment with the finger, we uninsulate it, and allow its electricity to spread over the earth and become lost. Only the positive, however, will escape; the negative will be held *bound* to the positive inducing charge. If *after* thus touching the cylinder, we remove the ball, we shall have remaining on the cylinder *only negative* electricity. This is very different from what we can do with magnetism. There seems here no second electric polarity.

The explanation, however, is not far to seek. All matter can be excited electrically, but only one kind magnetically. In the case of electric polarity, then, it is possible to transfer one of the poles by induction to surrounding objects, whereas, in magnetism, this transference cannot take place. Not only is it possible, but it is what must take place before we can have any electricity at all. Faraday has shewn that a body cannot be electrified at all, either positively or negatively, unless there be surrounding objects to which it can transfer the opposite electricity by induction, and that the degree of charge which it can take is just in proportion to this facility for induction.

When a body is charged by induction, then, we see its electricity is opposite to that of the charging body. But when we charge it by contact or by spark, the electricity is of the same name as that of the charging body. Yet the latter is due to induction as well as the former. For when we bring the ball (fig. 7) near the cylinder, the positive electricity of the ball tends to unite with the negative it induces next it. The tendency increases as they approach, till at last it is sufficient to burst through the interval of air; and the two flash together with a spark, and neutralise each other. Thus, the positive electricity at the other end of the cylinder is left alone without its negative, just as if the positive of the ball had passed or flowed over to it.

Faraday shewed that the air is the medium by which the electric force passes between an inducing and an induced body. He found that, if he changed this medium and put shellac for air, the amount of electricity induced was about twice as much as with air. Hence he called shellac a better *dielectric*, or medium of induction, than air. Bodies, he would say, differ merely in the facility with which their molecules communicate the electric state. If induction, then, be an action at a distance, it is at no greater distance than between the molecules of bodies.

Distribution of Electricity.—Whatever may be the nature of electric force, it may be assumed as self-evident that its intensity, or tension at any part of the surface of a body, will be less in proportion as the surface is increased. If two insulated balls, one electrified and the other neutral, be made to touch, the charge will be just divided between them in proportion to their size. The intensity of the excitement has nothing to do with its quantity; and the same quantity may, in different circumstances, possess very different intensities.

Not only does the size, but even the *shape* of a body very materially influence the intensity of the excitement at different parts of its surface. A ball, since every part is alike, will have the same intensity all over its surface. But an electrified cylinder will have the greatest intensities at its ends. With a body such as that in fig. 8, the tension will be far greater at the ends than at the middle. In general, the farther a body is from the spherical shape, the farther will its intensity be from uniform distribution. When the body ends with a sharp point, the electricity seems all to accumulate at the point, so that it is too great to be retained on the body, and it bursts from it instantly.

Fig. 8.

ELECTRIC MACHINES.

The ultimate object of all electrical machines is the conversion of mechanical into electrical force. We have, in the glass tube and silk rubber, the embryo of such a contrivance. The mere form which may be given to it for convenience does not affect the principle.

Cylinder Machine.—Fig. 9 represents one of this class of machines in its very simplest form. It consists of a strong glass cylinder, A, which can be turned by a handle. Against one side of it presses the rubber, E, which is a cushion of leather stuffed with horse-hair, and having its pressure regulated by means of screws. Facing the opposite side is a row of brass points, near to, yet not touching the glass. These metal points communicate with a brass cylinder, G (rounded at the ends, and mounted on well insulating glass supports), which is called the *prime conductor.*

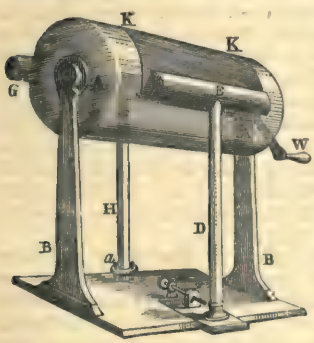

Fig. 9.

When the handle is turned, the friction of the rubber excites positive electricity on the glass, and negative on the rubber itself. Being a non-conductor, the glass retains its electricity till brought opposite the points, when it is discharged or picked up, as it were, by the action of these. Were a metal cylinder used in place of a glass, the electricities would combine at the rubber as fast as they were produced, and the mechanical energy exerted in turning the cylinder would appear as *heat*, instead of being transformed into electricity. To prevent dissipation of the electricity from the glass as it rushes through the air, a flap of silk lies over the cylinder from the rubber to near the metal points. In this way, then, positive electricity collects on the prime conductor, and negative on the rubber. If the latter were insulated as well as the former, the tendency of the electricities to unite at the rubber would increase with its charge, and a limit to the power of friction to prevent this would very soon be reached. By connecting the rubber with the ground, we get rid of the negative electricity, and can thus go on accumulating to a much greater degree the positive. In many instruments, the rubber is connected with an insulated cylinder similar to that of the prime conductor. Positive or negative electricity may then be had at pleasure, by connecting with a metal rod or chain either the rubber or the prime conductor with the ground. But except for this choice which it puts in our power, it is not necessary to insulate the rubber at all.

Plate Machine.—One of the best existing forms of plate machines is that shewn in the figure, and known as Winter's machine (fig. 10). A round

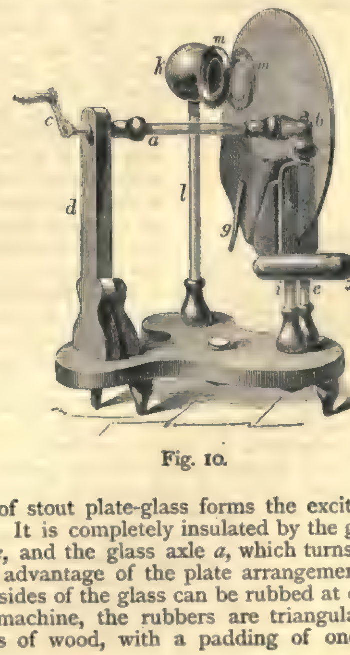

Fig. 10.

disc of stout plate-glass forms the excitable surface. It is completely insulated by the glass support *e*, and the glass axle *a*, which turns it. The chief advantage of the plate arrangement is that both sides of the glass can be rubbed at once. In this machine, the rubbers are triangular-shaped pieces of wood, with a padding of one or two

layers of flannel covered with leather; and a large flat rubbing surface thus acts on the glass.

From these rubbers a flap of oiled silk passes on each side of the plate to near the collecting points, to prevent loss of electricity. The attraction of the rubbed plate keeps these flaps in position when the machine is in action; at other times a split pin, *g*, is used to keep them up.

A peculiar feature in Winter's plate machine is a large ring which fits into the ball of the prime conductor. It is apparently a wooden ring, but the core consists of a metallic wire, which communicates with the prime conductor, when it is fitted in its place. The figure (fig. 11) shews a section of the ball of the prime conductor with the ring so fitted on. It serves to increase the accumulation of electricity enormously; the wooden envelope appears to prevent the discharge into the air, as the silk flap does with the electricity of the plate.

Fig. 11.

But we must not omit to notice that the frictional excitation of electricity is, in all these machines, very greatly enhanced by covering the surface of the rubber with an *amalgam*, or metallic compound. It is in the shape of a fine powder, and is usually made of mercury, zinc, and tin; it is spread on with a knife, and made to adhere by the aid of a little grease.

The Electrophorus.—This is the least expensive of all electric machines, and forms a useful piece of apparatus when we do not require electricity in great quantity.

It usually consists of a tin mould filled with shellac, and a movable tin cover with an insulating glass handle, as seen in fig. 12. The shellac is generally mixed with wax, to make it less brittle; but any resinous cake will do, if it be even and smooth on the surface. A round disc of vulcanite forms an excellent substitute for the shellac.

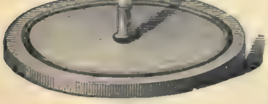

Fig. 12.

The principle of action of the electrophorus depends on induction, and is easily understood. If the cake be excited, say negatively, by striking with a cat-skin, it will not give up its electricity readily, because it is a bad conductor. Now, this negative electricity will induce positive on the adjacent sides of all objects round the cake. But as shellac is a splendid dielectric or medium of induction, the power will almost all act through it, and so keep positive electricity *bound* on the face of the mould next the cake, the negative being diffused over the earth. If, now, we put on the cover, the electricity, loath to leave the cake, will act on it by *induction*, rather than pass to it by *conduction*, and by induction powerfully, because the cover is so near. So, then, if we touch the cover for an instant, the negative induced on its upper side escapes; but the positive is kept *bound* by the cake, till we lift the lid by its handle, when a sharp spark passes to the knuckle held near it. By putting on the cover, touching, and then lifting it, we may get any number of sparks from the cake. Once excited, it will keep its power for a long time, sometimes for weeks or even months together. The mould shields it by induction, as the armature of a magnet does its magnetic charge.

Within the last few years, some machines have been invented by Holtz of Berlin and Tœpler of Riga, which have become very popular. They are generally called *double induction machines*, and are founded on a principle somewhat analogous to that of the electrophorus. A description of them will be found in any of the recent larger treatises on electricity.

Experiments with the Electric Machine.—(1.) The phenomena of *electric attraction* and *repulsion* may be illustrated in hundreds of ways. If a common glass tumbler be electrified inside, by a number of sparks from the machine, and then inverted over a few piths on a table, the piths will dance up and down within the tumbler in an amusing manner. They are gradually discharging the electricity of the tumbler, and the dance may be kept up for hours. Small pith figures will dance between two metal plates, the lower of which is uninsulated, and the upper in connection with the prime conductor.

The repulsion of similarly electrified particles is shewn very nicely by the *electric water-pail.* This is simply a small tin pail with fine holes pierced in the bottom. If filled with water, it will, when held in the hand, trickle out in drops merely; but if hung on the prime conductor, the water particles becoming electrified mutually repel, and issue in a multitude of fine jets. The *electric wind* is a somewhat similar result of the electrification of the particles of the air. If a pointed rod be stuck in the prime conductor, and the machine worked, the hand placed before the point will feel a sort of wind. The experiment may be made pleasing to the eye, by making the wind drive small models of mills or a small paper orrery.

This action of points is very curious. So long as the electricity escapes from the prime conductor by a point, no spark can be drawn from it. Nor, on the other hand, can any spark be got, if a pointed conductor be held at a distance of a few feet from the machine. This is because the electricity escapes silently in each case, and cannot acquire a tension sufficient to give the spark. The snap, heard when a spark is drawn, is due to the disruption or scattering of the air particles, caused when the positive electricity of the machine combines with the negative it induces on the hand or the object brought near it.

(2.) The *heating effects* of electricity are also very powerful. If a spark be drawn from the prime conductor by an iron spoon containing a little ether or alcohol, the liquid will instantly inflame. It will also light a candle newly blown out. A gas-jet issuing from a metal burner is instantly lighted by a spark from the machine, or from the finger of a person standing on a stool with glass legs and touching the prime conductor.

(3.) The *luminous effects* of electricity are, of course, most visible in the dark. The light of the spark is intense when the machine is powerful and in good order. When short, it seems straight, but it gets more and more irregular and zigzag the longer it is. If the ball of a Winter's machine be allowed to discharge into the air, the spark will be seen to spread out into the form of a *brush*. But if it be made to discharge silently from a point, the point will be seen, in the dark, crowned with a tuft of light, which is usually called the *glow*. The glow is more readily got, and becomes much more extended in rarefied air. A tall glass jar, from which the air can be pumped out, is used to shew this. It has a brass ball at each end, and the electric spark passes between these by putting one end in connection with the machine, and the other with the ground. The glow throughout the jar has the appearance of a column of mauve-coloured flame. But the colour of the luminous discharge varies with the nature of the metals between which it passes, and also with the nature of the gaseous medium. The flickering light thus produced has a striking resemblance to the Aurora Borealis.

ELECTROSCOPES AND ÉLECTROMETERS.

Instruments for *detecting* the presence of feeble electricity are called *electroscopes;* and those for *measuring* the degree of excitement present in any body are termed *electrometers.* Both are indispensable in electrical inquiries.

The simplest form of electroscope is the electric pendulum already mentioned.

Far more delicate, however, is what is known as the *gold-leaf electroscope.* A good form of this is shewn in fig. 13. Two strips of gold-leaf about half an inch broad are fixed to a brass rod so as to hang inside a glass globe of about four inches diameter. The brass rod ends externally in a ball, and is insulated with sealing-wax from the brass fitting of the neck. Before the rod and leaves are finally fixed, the interior of the globe is thoroughly dried, that the insulation of the leaves may be as perfect as possible. When so finished, this forms a very sensitive instrument: an extremely small amount of electricity being sufficient to make the leaves diverge. A strong charge would be very apt to tear the gold-leaves, and it must therefore be used with care.

Fig. 13.

When we simply wish to test the kind of electricity on a body, induction is generally employed, and in this way. The electrified body under examination is brought near the electroscope, and the knob of the instrument touched in presence of the body. By withdrawing the electrified body, we leave the leaves charged oppositely to itself, and so they diverge. To find if they are positively or negatively charged, we rub a glass rod and bring it *near* the knob: if *positively*, the leaves will diverge still more under the induction of the glass; but if *negatively*, they will collapse by the negative being attracted to the positive of the glass rod.

Of electrometers, one of the first and simplest is that shewn in fig. 14, and called the *quadrant pith electrometer.* It consists of a conducting-rod of brass or of box-wood, with a divided semicircle of cardboard attached. A straw ending in a pith-ball moves about a pivot at the centre of the semicircle, and indicates, by the extent of divergence from the brass rod, the degree of electrification of the instrument. It is very far from delicate, however, and gives but a rough test of electric tension. Its chief use is to put on the prime conductor of a machine, to give an idea of its condition.

Fig. 14.

A much more delicate instrument of this class, and one which has had a considerable effect in rendering electricity an accurate science, is *Coulomb's torsion electrometer.* It is represented in the figure, and merits a short description here (fig. 15). A light rod of shellac, carrying a small disc of gilt paper at one end, is suspended by a silk fibre, or fine silver wire, within a glass cylinder A, and a glass tube, B, surmounting it. The cylinder is divided into degrees by a graduated strip of paper pasted round it; and the position of the gilt disc is known by reference to this graduation. Through an opening in the lid of the cylinder, a brass ball, at the end of a shellac rod, can be passed so as to be supported on a level with the gilt disc.

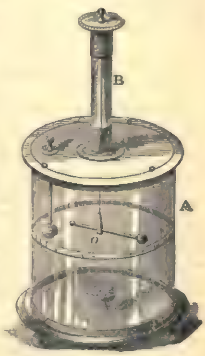

Fig. 15.

Before using the instrument, we must adjust it so that, when the fibre hangs free from twist, the gilt disc just touches the ball. If this ball be electrified, it electrifies, and then repels the disc, to a distance depending on the strength of charge in the ball. Now, the principle on which its use depends is that—*the force required to keep a fine wire or fibre twisted through any number of turns and parts of a turn, is just proportional to that number of turns and parts of a turn.* By turning the button, to which the fibre is fixed at the top of the tube, we can bring the disc to any distance from the ball that we please, say to 30°, as read off on the cylinder. Then the number of turns and parts of a turn (read off by reference to a graduated ring on the top of the *tube*), added to the 30° between the ball and the disc, gives the whole amount of twist of the fibre from the first position of no twist. This force of twist is just balanced by the repulsion of the electricities in the ball and disc, and is therefore a measure of that repulsion. By a great number of such experiments, Coulomb established the following laws of electrical attraction and repulsion:

(1.) The force of attraction or repulsion between unlike or like electricities *decreases* as the distance between them increases, and decreases as the *square* of the rate of increase of the distance. Thus, the force of repulsion between two similarly electrified piths, 1 inch apart, would be reduced

to ¼ of that at 2 inches', and to ⅑ at 3 inches' distance.

(2.) This force depends also on the *product of the intensities* of the electricities that are acting on each other. So that, if one ball had its electricity raised to three times its first amount, and another to twice, the resulting action between them would be six times as strong as at first.

The construction of delicate electrometers has of late years occupied the attention of our greatest authorities on this subject. Their aim has been to render electricity a strictly accurate and mathematical science; and the labours of Sir William Thomson and others have done more to effect this than any have ever done before. Sir W. Thomson has himself invented several forms of electrometers from time to time, each more accurate than the former; and his *Absolute Electrometer* and his *Quadrant Electrometer* seem as perfect as is reasonably to be expected. The latter is out of sight the most delicate instrument of the kind. A description of these is beyond the scope of this article, but may be found in the various works on electrical science or apparatus.

CONDENSED ELECTRICITY.

There is a limit to the accumulation of electricity on any surface. After it has reached a certain degree of intensity or tension, it discharges into the air as fast as it is produced. But if we bring another conducting surface *near to* the charged one, the latter may be much more highly electrified than before. This is the principle on which the *Leyden jar* depends, and a description of it will serve to explain the nature of condensed electricity.

The *Leyden jar* is simply a wide-mouthed glass bottle with two coatings of tinfoil, pasted one outside, and the other inside (fig. 16). The coatings reach only about four-fifths of the height of the jar, and the bottom is also covered inside and outside. A brass rod ending in a knob passes through a wooden plug in the mouth of the jar, and communicates with the inside coating by a piece of chain. If, now, we set such a jar on an insulated support, so that sparks can pass from the prime conductor of a machine to its knob, a few sparks will pass, and then it seems charged, and will take no more. But if we hold a knuckle near the *outer* coating, sparks will again pass freely to the knob; and for every spark to the knob, a similar one passes to the knuckle from the outer coating.

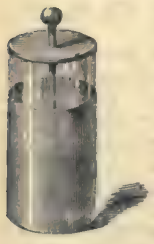

Fig. 16.

This continues for some time, till again the jar becomes fully charged or saturated. So long as it remains on the insulated support, we may touch *either* the outside coating *or* the knob. But if one hand touch the outside, and the other be brought near the knob, a bright spark passes to it, and a very violent shock is experienced. If the same thing be done again, a feebler spark and shock ensue, and then the jar is quite discharged. This experiment had better be made, however, with a pair of discharging tongs (fig. 17), as it is neither pleasant nor safe to do it with the body. They are simply two brass arms ending in balls, and movable about a hinge by means of glass handles. One ball is made to touch the outer coating, while the other is brought near the knob. The usual way of charging the jar is to hold it in the hand, and present its knob to the prime conductor of a machine.

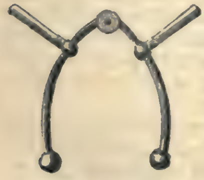

Fig. 17.

Its theoretical explanation is just a case of the general principle, that the charge which a body can receive is greater in proportion to its facility for induction. Now, when the inner coating is positively charged from the machine, it acts by induction on all neighbouring matter, and the nearer and larger this matter is, the greater will be the charge it can take. If, then, the jar be uninsulated, we have really the surface of the earth brought within the thickness of the glass from the inside coating. The glass, too, which intervenes is a very good dielectric, much better than air; at the same time its tenacity can resist the strain of a far higher polarisation of its particles than air would do. Thus we have every facility for a high charge of the interior. It would, of course, be greater, the thinner the glass; but thin glass is easily ruptured, and would be of no use. If we could have a jar of indefinite thinness, and yet of great strength, the charge which it could take would be unlimited. As this is not the case, other bodies round about compete, for induction, with the outer coating. Ultimately, the facility of induction through the air on these becomes greater, and there is an end of the charge.

If the inside is positively charged, the outer coating is negatively next it, and the two are bound together by the action of the glass, which is such a good dielectric. The glass also seems to be the chief seat of the charge, and the coatings seem to serve merely to distribute it over the non-conducting glass. This is usually illustrated by having a jar with movable coatings. After it is charged, we may remove each coating, handle them, put them back in their place, and get almost as strong a discharge as ever. The *secondary* discharge, which is got by connecting the coatings after the first discharge, is ascribed to the same cause. The glass does not give up all its charge at once, and sometimes three or four subsequent discharges may be got.

For great power, large surfaces are necessary. A large jar would give this, but it is preferable to use several moderate-sized ones, and unite them to form what is called an electric battery. The jars are placed on an insulated stool covered with tinfoil, and their outer coatings are thus in communication. All the knobs are connected by metal rods, and so all the inner coatings act as one. If, after charging, we connect any knob with an outer coating, the whole battery will be discharged, and with a force which, for the same degree of charge in a single jar, will be proportional to the number of jars employed.

The effects of condensed electricity are very powerful. If the spark be passed through a bad conductor, such as shellac, resin, or glass, it may be shivered into powder. A fine wire of metal will be made red-hot, or even melted, by the discharge of a good battery. The physiological

effects also are tremendous. A single jar, of moderate size, is sufficient to give a shock to a whole regiment. The men have simply to join hands and form a ring, the first man holding a jar, and the last man touching its knob. All will feel the shock at the same instant, so rapid is the rate of discharge. Indeed, the velocity of electricity, or of electric discharge, is almost incredible. Wheatstone, by a very ingenious method, has calculated that it can be no less than 288,000 miles a second—that is, it might flash round our earth in one-tenth of a second. More recent experiments and calculations, however, bring the velocity much nearer to that of light, which is about 190,000 miles a second.

ATMOSPHERIC ELECTRICITY.

Lightning.—Franklin was the first to identify the lightning flash with the electric spark. By his famous kite experiment, he found that the thunder-cloud acts just like the charged conductor of an electric machine. The same disruptive, burning, and luminous effects are common to both, though in vastly different degrees. There are several kinds of flashes. First, there is the zigzag flash, or *forked-lightning*, which appears as a broken line of light, bright, thin, and sharp at the edges. It may pass between clouds, or it may dart from the clouds to the earth. Often it splits up into branches as it approaches the earth, and they may be sometimes several thousand feet apart. Its zigzag form is owing to the resistance of the air. Second, there is the large indefinite blaze of *sheet-lightning*. It seems to spread over a large space, and is not so intense as forked-lightning. It is ascribed to an electric discharge within the clouds themselves, which illuminates their mass for a moment. When it occurs at a great height or distance, no thunder is heard, and a vague flash passes across our field of view. Such is common in summer evenings. A third and less frequent form is that of *ball-lightning*, which is perhaps rather a meteor than an electric phenomenon. It is said to occur in this way. After a violent explosion of lightning, a ball is seen bounding like a bomb to the earth. When it reaches the ground, it either splits up at once and disappears, or it rebounds like an elastic ball before doing so. It may last as long as ten seconds, and is thus very different from the flash, which has been proved to last less than one ten-thousandth of a second. It is very dangerous, and readily sets fire to any building in its way.

Thunder.—The *snap* of the electric spark is heard on a grand scale in the thunder-clap, which accompanies the lightning. Whether it is due to the disruptive scattering of the air particles in the line of discharge, or to the rushing in of air to fill up the vacuum produced, is not quite clear. Nor can the prolonged rolling, the strange rising and falling of the peal, be properly accounted for. When the thunder is near, it is short and sharp, though the same report may have been heard as a long roll at a distance. The echoes sent between the clouds and the earth may account for this rising and falling to some extent, but not fully. Some assign the cause to the zigzag path of the flash, forming a series of centres of sound, not all in a line. The waves of sound may alternately swell into one roar, or meet and weaken each other. Thunder is not so loud as we are apt to fancy it. It has never been heard more than 14 miles from the flash. The cannonading at Waterloo was heard at Creil, in the north of France, about 115 miles from the field.

Lightning-conductors.—Electricity, like any other force, always takes the easiest route. We have seen that, if we hold a pointed rod of metal to the prime conductor of a machine, its electricity will be all drawn silently off to the ground, as fast as it is produced. In the same way, if we present a pointed rod near to a charged cloud, its electricity will pass silently and harmlessly to the earth. This is the principle of the lightning-conductor. It is a pointed rod of copper or galvanised iron, reaching from 8 to 30 feet above a building, and carried down to the earth, in which it is carefully buried. The part above the building is called the *rod*, and the rest the *conductor*. They must be very carefully constructed, otherwise their presence is the opposite of protective. It is led down two feet or so into the ground, and then turned away into a well or water, if possible, or else into a drain filled with charcoal for 12 or 16 feet. In large buildings, there are several rods all connected to one common conductor. In ships, there is one on each mast, leading to the metal of the keel. When properly made, they are, beyond all doubt, sufficient protection from the ravages of lightning.

Ordinary Electricity of the Atmosphere.—In all kinds of weather, clear as well as cloudy, the air is more or less electrified. With a clear sky, it is always *positive*, and more or less at different times during the day. It is most strongly electrical shortly after sunrise, and again shortly after sunset. It is least when the heat of the day is greatest, and also just before sunrise. These changes are explained by the effect of the sun's rays on the moisture present in the air. In cloudy weather, it is sometimes positively, sometimes negatively, electrical. Rain, snow, hail, &c. when caught on an electroscope, are found sometimes positive, and sometimes negative. The cause of this electricity of the air is not satisfactorily explained. Some ascribe it to evaporation and vegetation. Some ascribe it to induction by a permanent negative electricity, resident in the earth.

GALVANISM.

The discovery of galvanism was the beginning of a new era in the history of electrical science. No results of great practical value had followed the study of the electricity of friction. Its nature was so capricious. A constant tendency to escape made it difficult to excite, and yet more difficult to control; and it found a place merely in the laboratory of the philosopher, or among the curiosities of the drawing-room. But the revelation of another and an easier mode of producing the excitement soon drew the attention of the whole scientific world. This new field of investigation displayed an entirely novel class of phenomena; and the short period of half a century saw marvellous and unexpected results. Frictional electricity thus became of subordinate importance, while galvanism or voltaic electricity became of the highest practical interest.

Elementary Facts.—Galvani, an Italian professor of anatomy, discovered, about the year 1780, that the limbs of recently skinned frogs were convulsed, if near an electric machine, whenever he drew sparks from the prime conductor. Experimenting on this electric susceptibility of frogs, he accidentally noticed one day a similar convulsion from a totally different cause. This was when a copper hook, stuck through the spine of a frog, came in contact with a piece of iron which was touching the muscles of the leg. The same action, though less energetic, took place when he connected the nerves of the back with the muscles of the leg by a single metallic conductor. Galvani identified the effect with that produced by the electric machine; and, after a great number of experiments, he ultimately ascribed it to the flow of a vital electric fluid from the nerves to the muscles. One fluid he considered peculiar to the muscles, and the other to the nerves.

Volta, an Italian professor of natural philosophy, repeated these experiments, but came to a different conclusion. As the action was much more violent when *two* metallic conductors were used, he inferred that the mere *contact of the different metals* was the exciting cause of the electric flow. One of the metals assumed the positive, and the other the negative electricity, and the frog's limbs but served as a sensitive connector. Such was the voltaic view.

It was, however, a problem which of the explanations was the true one. Each theory had its advocates and supporting experiments, and each party its name for the new species of electricity. Thus came the origin of the two terms galvanism and voltaic electricity, which are now used indifferently. Volta's theory had perhaps most support at the time. Yet Galvani's is not without reason, and may be said to be re-established by modern experiments on animal electricity.

In support of his theory, Volta devised many ingenious experiments, and among others was a simple apparatus, which excited extraordinary interest in its day. It is called *Volta's pile*, and was invented by him to shew the effect of a combination of metallic contacts. It consists of a number of pairs of round discs of copper and zinc piled together, as shewn in fig. 18. The copper and zinc of each pair were soldered together, and the zincs all faced the same way in the pile. Moist discs of cloth were put between each pair, merely, as Volta held, to prevent direct contact between the pairs, and yet be a sufficient conductor. The pile is insulated, and, as afterwards modified, ends in a copper plate above and a zinc plate below. By this means, a powerful accumulation of positive electricity was found at the copper plate, and of negative at the zinc. When the two ends of the pile were connected by a wire, a strong and steady flow of electricity set in from the one side to the other. On the limbs of a frog, the effect was much more violent than that of a single pair of metallic conductors. So, then, argued Volta, the mere contact of the copper and the zinc produces opposite electricities in each. For the more he multiplied the contacts, the greater was the electrical power of the pile.

Fig. 18.

Volta's theory took little account of the moisture of the cloth, but its importance was not to be overlooked. It was observed that, after a time, the zinc plates got corroded by the action of the moisture; and, if the cloths were wetted with salt water, a stronger electric action resulted, as well as a faster corrosion of the zincs.

Suspicion fell on this very *corrosion* as the real active agent in the matter. The doctrine of Volta was challenged by several eminent philosophers; and a theory tracing voltaic electricity to chemical action was set up against it. By the genius and labours of such men as Davy, De la Rive, Becquerel, and Faraday, a vast array of evidence has been brought to bear in favour of the chemical theory. It has been shewn, on the one hand, that in the experiments which were given to *demonstrate* the contact theory, chemical action is really at work, and that, if it be prevented, no electricity appears. On the other hand, it is proved that chemical action, or the union of two substances having a *chemical affinity or attraction*, is always accompanied by the liberation of electricity.

To put such matters beyond dispute is extremely difficult. There are no theoretical reasons why mere contact of dissimilar metals should not give rise to a statical charge, or, in more modern language, to a difference of electric potential in the metals. Recent experiment seems to reassert that mere contact does actually produce electricity, and that Volta was perhaps not so far wrong after all.

General Idea of Galvanic Action.—It is in accordance with the chemical view, that we proceed to examine the conditions essential to the galvanic current. The elementary form of arrangement, seen in fig. 19, is called a *galvanic element or couple*, and will serve to explain the nature of the action. A plate of copper, C, and a plate of pure zinc, Z, are put into a vessel of water, mixed with a little sulphuric acid. So long as they do not touch, nothing is seen, and no chemical action goes on. But the moment they touch at any part, either within or out of the liquid, bubbles of gas are seen at the copper plate, and they continue to form till we separate them again. We have the same result if we connect the plates, not directly, but by wires fastened to the plates. All that is visible is the production of the gas bubbles. But a hidden and most curious electric action is going on along the

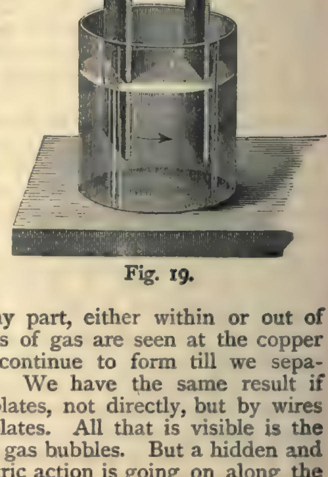

Fig. 19.

wire, and, indeed, through the whole arrangement. If we break the connecting wire, we may find, by the gold-leaf electroscope, that the end of the wire fixed to the copper is positively electrified, and the other wire negatively, though each in an extremely feeble degree. There the electricities remain shut up, and the chemical action suspended, till we bring the ends together. Then the opposite electricities combine and neutralise each other; and the whole, plates and wires, will be discharged or reduced to electric rest. But only for the instant; the action of the acid water sends a fresh supply of opposite electricities to each plate. So there is an incessant production and combination of the two electricities.

This constant succession of electric discharges is called a *current*, and it is said to *flow* in a *circuit* through the liquid, plates, and wire. If the circuit be *anywhere* broken, as by cutting the wire or lifting one plate out of the liquid, the *flow* of electricity instantly ceases. But the ends of the circuit, where the break is, become charged with opposite electricities; and the excitement is then said to pass from the *dynamic* or motive state to the *static*, or reposing state.

Theory of Action of a Galvanic Couple.—On collecting some of the gas, which is seen to form at the copper plate, we find it to be hydrogen. Why it should appear there, and not at the zinc, and why it should be formed at all, we shall now explain. When the plates of a galvanic pair are put in acidulated water, they are instantly thrown, by the action of the acid on the zinc, into opposite electrical states. The *zinc* becomes *positively*, and the *copper negatively*, polarised on the face next the liquid. But between the two plates, the liquid is also thrown into a polarised state. Water, as has long been known, is not a simple but a compound body, formed by the chemical union of oxygen and hydrogen. Each molecule of water may be looked on as an atom of oxygen bound to one of hydrogen, and these molecules are perfectly movable amongst each other, so that they can take up any position. Zinc and copper have each an affinity for oxygen, but zinc far more than the copper. When a plate of each is put into acid water, then we have this result along each line of molecules. The zinc plate turns the oxygen end of the first molecule to itself, and weakens its attraction for its hydrogen fellow. The latter turns its spare strength to attract the oxygen of the next molecule, and so on, till ultimately the positive hydrogen is presented to the copper, for which it has no liking, and induces on its face a negative polarity. In this way, then, we see the action of the acid water on the zinc, or the chemical affinity between the two, is a force urging all the particles of the liquid to set in a certain direction. In like manner, the chemical affinity of the copper for the oxygen tends to set the particles all in an opposite direction. The difference between these two forces constitutes what is called the *electro-motive force* of the couple. Had we taken a plate of silver with the plate of zinc, the resulting electro-motive force would have been still greater, because silver has less affinity for oxygen than copper has. But had we taken two plates of zinc, or two of copper, we should have been setting two equal forces against each other, and the electro-motive force would be *nil*. As a general rule, *the electro-motive force is greater the greater the difference of the metals in their liability to be acted on by the liquid.*

The face of the zinc, then, has positive, and the face of the copper negative, electricity; and all their molecules will be thrown into a polarised state, in accordance with our previous notions of electric action. By the doctrine of polarity, the further ends of each wire attached to the plates will have an opposite electricity to that on their faces. That is to say, the end of the wire from the copper will have positive, and the end of the wire from the zinc negative electricity. But the whole system, we are to remember, plates, wires, and liquid, is really in a polarised state.

When, now, we bring the ends of the two wires together, the positive electricity in the end of the copper wire tends to unite with the negative at the end of the zinc wire. Yet so feeble is the degree of polarity, or so weak is the *tension* of each electricity, that they are unable to unite unless there be absolute contact. When there is this, the two combine, and an instantaneous electric discharge is set up along the whole polarised course. The zinc can now unite with the oxygen atom next it; the hydrogen atom thus set free unites with the oxygen of the next molecule to re-form water; and so the hydrogen and oxygen atoms pair off, till next the face of the copper is left an unmatched atom of hydrogen. Having no affinity for copper, the hydrogen escapes in its natural form of gas. There is thus, with such a galvanic couple, an incessant union of oxygen with the zinc plate to form zinc oxide, and a setting free of hydrogen at the copper.

For the sake of simplicity, we have here supposed the liquid to be pure water. But this would only give a very feeble current, for the oxide of zinc, being a bad conductor, would stick to the surface of the plate and stop the action. A little sulphuric acid added to the water serves to dissolve this zinc oxide, and keep the surface of the plate clean and ready for action. Theoretically, the action is the same as before. The liquid may be regarded as formed of two atoms, one of hydrogen and one of *sulphion*, formed by the union of the sulphuric acid with the oxygen of the water. This sulphion atom behaves exactly as the oxygen did: it unites with the zinc to form sulphate of zinc, and hydrogen escapes at the copper plate.

Electro-chemical Order of the Elements.—We have just seen that zinc takes positive, and copper negative, electricity, when they form a galvanic pair, simply because zinc is the more oxidisable of the two. If we form a pair with copper and gold plates, we find the copper plate is now the positive one, and the gold the negative, because gold is even less oxidisable than copper. The plate which is more oxidisable, or more readily acted on by the liquid, always becomes positive, and is therefore said to be electro-positive to any less oxidisable metal. Knowing the relative degree of oxidability of any two metals, we can at once tell how they would act as a galvanic pair. The direction of the current is *defined* as being from the positive plate to the negative *within* the liquid, and from the negative to the positive *without*. Therefore, we have a general rule that, if we form a galvanic couple with any two metals and a dilute acid, the current will flow *outside* the liquid, or in the communicating wire, *from the metal which is least acted on by the acid to the other.*

In the following list, the more common elements are arranged in order of their oxidability, or in electro-chemical order: *Potassium, sodium, manganese, zinc, iron, lead, tin, bismuth, copper, silver, mercury, platinum, gold, hydrogen, carbon, phosphorus, chlorine, nitrogen, sulphur, oxygen.*

From this we know at once that a zinc-carbon pair will give a current flowing, *within* the liquid, *from zinc to carbon.* It follows, from what has been said, that the electro-motive power of any combination will be greater the farther apart they are in this list. For example, a zinc-platinum pair will be more powerful than a zinc-copper one.

But this is the electro-chemical order only for dilute acids as the exciting liquid. With other liquids, we may reverse the order of the polarity. In a solution of common salt, iron is positive to copper negative; while in ammonia, or hartshorn, iron is negative to copper positive. For dilute acids generally, however, the order is exactly the same, and such as we have given it above.

Galvanic Choice of Corrosion.—It is a curious fact, that if two metals be placed in contact, in a liquid which can act on both, only the one which is more oxidisable will be attacked. In the galvanic pair, the zinc only is eaten away, though the acid would act on the copper if no zinc were present. Hydrochloric acid (or spirit of salt) acts readily on iron, but much more readily on zinc. If, then, a piece of zinc and iron be put in the acid, and made to touch, the zinc will be all dissolved before the iron begin to be corroded.

Another illustration of the same fact is seen in the action of sulphuric acid on zinc itself. If the zinc of a galvanic pair be pure, the acid scarcely acts on it at all until the circuit is complete; but if it be impure, then, as soon as it enters the acid, there is a strong effervescence. The reason is, that the other metal particles, such as lead, carbon, iron, &c. present in the zinc form with it just so many closed galvanic circuits, and the zinc wastes rapidly away. This *local action,* as it is technically called, causes not only a useless waste of zinc, but also a serious enfeebling of the current. Pure zinc would be far too expensive to use for galvanic purposes; but happily it is found that *amalgamating* the plate, or rubbing some mercury over its surface, renders the ordinary commercial article as good as the pure zinc for the purpose.

Comparison of Voltaic and Frictional Electricity.—Although the electricity of galvanism is undoubtedly the same natural agency as that of the machine, there is a marked difference between the two, of which it is important to have a clear conception.

The difference is expressed by saying that, in the voltaic current, we have a large amount or *quantity* of *very feeble* electricity; while, in the electricity of friction, we have *great intensity or tension, but no great quantity.*

A very good illustration of the distinction between *intensity* or *tension* and *quantity* is furnished by the allied excitement of *heat.* The temperature of a body may be called its *heat-tension,* and has very little reference to the *absolute quantity* of heat-motion or excitement possessed by the body. A red-hot poker, for example, has heat of a very high tension, though the quantity is very much less than that of a warm-water bath.

Nor need we be surprised that the properties of voltaic and frictional electricity should differ so widely. The difference is not perhaps greater than that of the powers and properties which belong to heat of weak and of strong intensity. A small wire, made red hot, will suffice to burn the finger or explode gunpowder, though an infinite quantity of heat applied at low tension has no such effect.

In modern language, the electricity of the current is *kinetic* electric energy; that of the machine is *potential* electric energy. The former —or actual motive form of the force—is electric energy in the course of transformation into another form. It will appear wholly as *heat* in the circuit, if it be used to do no *work;* or it may appear partly as heat and partly as chemical or mechanical energy. The sum of the new forms of energy is always an exact equivalent of the primary energy of the current. The potential energy of frictional electricity is, like that of magnetism, power in store, ready to be transformed into *kinetic* energy, such as attraction, when suitable circumstances arise.

GALVANIC BATTERIES.

When a number of galvanic pairs, such as we have described, are put together, so that the currents given by each shall all unite and flow in the same direction, they form a galvanic battery. The copper plate of each cell (fig. 21) is connected, by a strip of copper, with the zinc of the next, so that we have a zinc plate left alone at one end, and a copper at the other. These are called the poles of the battery, and the circuit is completed by joining the poles with a wire or conductor. The group thus acts exactly as a compound galvanic couple, the copper plate being the positive pole, and the zinc the negative. In the *outside* parts of the circuit, the direction of the current is always *from the copper to the zinc,* and in the *inside* or *liquid parts, from the zinc through the liquid to the copper.* By thus joining several couples, the polarisation of the first copper is transmitted to the second zinc by the connecting wire, and serves to heighten the effect of liquid number two in polarising zinc and copper number two. Obviously, therefore, the electro-polarising force of each cell serves to increase that of the next; and the result is, that at the final pole C, the electro-motive force or power to set up polarity along the wire leading from it is very great. It is just as many times greater than that of a single cell as there are cells so linked together.

We must, however, carefully distinguish between the *electro-motive force* of a battery and the *strength of current which it transmits.* In certain circumstances, *one* of the cells will give as *strong a current* as a hundred joined together as a battery, though the electro-motive force of the former is a hundred times smaller. Thus, the strength of the *current* is not to be confounded with the strength of the *cell* or *battery.* The strength or electro-motive force of a battery (or cell) is estimated by the amount of *statical charge* in the ends of the wires, before the circuit is joined—that is to say, by the amount of attraction or repulsion they can produce. So measured, then, the *strength of a battery* may be defined as *its power to propagate electricity, or push forward the polarisation against*

resistance. Now, if this resistance be *small*, the single cell will transmit the polarity as easily as the battery. That is to say, with a short good conductor between the poles, a single cell will give as *strong a current*, and deflect the magnetic needle as much, as a hundred. The superior electro-motive force of the battery has, as it were, no opportunity of exhibiting its power. With a long and difficult conductor between the poles, it is not the same. Here the strength of the battery is seen. One cell may nearly or even utterly fail to establish a polarity throughout such a circuit; yet the battery will push the polarity on in the face of it, and give a strong current, while the cell gives little or none at all.

Requisites of a good Battery.—The objects to be attained in a battery are chiefly two: first, that the strength of the battery, and, therefore, the electro-motive power of each cell, should be as great as possible; and second, that the battery should be able to keep up steadily, and for a long time, its original strength. The first condition must be provided for by selecting metals widely apart in the electro-chemical list, and by avoiding *local action.* As to the second condition, it is not such an easy matter to secure a battery uniform in its action. Several causes operate to impair its strength in course of time. The acid gets weak, and must be strengthened from time to time. Another injurious influence is at work always when the plates are placed in *one* liquid, and face each other directly. This is a tendency of particles of the one plate to pass to the other, and so to reduce that difference in the surfaces which is essential to the action. In the copper-zinc couple, for example, the dissolved sulphate of zinc forms a deposit on the copper plate, while some of the copper also passes to the zinc; so that in course of time the two surfaces become almost alike, and the current almost nothing. This is a grievous fault, but, as we shall see, it can be prevented by placing a porous partition between the plates. It gets soaked with the liquid, and so allows communication to pass. Yet it is close enough to prevent the exchange of metallic particles.

Besides these, there is another very serious cause of weakening, which requires special provision. It is known as *polarisation of the plates.* In all batteries, where hydrogen is set free at the negative plate, there is a tendency of the hydrogen bubbles to adhere to the plate, and a rapid fall in strength of current is the result. The hydrogen not only forms a non-conducting layer over the surface of the plate, but, what is worse, gives rise to a *counter* or a *secondary current.* This hydrogen deposit is prevented by using *two* liquids in place of one. Both must be conducting, and the *unaffected* or *negative element* is immersed in a separate liquid, of such a nature that the liberated hydrogen can act chemically on it, and thus be absorbed as fast as it is formed.

Various Forms of Cells and Batteries.—(1.) *Cruikshank's Trough Battery* was the first improvement on Volta's pile, of which it is but another form. Pairs of copper and zinc plates, soldered together, are fixed in a wooden trough, coated with some insulating varnish. The cells are filled with dilute acid, and correspond exactly to Volta's cloth discs. The defects of assimilation and of polarisation of the plates, described above, combine to make this battery unsatisfactory.

(2.) *Wollaston's Battery* is shewn in fig. 20, and is an improvement on the last. The copper plate is bent up so as to face the zinc on each side.

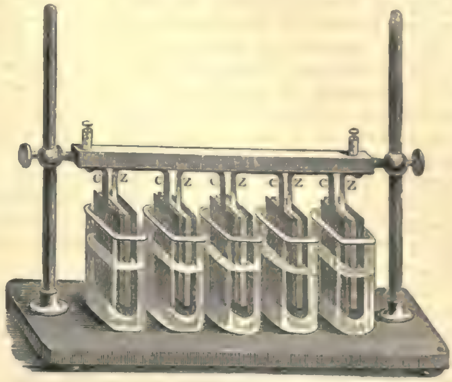

Fig. 20.

This clearly brings twice as much zinc surface into action, and so doubles the *quantity* of electricity which each cell will give. Each couple is immersed in a separate trough, to insure insulation. The zinc of one cell is connected to the copper of the next by a strip of copper soldered to each; and the whole may be raised out of the cells, when not in action, by means of the wooden rod supporting them.

(3.) *Smee's Battery* is, in general, similar to the former; only, in place of a copper, there is a thin *silver* plate, which is more electro-negative, and gives, therefore, greater current power. The positions of the plates are also reversed, to save silver, there being a zinc on each side of the silver, and kept from touching it by strips of wood or cork. The zinc plates are bound together by a coupling, to which the connection from the next silver is fixed. Polarisation of plates may be lessened by covering the surface of the silver with finely-divided platinum.

(4.) *Daniell's Battery*, invented in 1826, was one of the first, and is still one of the best arrangements for constancy. It is a zinc and copper combination, the copper being in the shape of a jar, and serving as the outer dish of the cell.

Fig. 21 represents a Daniell's cell. The zinc, *z*, is formed into a rod, and is placed inside a porous jar, *d*, of unglazed porcelain or earthenware, which again stands inside the copper cylinder, *c*. In the porous dish, dilute sulphuric acid (one part acid to 10 or 12 of water) serves to excite the zinc. As a conducting and absorbent liquid, between the porous vessel and the copper, is put a *strong* solution of the blue crystals known as *sulphate of copper* or *blue vitriol.* Let us have a clear idea of the action of this sulphate of copper solution. It is a beautiful arrangement. Sulphate of copper is what is formed when sulphuric acid acts on copper; and chemistry informs us that, in the process, an atom of copper expels and takes the place of the atom of hydrogen which is present in each

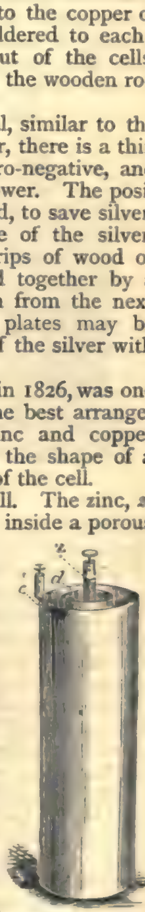

Fig. 21.

molecule of sulphuric acid. In ordinary circumstances, the affinity of the copper for the other elements of the sulphuric acid is greater than the affinity of the hydrogen for them. But when any gas is being set free from a previous combination, its *nascent* or new-born state is a most highly active one. Thus, the hydrogen which is being liberated, at the copper plate, from the water of the solution, is able to displace the copper in it, and return to the bosom of the sulphur and oxygen atoms to re-form sulphuric acid. The copper, deposed from its place, is thrown on the copper dish, and instead of hindering the action, as the hydrogen would do, keeps the surface bright with metallic copper, and so constantly fit for service.

The action of the battery is therefore to form sulphate of zinc in the porous dish, and to consume sulphate of copper in the outer. We must thus keep the solution saturated with sulphate of copper, by having some crystals of the salt lying at the bottom of the cell. Usually, there is a small shelf of copper gauze near the top of the copper vessel, on which crystals may be placed for this purpose.

(5.) *Grove's Battery* has a greater electro-motive power than any we have described, the plates being platinum and zinc; but it is inferior in constancy to Daniell's. Fig. 22 shews an excellent form of a Grove's cell. As in Daniell's, we have a porous dish, *d*, but containing, in this case, the

Fig. 22.

Fig. 23.

platinum plate, *p*, which is bent into the form seen in fig. 23, to increase its surface. Outside of *d* is the rolled-zinc plate, *z*, standing in a glass jar, *g*. The liquids used are dilute sulphuric acid in the outer dish, and strong nitric acid in the inner. When the poles are joined, zinc sulphate forms in the outer vessel, and an unhealthy gas (vapour of hyponitric acid) at the platinum plate, which must be kept from escaping by plugging the mouth of the porous dish. The nitric acid absorbs the hydrogen, and prevents polarisation of the plate.

Platinum is about four times the cost of silver, and that is the only objection to the battery. But it has the advantage of great power, and is very easy to manage; and the platinum does not get useless, as other negative plates do, by the action.

Iron, it is found, may be used for the platinum, with almost equal effect. Only, care must be taken to keep the nitric acid *concentrated*, as it is only then that it does *not* attack iron.

(6.) *Bunsen's Battery* was invented in 1843, and is most powerful. It differs, in principle, from Grove's only in the use of a *carbon* or *charcoal* electrode for a platinum one. In the original form, as devised by Bunsen, the carbon was in the shape of a jar, and the porous dish with its zinc stood inside it. But the modified form, most common here, is shewn in fig. 24. The carbon exactly takes the place of the platinum in Grove's element, and a greater quantity of electricity is obtained from the larger zinc surface. Bunsen's is the most energetic of all the constant batteries, and is almost universally employed on the continent. But it requires very careful preparation, and extreme care in making the carbon connections.

Fig. 24.

We need not describe the process of making the carbon plates, as they are now easily obtained, ready for use, from any electrician.

Recent Forms of Battery Cells.—The extensive use of the telegraph within the last few years has rendered the possession of a simple and cheap battery of good power very desirable. Many forms of cells have accordingly been suggested, and adopted with more or less success. We have here space to notice only those most favourably received.

(7.) The *Daniell Trough* has been adopted by the Post-office, and is said to be a good and economical battery. A wooden trough is divided into cells by glass plates, or varnished slate slabs. These are again subdivided by slabs of porous earthenware. Cast zinc plates and dilute acid go to one division, while copper and its sulphate go to the other. The action is, of course, identical with that of a Daniell.

(8.) The *Density Battery* of Calland is derived from Daniell's principle. Here the porous cell is dispensed with, and the two liquids are kept apart merely by their difference of density or weight. The copper plate is placed at the bottom of the cell among crystals of blue vitriol. A copper wire soldered to it, and protected by gutta-percha, passes up through the liquid to join the next zinc. Over the crystals of copper sulphate is poured a weak solution of sulphate of zinc, in which the zinc plate is suspended so as not to reach the copper solution. The zinc sulphate solution is lighter than the other liquid, and so floats on it without mixing. It is said to be very effective, and to give a constant current for months.

(9.) The *Minotto Battery*, somewhat like the former, has also come into telegraphic use. Coarsely powdered crystals of copper sulphate are placed at the bottom of the cell, the copper plate being under the crystals. A layer of clean sand (or even sawdust) is put over the crystals, with a piece of cloth or porous paper between, to prevent mixture.

The cell is filled with acid water, and a plate of

unamalgamated zinc laid on the sand, or hung perpendicular to the face of the copper plate.

(10.) The *Bottle Battery* of Faure must not be omitted, on account of its neatness and novelty. It is on Bunsen's principle, but no porous vessel is required, the carbon being at once the porous vessel and negative element. The carbon is made in the shape of a common bottle, with a carbon or platinum stopper to which the wire is attached. Nitric acid is put in it nearly up to the neck, and the stopper prevents the escape of nitrous fumes, which are both disagreeable and dangerous. The outside zinc is put in weak acid, as in Bunsen's cell, and the action is identical. Besides dispensing with the porous dish, this form is extremely convenient, and is superior in power to either Bunsen's or Grove's element.

(11.) The *Marié-Davy* or *Sulphate of Mercury Battery* is a Bunsen battery with another liquid in place of nitric acid in the porous dish. This is a solution, or paste, rather, of the white crystalline bisulphate of mercury. Sulphate of zinc is, of course, formed in the outer jar, while metallic mercury is deposited on the carbon, and, from its weight, falls to the bottom of the jar. Any sulphate of mercury passing through the porous dish will do no harm, as it will only amalgamate the zinc. The arrangement is powerful and ingenious, but it is rather expensive. A battery of eight cells gives as strong a current as twelve of Daniell's, but, with steady action, it falls much more rapidly than Daniell's. For interrupted work, such as telegraphy or ringing of bells, it is better suited, and will serve for three or four months.

(12.) The *Leclanché Battery* is the last we shall mention, as it is one of the most recent, and perhaps one of the most successful. It is a zinc-carbon combination. The carbon or negative plate is put in a porous jar, filled with a mixture of gas-coke or carbon, and the black dioxide of manganese. Both the carbon and manganese have first to be broken and sifted free from dust. For the zinc liquid there is a solution of common sal-ammoniac, or chloride of ammonium. Chloride of zinc is formed in the zinc dish, and this is soluble in the sal-ammoniac solution. In the other jar, the dioxide of manganese is reduced to a lower oxide, and ammonia is formed in small quantities.

This cell has great electro-motive power, ten of it being as powerful as sixteen Daniells, and it is thus specially suited for long lines of telegraph. It requires very little attention, and the zinc and chemicals need renewing only about once a year.

GALVANOMETRY, OR THE MEASUREMENT OF CURRENTS.

The magnetic, chemical, or heating effects of a current may, any or all, be taken as a measure of its strength. Sometimes one test is preferable, sometimes another. But, in general, the most convenient test of current strength is the extent to which it deflects a magnetic needle.

Nor does the needle only measure the strength; it also defines the direction of the current by the side to which it swings. Ampere's rule is a simple way of recollecting the connection between the flow of the current and the swing of the needle. It is this: *A person supposed to be swimming with the current in the wire, and having his face to the needle, sees its north pole turn to his left.* This always supposes the current-wire to lie in the magnetic meridian.

From this rule, it is obvious that a current passing *above* a needle turns it to the same hand as an *opposite* current does *beneath* the needle. But by *doubling* a conducting wire, so as to be over and then under the needle, we have clearly the same result. One current will then act twice on the needle, and each time to turn it to the same side. So, by bending the wire round and round the needle, and keeping the different turns separate, we can multiply the effect of the same current to any desired degree. This, then, is the principle of the *galvanometer multiplier*, or *galvanometer*. There are three forms of it on this principle.

(1.) The *Simple Galvanometer* consists of a magnetic needle poised or suspended delicately over a graduated card, and placed within a coil of *insulated copper wire*, so that its oscillations can be seen. Wire is insulated by being covered with gutta-percha, or by being overspun with cotton, or, far better, silk. This is found to be quite sufficient to prevent the current passing from one turn of the wire to another.

(2.) The *Astatic Galvanometer* is the form most commonly used; it is far more sensitive than the last. In place of a single magnetic needle, an *astatic pair* is employed. An astatic pair of magnetic needles is simply a pair of similar needles, with their poles turned opposite ways, and stiffly connected at their centres, so that both will swing together. The one tends always to turn in an opposite direction to the other under the earth's magnetic attraction. If, therefore, they were perfectly alike, we should have a perfectly *astatic* pair, or pair without *set;* that is, they would remain indifferently in any position, neutral to the direction of the earth's axis. It is impossible in practice to have a perfectly astatic pair; there is always more or less a tendency to *set* in one direction. The figure (fig. 25) shews how the astatic pair is used to form an astatic galvanometer. One needle swings within, and the other without the coil, and we have thus a double improvement on the single needle. First, the magnetic force constraining the needle to keep its north and south position is very small; only the difference of magnetism in the needles. Second, the current acts again on the outside needle, tending to turn it to the same hand as the inside one, as Ampere's rule at once shews. By such an arrangement, then, a galvanometer of extraordinary delicacy may be obtained. Fig. 26 shews the usual form which is given to the instrument.

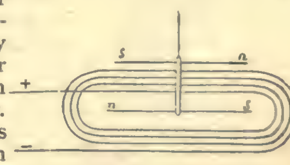

Fig. 25.

Round a bobbin, AB, of ivory is wound a coil of fine, silk-covered copper wire. The number of turns and thickness of wire depend on the use we are to put the galvanometer to. About six hundred or eight hundred does for all ordinary purposes, but for some delicate experiments as many as thirty thousand turns have been made. A slit is usually left in the coil, to admit the lower needle; and the upper needle moves over a

graduated circular rim. The whole is protected by a glass cover from the disturbance of the air,

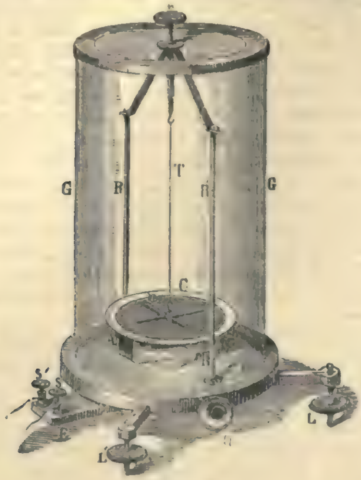

Fig. 26.

and rests on a stand supported by three screws, for levelling the instrument, that the needles may hang free. When used, the bobbin is turned round by the screw, Q, until the needle stands at the zero-point; and the wires through which the current is sent are fixed to the binding-screws, s, s', which communicate with the ends of the bobbin wire. The number of degrees that the needle deflects may then be read off, and this gives an idea of the strength of the current. It is to be observed, however, that twice as great a deflection does not shew twice as strong a current, because for different angles of deflection the coil is differently situated towards the needle. Still, we are sure that a greater deflection indicates a stronger current; and for about 20° on each side of the zero, the strength may be taken as proportional to the angle of deviation.

The third form of galvanometer multiplier is called the *Differential Galvanometer*. It is used for comparing the strength of two currents, and is a simple modification of the last.

For the description of other forms of current measurers, such as the *Tangent Galvanometer* and the *Sine Galvanometer*, the reader may refer to any of the larger treatises on the subject.

The *Reflecting Galvanometer* of Sir William Thomson is by far the most delicate of all our galvanometers. It was invented by him in connection with the Atlantic telegraph, and we shall describe it under *Submarine Telegraphy*.

Measure of Current Resistance.—Bodies differ to an almost incredible degree in the resistances they offer to the passage of a current. When a current has to face great resistance in its course, part of its power is spent in overcoming this resistance, and *disappears as heat*. Thus the current is weakened in the same degree as it is resisted; and it is *interrupted* when it is wholly *unable to overcome the resistance in its path.*

The determination of the relative resisting powers of metals is thus a matter of great importance. But it is also a matter of extreme difficulty, for temperature and purity of metal have a great effect on it. Thus $\frac{1}{8}$th per cent. of iron present in copper will increase its resistance to the current by as much as 25 per cent. Silver offers the least resistance of all our conductors, and copper the next smallest. The other metals follow in this order—gold, zinc, platinum, iron, tin, lead, mercury. Between silver and mercury there is a wide difference in resisting power; mercury offers fully sixty times the resistance of silver. But between the metals and liquids there is a yet wider difference. If copper offer a resistance of 1, then dilute acid offers a resistance of 1 million; a solution of copper sulphate, of 17 millions; and pure water has the almost incredible resistance of 6700 million times that of copper.

The law which the resistance of wires has been found to follow is, that it is greater the greater the length of the wire, and less the greater its area of cross section. Or, in more precise language, *the resistance is proportional directly to the length of a wire, and inversely to the area of cross section or square of its diameter.* Thus, we should have as strong a signal by a telegraph wire $\frac{3}{8}$ inch diameter, and nine miles long, as by one $\frac{1}{8}$ inch diameter, and only one mile long.

EFFECTS OF THE GALVANIC CURRENT.

These may be classified as mechanical, magnetical, physiological, heating, luminous, and chemical.

The first two classes of effects will be described under the distinct head of Electro-magnetism. We have seen that the physiological were the first observed effects of the current. They will be more particularly noticed under Animal Electricity, to which Galvani's experiment properly belongs. It is remarkable that when the current passes through the human body, nothing is felt except at the beginning and end of the current flow. It is the sudden change of tension that affects the nerves; and that is the reason why the frictional shock is more painful than the galvanic. A battery of even fifty Bunsen cells may be handled without much inconvenience. Only this is so far owing to the insulating nature of the skin. If we wet our hands with salt water, the effect is greatly increased; and a very *weak* current will be felt if we let it enter by a cut in the skin.

The senses may be readily affected by the current, especially those of taste and sight. If we put a half-crown under, and a piece of zinc above the tongue, a peculiar salt taste is perceived whenever we make them touch. When the pieces are put between the gums and the cheeks, a flash of light is seen each time they are joined. The nerves of hearing are not so quick, but with the poles of a battery of thirty cells inserted in the ears, it is said that a continuous noise is heard.

Heating Effects.—When a current passes through a thin wire, the wire becomes heated, more or less according to the strength of the current and the resistance of the wire. A fine steel wire, which offers great resistance, may be made white-hot, melted, or even dissipated into vapour. Even platinum, which cannot be fused by the heat of a furnace, may be melted and volatilised by a battery of thirty to forty Bunsens.

A useful application of the heating power of the current has been made to the firing of gunpowder. If the wires from a battery communicate with a fine steel wire embedded among gunpowder, the passage of a current will heat the steel red-hot,

and produce an explosion in a moment. This principle has been employed with great success in the construction of cartridges for use in blasting operations, and they have become very common on account of their safety and certainty of working.

Luminous Effects.—When the wires from a powerful battery are brought near to each other, no current passes till they touch. On separating them, a bright spark passes, due, as we shall afterwards see, to *induction.* Nor does the current cease after a *small* separation. It forces its way across the short interval of air, producing a brilliant light, and a heat so intense as to melt the most infusible metals. The ends of the wires will therefore be burned away, and we must seek for some more infusible conductor, in order that the current and the light may continue. This is found in the various kinds of carbon, such as charcoal, coke, &c. By far the best form of carbon for this purpose is the charcoal deposited in the retorts of gas-works. The carbon is formed into pointed

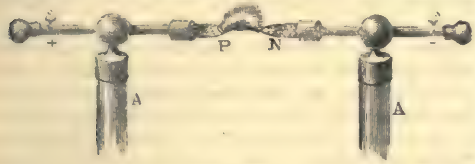

Fig. 27.

sticks or pencils, to fit two metal-holders such as are shewn in fig. 27. They can be adjusted to any distance by sliding-rods, to which they are fixed, and which communicate with the wires of the battery. When the current is on, and the points separated by one-tenth of an inch or so, a most dazzling light is produced, rivalling that of the sun in purity and splendour. It is too bright for the eye to examine it; but an image of the points can be cast on a screen, and then there will be seen, as in the figure, an arch of flame between the points. This arch of flame, or the *voltaic arc* of the electric light, is composed of white-hot particles of charcoal flying from the one pole to the other. The positive pole gradually gets hollow, while the negative remains pointed, apparently by the addition of matter.

The heat of the voltaic arch is the most intense that can be artificially produced. Platinum melts in it like wax in the flame of a candle. Quartz, lime, and magnesia are fused by it; and the diamond itself is not only fused, but reduced to a black mass like coke.

As the carbon points waste away, and the positive much more rapidly than the negative, some arrangement is necessary to keep the points at such a distance that the current can pass, and so the light continue. This is the object of the *electric lamp.* For an account of the principal lamps in which the voltaic arc is used, and the other species called *incandescent* lamps, see page 496 of the present volume.

Great progress has recently been made in methods for applying the electric light to the illumination of streets in cities; and its close rivalry has led to more economic and effective methods of using coal-gas, which for ease in use and cost has still for general purposes the superiority. The electric light has, however, been used for streets and public buildings. It has also long been used with excellent effect where a limited space had to be lit up for a few nights, as in the construction of bridges across rivers, and the like.

For lighthouses it is specially suited, and has been successfully adopted in many of them. That at Dungeness has been lit up with it since 1862; and that at La Heve, near Havre, since 1863. It is decidedly superior to oil-lamps in such cases, as its illuminating power is very great, and remarkably penetrating in hazy weather.

Chemical Effects.—When a current passes through a liquid, composed of two or more simple elements, there is in general a separation of the elements or a decomposition of the liquid. *Electrolysis* is the name given to this decomposition, the liquid so broken up being called the *electrolyte.*

The analysis of water by the current may be taken as the type of electrolytic action, and a very simple method of shewing this is seen in fig. 28.

Two slips of platinum are soldered to two copper wires, which are passed through a cork at the bottom of a glass basin. The basin is filled with water, slightly acid to make it conducting. Now when the platinum plates are connected with the wires from a battery, the liquid is polarised, oxygen going to the positive plate, and hydrogen to the negative. If the current be strong enough, these elements will be separated from the liquid, and as platinum combines with neither, each will bubble up at its platinum pole. They may easily be collected separately by filling two glass tubes with the acid water, and inverting them over the plates. Doing this, we find that the hydrogen is produced in twice the quantity of the oxygen; and we learn from this the important fact, that *elements are decomposed by electrolysis in the very same proportion as they are united in the compound*, for water, we know, has two atoms of hydrogen for each of oxygen.

Fig. 28.

Faraday called the two poles at which the elements appear, the *electrodes*, that is, electric ways, the positive pole being called by him also the *anode* (or *up* way), and the negative, the *cathode* (or *down* way). The element that goes to the anode he called the *anion* (or *up-going* one), and that to the cathode, the *cation* (or *down-going* one). In the case of water, oxygen is the anion or electro-negative element, and hydrogen the cation or electro-positive one.

It is to be noted that a *single cell* can never decompose water, or any electrolyte; at least two are required to overcome the polarisation of the plates or counter-current which the anion and cation tend to set up. The greater the strength of the current, the more rapidly are the elements liberated; and the quantity of gas given off corresponds exactly to the current power.

Faraday turned this to practical use as a *voltameter*, or current measurer, and its value is that

it gives us a *uniform standard* for comparison of currents. The gases are collected either together in a single vessel, or each in a separate one; the vessels are graduated, and the number of cubic inches of gas which a current gives in a certain time, say a minute, is an exact measure of its power.

Any other substances, if in a liquid state, composed of two elements, a metal and a non-metal, can be broken up by the current exactly like water.

The metal always corresponds to the hydrogen, and goes to the negative pole.

In the electrolysis of a solution of a salt, such as copper sulphate, we have an interesting case. If two platinum poles are put in a solution of this, pure metallic copper is deposited on the negative pole, and free sulphuric acid and oxygen appear at the positive; and layer after layer of fine copper-dust will be showered on the negative plate, so long as the sulphate of copper lasts.

In the same way with a solution of nitrate of silver, pure metallic silver will be deposited on the negative pole, and acid and oxygen on the other. All the common metals, gold, silver, platinum, copper, zinc, &c. can be deposited in this manner.

Electro-metallurgy is the practical application of this power of the galvanic current to precipitate a metallic layer on any surface which forms a negative electrode of a battery or cell. It is divided into two sections—*electro-typing*, where the coating of metal must be firm, and has to be removed from the surface, and *electro-plating*, when it is to remain fixed on the surface.

(1.) *Electro-typing* is the process by which seals, medals, engraved plates, ornaments, &c. can be most accurately copied, and reproduced in metal, more especially copper. We can best explain how this is done by taking a particular instance.

Suppose we wish to copy a seal in copper. An impression of it is first taken in gutta-percha, sealing-wax, fusible metal, or other substance which takes a sharp impression when heated. A wire to convey the current is stuck into the impression while soft, and, if the surface be non-conducting like gutta-percha, it is brushed over with plumbago or black-lead. Then it is attached by its wire to the negative or zinc pole of a weak Daniell's cell, while a plate of copper is attached to the other pole. The two are immersed in a strong solution of copper sulphate. Gradually, the copper from the sulphate is deposited on the black-leaded surface, until in a day or so a tolerably thick plate is formed. It may easily be detached by the point of a knife, and then we have a faithful copy of the original seal to the minutest line.

But we may even do without a battery cell altogether, and make a galvanic pair out of the object to be coated and a plate of zinc.

Electro-typing is of great importance to the engraver. Copper plates may be multiplied to any extent; and woodcuts, which would soon become useless, if printed from directly, can be converted into copper plates. Indeed, nearly all the illustrations in popular works are now printed from electro-types.

(2.) *Electro-plating* is the art of coating by the galvanic current the baser and cheaper metals, such as brass, bronze, copper, nickel silver, &c. with the more precious ones, such as silver and gold. Theoretically, the process is simple enough, but practically, it requires much experience and skill. When an article is to be electro-silvered, it is first thoroughly cleansed, and then washed with nitrate of mercury. This leaves a thin film of mercury, which acts as a cement between the article and the silver. It is then put in a silver bath, a weak solution of cyanide of silver in cyanide of potassium, and attached to the negative pole of a battery; while a silver plate is attached to the positive, to keep the solution, by its decomposition, from getting poor. The process of electro-gilding is very much the same; only the article first gets a layer of copper by electrolysis, and is then immersed in a gold bath. A piece of gold is suspended from the positive pole, and the bath must in this case be kept hot.

ELECTRO-MAGNETISM.

Hitherto, we have considered only the *internal* powers and properties of the galvanic current; we now pass to the effects produced by it *outside of its path*, that is, to its *mechanical* and *magnetical* effects. The former include the mutual attractions and repulsions of currents, and are usually treated of separately, as *electro-dynamics*. The latter include all the phenomena where magnetism is produced by the current, and form the subject of *electro-magnetism*. So closely allied, however, are the two, that the laws of the one class of effects can be deduced from those of the other. Electro-magnetism may thus be employed as including electro-dynamics.

The influence of currents on magnets, to which we have already referred in speaking of galvanometers, is mutual: magnets act on currents, attracting and repelling them just as currents do on magnets. Not only so, but currents also attract and repel each other according to very simple laws.

Now, so close is the connection between magnetic and current action, that there is no reason but to refer them to one and the same ultimate cause. Every case of magnetic action, whether of magnets on currents, currents on magnets, or magnets on magnets, can be at once explained by the theory that magnetism is due to electricity in current. Thus the laws of current action are at the foundation of electro-magnetism. They are two, though one is practically included in the other: (1.) Two parallel wires, capable of motion, or two flexible conducting chains, *attract* each other when currents pass along them in the *same* direction, and *repel* when they pass in *opposite* directions. (2.) Two wires or chains, not parallel, but crossing each other, attract when the current runs in *both*, either to or from the point of crossing, but repel when it flows in one to, and in the other from, this point.

These laws are easily proved by experiment with light frames of copper wire. They must be nicely movable upon pivots, and at the same time allow the current to pass round the frames without interruption. Many mechanical actions can be produced by the application of the two laws we have given. For example, a current flowing in a circle, may be made to cause a constant rotation of a wire conveying a current at right angles to the former.

A similar rotation may be produced by putting for the circular current, in the last case, a pole of

a magnet. In fact, the mutual action between a current and a magnet is of such a nature, that if either be fixed and the other movable, there will be a constant rotation of the one round the other; and a change in the direction of the current, or in the pole of the magnet, will reverse the direction of rotation.

Ampere's theory of magnetism furnishes the key to these actions, and forms the link between magnetism and current electricity. According to Ampere, magnetism is due to currents circulating round the particles of a magnet, and *all in the same direction.* The want of magnetism in a steel bar is simply owing to the currents flowing in all different directions, and so neutralising each other.

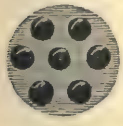

Fig. 29.

Fig. 30.

Fig. 29 shews a section of a magnetic bar with its currents all flowing one way. These are manifestly equivalent to one strong current flowing round the bar, as in fig. 30, for the internal currents destroy each other. Magnetisation is perfect when the currents are exactly parallel, and *coercitive force* is the resistance to this parallel disposal of the currents. Soft iron is more perfectly magnetic when under induction than steel, because iron has less coercitive force.

If this theory be correct, then we should find that circular currents should have magnetical properties. Experiment confirms the inference. When a current passes through a helix or spiral of copper wire it becomes exactly like a magnet. Each end has an opposite polarity; if suspended delicately, it will point north and south like a magnet; and spiral currents act on each other in every way as magnets do.

The nature of the poles is determined by the direction in which the current flows round the axis of the spiral. If, on entering the spiral, the current flow in a direction opposite to the hands of a watch, the spiral is said to be *left-handed*, and the N. pole will be as indicated in fig. 31. If it

Fig. 31.

go with the hands of a watch, it is *right-handed*, like a common screw, and the poles are as in fig. 32. This is in accordance with Ampere's rule;

Fig. 32.

for, if we imagine one swimming with the current and his face to the axis of the spiral, the N. pole is always on his left. In general, then, if we look along the axis at the pole of a magnet, it will be a *south* or a *north* pole according as its currents are seen to flow in the *same* or *opposite* direction to that of the hands of a watch.

Electro-magnets.—Perhaps the strongest proof of Ampere's theory is that a piece of soft iron, placed within a spiral current, becomes *for the time* powerfully magnetic. If bars of steel be placed inside, they are *permanently* magnetised; and a spiral current is thus a very ready and powerful means of magnetisation. Where powerful magnets are required, this is by far the best way of making them, and there is nothing easier: a few turns of insulated copper wire conveying a current will at once convert a steel bar into a magnet by passing it over the bar.

Magnets produced by the action of the current on soft iron are termed electro-magnets. They far outrival permanent magnets in strength; and their value lies in this also, that we can change their poles, or make their magnetism come and go in a moment, as if by magic. If the iron core be very soft, its power is gone the instant we stop the current.

Electro-magnets are generally made of the horse-shoe shape, as in fig. 33, and it matters not whether the coils be wound all over the magnet, or accumulated at the two ends. The power depends only on the number of turns of the coil, and the strength of the current. But there is, of course, a limit to the number of turns; for the advantage of increasing them may be counteracted by the weakening effect of the long wire on the current. The wire which is wound on the core should be thick, so as to be of small resistance, and covered either with silk or cotton. For ordinary sizes, the latter is sufficient, as the electricity most suited to develop magnetism is of small tension and easily insulated. Usually, it is wound, not on the core directly, but on two pasteboard cylinders or bobbins, which can be taken off the magnet at pleasure. With a very thick core, a sufficient number of turns, and a strong battery, we may have any power of electro-magnet. Some have been made capable of sustaining several tons weight. By far the largest that has ever been constructed is that just made for Lord Lindsay. It is said to weigh over 6 tons, and to have 14 miles of copper wire, ¼ inch thick, wound on its core. An equally colossal battery is now under construction for it. The battery will consist of 150 Grove's elements, each exposing a square yard of platinum surface. This gigantic size has never before been approached.

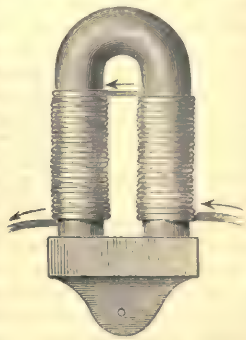

Fig. 33.

The application of electricity to the moving and regulating of clockwork will be found described in the number on HOROLOGY.

ELECTRIC TELEGRAPH.

By far the most wonderful and important application of voltaic electricity is the electric telegraph. The idea of transmitting a signal to a distance, by electricity conveyed along an insulated wire, had suggested itself long before it was practically carried into effect. An attempt was made to employ frictional electricity for this purpose, and the discharge of a Leyden jar was even effected

through two miles of wire. But the appeal to so fickle an agent was fruitless. It was only when the properties of the galvanic current became known, that a solution was found to the problem.

The essential parts of every electric telegraph are three. There must be, first, a *complete circuit* for the current to traverse, including one or more batteries for the generation of the current. Secondly, there must be a *communicator*, or means of producing the signals at the sending station. Thirdly, there must be an *indicator*, or apparatus for shewing the signals at the receiving station.

With regard to the first, there is not much variety or choice of contrivance. A single insulated wire is enough to put two stations in telegraphic communication. Although two wires were at first supposed to be necessary, it was soon found that the *earth* might be made to act the part of a *return wire* to complete the circuit. Thus the current passes from one pole of the battery through the communicator, along the insulated wire to the distant station. After producing the desired signals there, it passes to a large metal plate buried deep in the earth. A similar plate is sunk at the signalling station, and is connected with the other pole of the battery there. Now, we may either regard the earth between the plates as a huge conductor, allowing the currents from the opposite poles to neutralise—that is, as a real return path—or we may simply suppose that equal amounts of positive and negative electricities are drawn off at each end. The current depends on a constant neutralisation of the opposite electricities polarised at the opposite ends of the battery; and it matters not whether they neutralise directly, or the earth neutralise or drain off both together. In order to insure a proper draining off at each end, a very good earth connection, or 'earth,' must be secured, as in the case of a lightning-conductor. One good 'earth' serves for all the circuits of a telegraphic station.

There are three forms of insulation necessary, according as the wire is carried above ground, or under ground, or under water; and the three forms of line are named aërial, subterranean, or submarine, accordingly.

For aërial telegraphs, the wire is usually of galvanised iron, and is attached to glass or porcelain insulators, which are fixed to wooden posts some twenty feet high. Much attention has been paid to the manufacture of good insulators, as everything depends on proper insulation. A small loss or leakage at one pole may be inconsiderable; but in a long line, where thousands have to be taken into account, the loss may be so great, that only a small part of the current that sets out from the battery ever reaches the distant station.

Underground lines must have the insulation perfectly continuous, and the wire is, for that purpose, covered with gutta-percha or india-rubber. These lines are not much used, on account of the difficulty of 'faultless' insulation, the deterioration of the percha or rubber, and the expense of repairs.

In the case of submarine lines or cables, the very greatest care must be taken in the insulation. But on account of their importance, they will be specially described under Submarine Telegraphy.

The *communicator* assumes different forms according to the plan of the indicator or recording instrument. But the general principle is in every case the same. It is merely an apparatus for rapidly interrupting the circuit, and completing it again, or, in some cases, for rapidly changing the pole of a battery with which the wire communicates.

The *indicator* is perhaps the most interesting part of the telegraph, and the number of inventions connected with it is almost endless. In some, the signals are given by the deflection of a magnetic needle to the right or left. In others, again, they are given by mechanism connected with an armature of an electro-magnet. It sways to and fro under the action of the electro-magnet and a counter-spring, or between two electro-magnets.

Indicators of all kinds are either such as give merely a passing signal to the eye or ear, or such as permanently record the signals. *Cooke and Wheatstone's needle telegraph* is the best known of the former class, but it is now little used except in this country. At present, the form most widely used is of the second class, *Morse's recording telegraph.* It leaves, in point of simplicity and accuracy, little more to be desired. We shall, therefore, give the general arrangement of a telegraph chiefly on Morse's system.

Morse's recording instrument, or, as it is shortly termed, the 'Morse,' or Register, is shewn in fig. 34. L is the end of the line-wire which brings the current; E is the end of the wire which passes it

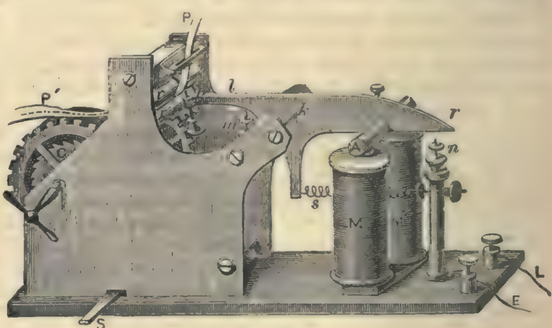

Fig. 34.

off to earth, after it has traversed the coils of the electro-magnet, MM′. When the current passes, and MM′ is magnetic, the soft iron armature, A, is drawn down, and thus the opposite end, *l*, of the lever *ll′*, to which it is attached, is forced up. When the current ceases, and MM′ can no longer attract A, the spring, *s*, brings back the end *l*; and as the current continues alternately to flow and to stop, the lever will keep oscillating between the stops *m* and *n*. At the end *l*, the lever carries a steel point or tracer, *p*, which, by the upward motion of that end, is brought against a strip of paper PP′. Now PP′ is carried towards P′ by the rollers *r*, *r′*, which are kept in motion by clockwork, quite independently of electricity. As long, then, as the pointer is pressed up, the paper strip is made to rub against it, and a line is thus embossed on its upper surface. To make sure of its doing this, there is a small groove in the upper roller, opposite the pointer. It is easy to see, then, that if the pointer press up for a moment only, a

dot will be imprinted, and if for a longer time, a line or dash. By a combination of dots and dashes, an alphabet is formed, the letters oftenest used being most easily signalled. Thus, E is one dot, and T is one dash; A is a dot and a dash, and I is two dots; and so on. But clerks do not spell out every word; they have a great many contractions, universally recognised. The paper is supplied from a large roll or bobbin (not seen in the figure) above the instrument, which turns round as the rollers demand. Of course, it is rolled off only while a message is being sent. When the clerk receives the signal for a message, he pulls out the switch, S, which liberates the clockwork, and sets the paper in motion. An experienced transcriber could easily make out the message though the paper never moved. In practice, he requires to look at the paper only when he has heard indistinctly, for the mere clicking of the lever has become to him a language perfectly intelligible, and it is much easier to hear and write than to look and write. But the printing of the message as well, relieves him of all responsibility as to its accuracy.

The *transmitting key* or *communicator* is seen in fig. 35. It is a brass lever, *ll*, with two nipples, *m*, *n*, one or other of which is in contact with one or other of the projections, *a*, *b*, according as H is pressed or not. The lever is in permanent connection with the line-wire L, *a* with the copper pole of the local battery, and *b* with the local

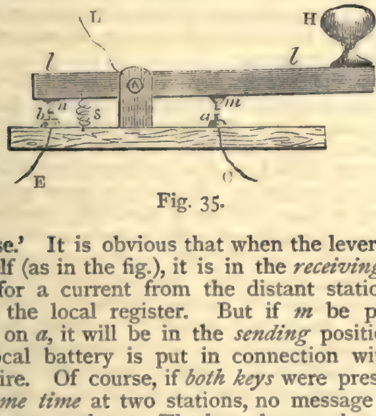

Fig. 35.

'Morse.' It is obvious that when the lever is left to itself (as in the fig.), it is in the *receiving* position, for a current from the distant station can reach the local register. But if *m* be pressed down on *a*, it will be in the *sending* position, for the local battery is put in connection with the line-wire. Of course, if *both keys* were pressed *at the same time* at two stations, no message could pass between them. The lever has a play of not over one-tenth of an inch on each side. This is quite sufficient to break contact, and it allows a very rapid manipulation. An expert telegrapher can transmit from thirty to forty words a minute.

How two Stations are connected.—The manner in which two stations are 'joined up' on Morse's system will be seen from fig. 36. Each station, S, S_1, is provided with its own communicator, indicator, and battery, included in the circuit in such a way that only one communicator and its battery, and the *opposite* Morse, can be in circuit at the same time. In the figure, S is supposed to be sending a message to S_1. Its key, *k*, is depressed, so that the current flows from the positive pole, C, of its battery to the key, and thence to a galvanometer *g*, included in the circuit, to shew the clerk that a current really passes. From *g* it passes through the wire LL to the receiving station S_1, where it passes first through a galvanometer, and thence to the key. The key, being in its natural position, allows the current to pass to the Morse, and there record its variations. Thence it passes to the earth-plate P_1, and is lost, while an equal amount of negative electricity is lost from the zinc pole at P.

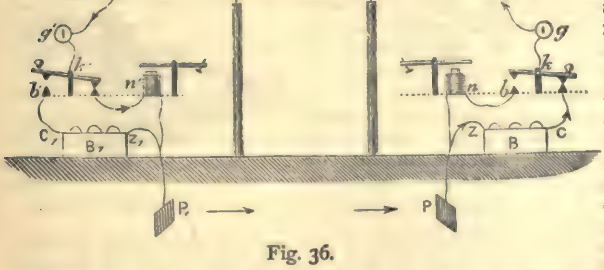

Fig. 36.

If *k* were left to itself, and *k'* depressed, then S_1 would be the sending, and S the receiving station, and the connections would be exactly as in the figure, only at opposite stations. When the clerk at S wishes to telegraph to S_1, he depresses the key several times, and sends a series of dots and dashes, giving the name of the station. The attention of S_1 is arrested by the clicking of the armature of his Morse, or, in some cases, by an alarm, which is made to ring till S_1 come and throw it out of circuit. He thereupon sends back to S that he is ready, and sets the clockwork in motion for the printing to begin.

Relay.—Hitherto, we have supposed that the recorder or Morse is worked *directly* by the line-current. This is only done on short circuits of less than fifty miles. There is so much leakage on a long line, that but a very feeble current

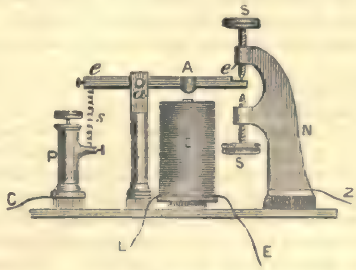

Fig. 37.

reaches the distant station; and to employ battery-power sufficient for direct working of the Morse, would be very expensive. In place, therefore, of passing the line-current through the Morse, it is passed through *a separate instrument*, called a 'relay,' which is much more sensitive than the Morse. It is shewn in fig. 37; and is simply an electro-magnet, E, with coils of very long fine wire, and an oscillating armature-lever, *eAe'*. A very feeble current is sufficient to magnetise the core of E, and to attract A, so that the interruptions of the current by the sending clerk will produce simply a series of oscillations of *eAe'*. Now, the zinc pole of the *local* battery is connected with the metal pillar N, and also with the screw S, but not with the screw S′, which is insulated from the pillar. A wire from the copper pole of the

local battery passes to the Morse, entering where the line-wire was supposed to enter in fig. 34, and a wire corresponding to E (in that figure) passes to the metal pillar, P, of the relay. Clearly, then, a current from the *local* battery will pass through the Morse, whenever a current from the distant station passes through the relay, and the duration of the one will exactly correspond to that of the other; for the local circuit is complete only so long as *e'* is drawn down on S. Thus, a current far too feeble to affect the Morse is sufficient to make the interruptions of a local circuit; and the result is precisely the same as if the Morse printed directly under the action of the line-current.

How several Stations are connected in one Circuit.—There are three ways in which a series of telegraph stations may be joined, so that each may send a message to another, and so that any one may send a message to all the rest at the same time.

The first method is called the *open circuit*, because the circuit is not completed except when the handle of *any* key is pressed down. Each station has a battery, which is brought into circuit by pressing down the key at that station. All the other batteries are out of circuit, and the current passes from the line-wire to the key, thence through the relay, and thence to the line-wire again, at each station without interruption.

Thus each may, if necessary, print a copy of the same message at one and the same moment. The interruptions of the current at the same instant in the different relays open and close the local circuits which include the Morses.

Second, there is the *closed circuit* method, by which the current *constantly* flows through all the keys and relays, *while no one operates.* A single battery at one of the terminals, or, better, one at each end, is quite sufficient for the whole series. The circuit is broken by any one key being pressed down.

A third method is adopted for long lines. It is called *translation.* The two methods of *open* and *closed circuits* are only for short lines of not more than 200 to 300 miles. When two stations, 500 miles or more apart, are communicating, the transmission is generally broken at one or two stages on the way, and retransmitted. This fresh transmission is done *mechanically*, without requiring any attention or hand-labour. The lever of the Morse is made to act as a relay to open and close the current transmitted from a *fresh* battery at its station. Thus, the Morse may register a copy of the message itself, while it serves at the same time to send it on to the next stage. All the intermediate stations may, of course, print copies of the message at the same time. It is in this way that parliamentary news is transmitted from London to all the important towns between it and Edinburgh or Aberdeen.

Cooke and Wheatstone's Needle Telegraph is the most common of non-recording instruments. It is nothing but an upright astatic galvanometer, with the needles loaded, to keep them vertical when at rest. The deflections of the needle to right or left, by the passage of the current through the coils in one direction, or the reverse, constitute the signals. All that is seen of the communicator outside the instrument is a handle under the dial. This handle turns a cylinder inside, which acts as a commutator or current-changer. When the handle is upright, it is in the receiving position, and allows the current from the distant station to pass to the coil of the galvanometer. But when the handle is turned to one side or another, it shuts off communication of the distant battery with its coil, and puts its own local battery in connection with the line-wire, and therefore with all distant stations whose communicators are in the *receiving* position. The needles deflect to right or left accordingly, both at the sending and at the receiving station. A combination of these right and left deflections is used as an alphabet. Thus, A is made by two left deflections; B, by three; M, by one right; R, by one left, then one right; and so on. This is the old way. Now, however, it is usual to adopt an alphabet corresponding to Morse's. A turn of the handle to the right, or of the needle to the left, corresponds to a dot; and a turn to the opposite hand, to a dash. (See fig. 45).

No relay is needed in this case, as the galvanometer needle is sensitive enough to be worked directly by the line-current. Several stations are connected on the *open circuit* arrangement.

There are many other forms of indicator that we have not space to describe. Perhaps the most wonderful contrivances in this branch of telegraphy are the *Type-printing Telegraphs.* That invented by Hughes of New York, in 1859, was one of the marvels of the last Paris Exposition. It actually prints the message in Roman characters on a strip of paper. Its construction is rather complicated, but others of simpler character have lately been invented.

Submarine Telegraphy.—The subject of ocean telegraphs has of late years assumed the greatest importance. From the first unsuccessful attempt at cable-laying, which was made in 1850 between Dover and Calais, to the achievement of laying the Atlantic cable in 1866, was a great stride in so short a time. Many difficulties, seeming at one time almost insuperable, have been overcome, and now the manufacture and management of cables are all but perfect. The points to be secured in their construction are mainly three. First, the insulation must be perfectly faultless, for the smallest flaw is infinitely more serious than in the case of land-lines. Second, the cable must be strong enough to bear the weight of a considerable length of itself, and to resist chafing on rocks and inequalities of the ocean-bed. Third, the very best conducting-wire must be used for the transmitting core, on account of the extremely feeble current which reaches the end of a long cable, even when the insulation is complete.

The construction usually adopted to satisfy these requirements will be understood from fig. 38, which shews (full size) the 'make' of the Malta and Alexandria cable.

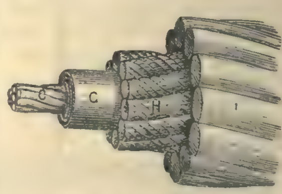

Fig. 38.

The core, C, is a strand of seven copper wires, embedded in an insulating substance, called Chatterton's Compound (= 1 part Stockholm tar, 1 part resin, 3 parts gutta-percha). A strand of wires, though not so highly conducting as a solid wire of the same diameter, is

preferred, because it is less likely to break. Covering the core are three layers of gutta-percha, G, with Chatterton's Compound between each. Over the percha is a coating, H, of tarred yarn, to act as a padding between the insulating material and the external sheathing, I. This consists of eighteen wires of galvanised iron, laid on spirally. It has to bear the strain of 'paying out,' and to protect from roughness of sea-bottom.

The two Atlantic cables, laid in 1865 and 1866, do not differ in any essential from the one described. Their external diameter is 1⅛ inch, and the sheathing consists of ten steel wires, each of which is separately surrounded with five strands of hemp. In water, they weigh about fourteen hundredweight per nautical mile, and each cable would bear about eleven knots of itself in water without breaking. Thus the difficulties of obtaining sufficient strength and insulation have been wholly overcome.

But there remains a more perplexing difficulty still. It is seen on very long land-lines; only it can be easily met in them by retransmission. The difficulty lies here. What is given as a momentary signal at one end of a cable, *oozes* out as a prolonged signal at the other. Time must thus be given for each signal to ooze out before another is sent; and the result is a great delay in the transmission of messages. Sir William Thomson has found that the greatest speed of signalling possible on an air-line, of iron wire ¼ inch diameter, and two thousand miles long, would be twenty words a minute. Now, with the two thousand miles of Atlantic cable, laid in 1858, the greatest speed attained was only 2⅓ words a minute, though its core was a better conductor than the ¼ inch iron wire. The cause of this extraordinary retardation of the current is usually ascribed to an *inductive* action of the water surrounding the cable. In fact, the cable is just an enormous Leyden jar, with its core for the inside coating, the gutta-percha for the dielectric, and the water and sheathing for its outer coating. When a signal is sent, but a very small part of the current instantly reaches the other end. The rest is absorbed on the way, bound as a statical charge by the electricity it has induced on the water. The gradual oozing out of the electricity stored up in the cable, after cutting off the battery connection at the signalling end, is like the residual charges of a Leyden jar. What should come out at the other end as a short, sharp discharge, comes drawling out as a series of them.

No way of preventing this inductive action has yet been found, except thickening the core and insulation. But, of course, only a certain weight of cable can practically be laid. Yet, though it cannot be prevented, its effect on the signals has been in a great measure obviated. The energy and genius of such men as Sir W. Thomson, Mr Varley, Mr Siemens, and others have wrought wonders.

First of all, the statical charge can be got rid of to a great extent in this way. After sending a short signal, the clerk sends a second of opposite name by rapidly reversing the poles of the battery which are connected with the cable. This sends a wave of opposite kind to the first, which serves to counteract its inductive action, and discharge the cable. More than one may be required. For the Atlantic cable, for instance, five signals were considered necessary to completely discharge it: first, a wave from the copper pole, then one half as long again from the zinc, then one from the copper four-fifths of length of the first, and so on.

Next, and not less important, is the invention of a sufficiently delicate indicator to be affected by the extremely weak current which escapes induction. This is found in Sir William Thomson's *Reflecting Galvanometer*, which was adopted for the Atlantic cable. Fig. 39 will give an idea of it. The current is passed through a *small* vertical coil, D, of fine wire, in the centre of

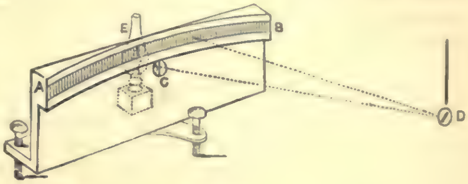

Fig. 39.

which swings a short magnetic needle hung by a silk fibre. The needle carries a small hollow mirror, and, mirror and all, only weighs about a grain and a half. At a distance of two or three feet from the mirror is a solid wooden stand, with a graduated scale, AB, forming part of a circle facing the mirror. In the stand, just under the centre of the scale, a hole, C, is drilled, and a fine wire stretched upright across it. A strong lamp, E, stands behind the opening, so that its light will fall on the mirror, and be reflected back on the scale. An image of the wire will thus be constantly thrown on the scale, and the slightest motion of the needle and its mirror will produce a much greater motion of the image index. As the current flows one way or another, the index will move to one side or another, and thus an alphabet may be formed as with the common needle telegraph. The Morse system is adopted, a dash corresponding to a right, and a dot to a left deflection of the image. To make it come quickly to rest after a deflection, a magnet is placed near the needle, and in this way a very delicate and quick indicator is got.

To the ingenuity of the same inventor is due an *ink-recorder*, which marks the right and left deflections on a paper ribbon. Here the *coil* is movable, and the magnet fixed. The coil is of very fine wire, and is delicately hung between the poles of a strong horse-shoe magnet, and so that the current from the cable can pass through it. It will turn to one side or another, therefore, according to the direction of the current through it. In front of the coil is placed an insulated vessel filled with common ink. Into this dips a very fine glass siphon, the leg of which is attached to the fine coil, and is made to turn with it. It is clear, then, that if ink issue from the siphon, it will trace a straight line (on the paper which passes under it) so long as no signals flow. But a signal will bend the line to one side or another according to its direction. By a very ingenious idea, Sir W. Thomson avoids the rubbing of the siphon against the paper. He keeps the vessel and ink constantly electrified, say positively, and the paper which passes under the end of the siphon also negatively. This produces

a steady flow of ink in a fine stream, just as in the case of the 'electric pail.'

As a proof of the skill and genius brought to bear on the Atlantic telegraph, and of the delicacy of Sir W. Thomson's instruments, it may be mentioned, that a tiny cell, consisting of a copper percussion-cap and a small piece of zinc, has been found sufficient to send a message across the Atlantic. In spite of all the difficulties of the case, signalling is now done as rapidly through it as on any land-line of the same length. Public messages are sent at the rate of eight to fourteen words a minute; but when the clerks communicate with each other, as high a speed as twenty words a minute is attained.

ELECTRICITY OF CURRENT INDUCTION.

Faraday discovered, in 1832, that current electricity may be developed by induction, in a manner somewhat analogous to that in which statical electricity is induced. If a wire, through which a current passes, be brought near to another whose ends are fixed in the binding-screws of a galvanometer, there is an instant deflection of the needle. It soon falls back, however, to its original position, and not the slightest effect is seen so long as the current continues steadily to flow. On withdrawing the wire, or on stopping the current, we again have a deflection of the needle, but this time to the other side. As often as we join and break the current, we have these momentary flows of electricity induced in the galvanometer wire, which will set the needle a-swinging from side to side.

In general, then, it may be stated that the passage of a current in a conducting circuit produces a sympathetic electric state in a neighbouring circuit; so that any change of condition of the first is accompanied with a corresponding electric throb of the second. The effect on the galvanometer circuit will be greater the more rapidly we change the state of the inducing electricity, and the greater the extent of the second circuit influenced by the current.

We must note the directions of the induced currents. By the *approach* or *commencement* of an inducing or *primary* current, a wave passes in an *opposite* direction through the induced or *secondary* circuit; and by the *break* or *withdrawal* of the primary current, a wave passes along the secondary circuit in the *same* direction as that of the primary. Or, shortly, *at make and break of primary circuit, an inverse and a direct secondary current are respectively induced.* There is thus a great difference between current and statical induction. So long as the prime conductor of a machine is charged, it has a *constant* inducing influence on all bodies near it. But it is only a change of *tension* in current electricity which has any inducing power, and the power is momentary as the change.

We shall now describe the method of producing these currents adopted in practice. The *induction coil* is the apparatus employed for this purpose, and the best form of it is that known as *Ruhmkorff's coil.*

Essentially, it consists of two bobbins or coils of insulated copper-wire, an inner and an outer. The inner coil is of thick wire, and through it passes the primary or battery current. It is called the primary coil. The outer is of fine wire, and in it is induced the secondary current, at make and break of the primary circuit. It is called the secondary coil. Sometimes the inner coil is made so that it can be withdrawn from the secondary at pleasure.

The object of this coil-arrangement of the wires is to make each turn of the primary or inducing wire act not only on the turn of the secondary next it, but also on all the turns near it. A vastly greater effect is thereby obtained than if the two wires were simply laid side by side in a straight line. For this reason, too—that the strength of the induced currents depends on the extent of secondary wire under the influence of the primary—very fine wire is used, to give as great a length of it as possible. Induced currents are of high tension compared with battery currents, and the fineness of the wire is no obstacle to the passage of the currents. Only, the finer the wire, and the higher the tension of the secondary currents, the more careful must be the insulation of the different turns and layers. Everything depends on the proper insulation of the secondary coil.

We have said that the wire of the primary coil is *thick.* This is to offer little resistance to the battery current, and to give the maximum of magnetic effect. For the inducing power of the primary increases with its magnetic power. In proof of this, it is found that the addition of a soft iron core in the primary coil increases enormously the strength of the induced currents; and we know it heightens the magnetism of the inducing coil. In further proof of this fact, and in singular confirmation of Ampere's theory of magnetism, a permanent bar-magnet may be put for the primary coil. A current in one direction, or the reverse, is induced when it is put in or taken out of the secondary coil.

Such are the general features of the induction coil. Fig. 40 will give an idea of its appearance. The primary coil is inside and out of view, and

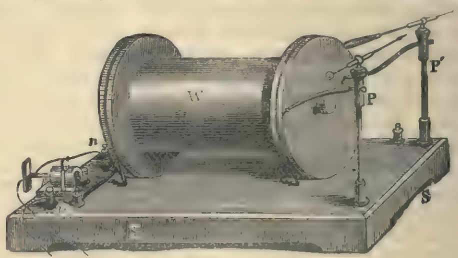

Fig. 40.

the secondary, W, alone is seen. The ends of the secondary wire are soldered to two brass heads, P, P', insulated on glass pillars, and carrying pointed brass rods, capable of universal motion. It is between these brass points that the induced current leaps across. The two battery wires are attached to the two binding-screws, *p* and *n*. Before reaching the coil, the current has to pass through, first, the commutator, C, and, second, a self-acting break not seen in the figure. With the commutator we can turn the current off or on, or reverse it at pleasure, by giving it a quarter or a half turn.

The automatic break interrupts the current with extreme rapidity, and so gives rise to an incessant stream of induced currents.

Extra Currents.—Not only does a current induce electricity in a neighbouring circuit, but it also acts inductively on itself. If we break a current passing through a *long* wire, we observe a bright spark at the part broken. This is very feeble if the wire be short, but very brilliant if it be long, and especially if it be wound in a coil. Obviously, it is not owing to the current being strong, for we know it is weaker the longer the path it has to traverse. The cause has been found to be due to *extra currents* in the wire, produced by the various parts of the wire circuit acting inductively on each other. They are *direct* when the current *stops*, and *inverse* when it *begins*. The effect of the *inverse* current, induced in the circuit when it is joined, is to oppose and so retard the instantaneous passage of the main current; while the *direct* extra current, which follows the break of circuit, has a very weakening effect on the tension of the *secondary* current, if it is allowed to pass by spark or otherwise. This is because it has itself a very high tension, and it tends to prolong the current in the primary wire, and so impair the suddenness of the break, on which the tension of the induced current depends.

The *condenser* is an important addition to the coil, and serves to get rid of the extra current, which, as we have said, forms in the primary wire. It is placed in the sole S, and does not meet the eye. It is simply a number of sheets of tinfoil separated by layers of oiled silk, the odd ones being all connected in one set, and the even in another. Each set communicates with an end of the primary wire, and acts like a coating of a Leyden jar. The whole, in some way or other not well explained, absorbs the extra current, and suppresses its injurious effects on the secondary current.

Some enormous induction coils have been made in recent years, the most powerful being one made for Professor Pepper. There are in it more than two miles of primary wire, and no less than 150 miles of secondary. The iron wire core alone weighs over a hundredweight, and the whole coil about three-quarters of a ton. It is said that, with a powerful battery, a spark of fully two feet can be got from it.

The electricity of the induction coil is more of the nature of the frictional than of the galvanic excitement. The sparks which pass between the 'points' are very like those of the machine, especially if the points be some distance apart. As with common electricity too, the physiological effects are very marked, and are a familiar object of exhibition. The beautiful luminous effects obtained by passing ordinary electricity through rarefied air or different gases, are shewn yet more brilliantly with the induction coil.

On the other hand, the induced current has little power to deflect a magnetic needle, or to effect chemical decomposition. All this shews that the electricity of induction may have enormous intensity or tension, and yet no great quantity; for we know that magnetic and chemical effects are due to electrical quantity only.

In fact, the secondary current is as deficient in quantity as it is superior in intensity to the primary current. Or, in the language of the day, the total energy of the primary current is exactly equivalent to the total energy of the secondary: the kinetic (or actual current) energy of the former is transformed into potential energy of the latter; the potential energy of the primary is small, as is the kinetic energy of the secondary. Induction is a signal example of the conversion of kinetic into potential energy.

MAGNETO-ELECTRICITY.

We have already seen that the action of the primary in induction coils may be exactly replaced by that of a magnet. The approach and withdrawal of a permanent magnet induces two powerful opposite currents in a coil. If, then, we had some means of rapidly removing the influence of the permanent magnet, as we had of the primary coil, by breaking its current, we should have induced electricity from magnetism, and altogether independent of galvanic batteries.

We shall now describe the usual mode by which such magneto-electricity, or magnet-origin electricity, is obtained. Fig. 41 represents one of the simplest forms of magneto-electric machines. NS is a large fixed steel magnet, and BB is a bar of soft iron, which, with the pieces of soft iron under the coils C and D, forms a sort of bent armature to the magnet. Now, it is evident that, as the armature turns round from being in line with NS, there will be first a gradual decrease of magnetic power in its cores, during a quarter of a turn, and then a gradual increase during the next quarter, till CD is again in line with NS. But the decrease of magnetic influence, or the withdrawal of it, induces a current in a coil; and the increase or approach of a magnet induces an opposite current in a coil. Thus, then, as CD turns round from the line of the poles, currents will be induced in the coils, if the two ends of the wire are joined. They will not be produced abruptly, but in a constant stream, as the change of magnetic influence is gradual; and during the first quarter of a turn they will be all in one direction. During the next quarter there is a gradual increase of magnetism in the cores, and this would produce currents in an opposite direction, were it not that there is also a change of poles. This double reversal, therefore, gives currents induced in the same direction as during the first quarter. So, then, during the first half-revolution from the line of the poles, a constant stream of currents is generated all in one direction. In the next half-revolution, the whole state of matters is of course reversed, and we shall have a current flow in the opposite direction. We have merely to introduce a commutating piece, F (which allows the springs, H, K, alternately to

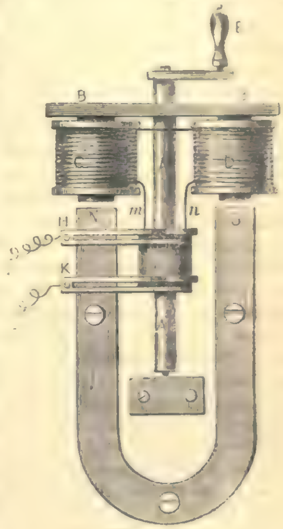

Fig. 41.

communicate with the ends, *m*, *n*, of the coil), to give us a constant flow of electricity in one direction.

With electricity obtained in this way, we may have all the ordinary current effects. Water may be decomposed, platinum wire heated red-hot, and soft iron magnetised. It has been much used for medical purposes, and the physiological effects are very powerful. Magneto-electric machines have also been used for firing gunpowder. *Abel* has lately constructed fuses which may be readily fired with a pocket-machine of this kind.

Such a machine forms a link of the chain that binds all the physical forces together. The force of a magnet, and the force of a man turning a handle, may seem very different, and they do differ widely. Yet they differ only in *form*. With a suitable arrangement, the one form of energy may be, as it were, remoulded and brought forth in the shape of the other.

Recent Magneto-electric Machines.—The magneto-electric machine has now come into extensive use, as being a readier, steadier, and cleanlier source of current electricity than the galvanic battery. Very powerful machines have been constructed on much the same principle as that we have just described. They have been employed for the electric light in lighthouses, and are driven by small steam-engines. We are to look upon them as simply the means of converting mechanical into electrical force or energy. But important modifications in the construction of these have been made in recent years.

Siemens' Armature.—In 1854, Siemens introduced a new form of armature, which brings the coil and its core nearer the poles of the inducing magnet or magnetic magazine. It has the wire wound *lengthways* or *parallel to the axis of its core*, and not across its length, as in common electro-magnets. The core is a cylinder of soft iron, with a large hollow scooped out on each side, leaving it somewhat like a piece of an iron rail. Insulated copper wire is wound along it till this hollow is filled up, and the cylindrical form restored. The *faces* of the core or rail, and not the ends, form the poles of this electro-magnet. It is not rotated *before* the poles of a steel magnet, as in the common machine, but *between* the poles of a series of magnets spanning it like a bridge, whose breadth is the length of the armature. A very rapid rotation can be given to the cylinder round its axis, and the iron faces are magnetised and demagnetised with corresponding rapidity.

Wilde's Machine.—Wilde of Manchester constructed in 1865 a magneto-electric machine of unequalled simplicity, which can be made to convert any amount of mechanical energy into electricity. It is formed on a new and seemingly paradoxical principle—namely, *that the weakest current or magnet may be made to induce any desired strength of current or magnet.*

Wilde's machine consists of two magneto-electric machines, a small one surmounting a large one of precisely similar principle, but of enormously greater strength. The figure (fig. 42), represents an end view of the machine. In the small machine, the inducing power is a magnetic magazine, *m*, of twelve to sixteen steel horse-shoe magnets. It evokes currents in a Siemens armature, which revolves between the poles, *a*, *b*, of the magnets, some 2500 times a minute. Two springs, connected with *n* and *p*, press on the commutator of the Siemens, and are the poles of the upper

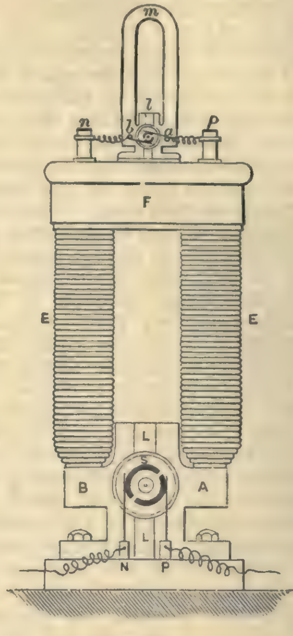

Fig. 42.

current. This current is not used directly, but is sent through the coils, E, E, of the huge electro-magnet of the lower machine. It has a Siemens armature, S, revolving between its poles, A, B, some 1800 times a minute. Both machines are precisely alike in action, and differ only in power. The armatures are both driven by belts from the same shaft. The arrangement of the magnetic poles is very ingenious. It is the same in both, but we shall refer only to the lower. They consist of two masses of soft iron, A and B, hollowed out so as to form the two sides of a tube to inclose the Siemens armature. Pieces of brass, L, L, serve to insulate the two poles magnetically, and to complete the tube. This protects the armature from the resistance of the air, and brings it as near as possible to the inductive influence of the poles.

The effects which this machine is capable of producing are almost incredible. When worked with a three horse-power engine, the current of the second armature consumes carbon sticks three-eighths of an inch square, and evolves a light of insupportable brilliancy. With one that consumes carbons half an inch square, a light so intense is got that, when put on a lofty building, it casts shadows from the *flames* of street-lamps, a quarter of a mile away. Mr Wilde succeeded in melting an iron rod fifteen inches long, and a quarter of an inch thick. Wilde has even employed the current of the second armature to magnetise a second electro-magnet still more powerful than the first. The whole required a fifteen horse-power engine to drive it, and the heat of the current was sufficient to melt a platinum bar two feet long and a quarter of an inch thick. Indeed, the only limit to the amount of electricity which might thus be

obtained, is the mechanical energy required to be expended.

Several modifications of Wilde's principle have been introduced within the last few years by Siemens, Wheatstone, Ladd, and others. Ladd's improvement makes the machine more convenient and simple in form, and promises to make it more popular. Theoretically, these machines are examples of the mutual convertibility of heat or mechanical energy into kinetic electric energy, and of this again into the energy of mechanical force or of heat and light.

THERMO-ELECTRICITY.

As the electric current produces heat, so we may invert the order of the phenomena, and from heat derive electricity. When any two metals, unequally susceptible to heat, are soldered together, and heated at the joining, an electric current is evoked. The two metals which shew this property most readily are *antimony* and *bismuth*. Thus, if a bar of antimony, A (fig. 43), be soldered to a bar of bismuth, B, and their other ends connected with a galvanometer, G, a current will pass when we heat the junction, S. Inside the couple, it flows from bismuth to antimony, and outside from antimony to bismuth, as we know by the side to which the needle swings. If any two of the following metals be joined in this way as a thermo-electric pair, a current will flow, *at the heated junction*, from the one which occurs first in the list to the other—bismuth, nickel, lead, tin, copper, platinum, silver, zinc, iron, antimony, tellurium.

Fig. 43.

If *cold*, instead of heat, be applied at the junction of two metals, it will produce a current opposite in direction to what the heat would. When we plunge the antimony-bismuth couple in ice-water, a current flows *from bismuth to antimony* in the outside wire. One antimony-bismuth pair has little power, but several may be joined, just as in a galvanic battery. Fig. 44 shews the arrangement of such a thermo-electric pile or battery. Obviously, only the odd junctions must be heated, for if all were, there would be no current at all. The current is from bismuth to antimony when a junction is heated, and from antimony to bismuth when it is chilled. Thus the strength of current produced will depend on the difference of temperatures in the two sets of faces. A pretty strong current may be evolved by keeping one set of junctions in ice, or a freezing mixture, and the other in boiling water. The electro-motive force is, however, very weak compared with that due to chemical action. In fact, it takes about one hundred and fifty bismuth-antimony pairs to give the electromotive force of a single Daniell cell, one set of joints being kept at the freezing, and the other at the boiling point of water. For this reason, heat is not available as a convenient source of electricity by any of the means yet discovered.

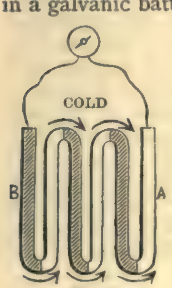

Fig. 44.

It is as a thermometer that the thermo-electric battery has its most important application. When employed for this purpose, it is called a *thermo-pile*. To form it, some twenty or thirty antimony-bismuth pairs are connected as in a battery, and compactly put together with varnished paper between the sides. The whole is inclosed in an insulating tube, so that only the junctions are exposed at each end, and these are blackened, to increase their absorption of heat. Wires connect the end plates with an astatic galvanometer, whose coil must be of *short thick wire*, on account of the feeble tension of heat-excited currents. If either face be heated, a current will arise: if one be heated, and the other cooled, the current will be stronger; but if both be heated alike, there will be no current. So sensitive is such an instrument, that the mere approach of the hand or of a piece of ice, though at a considerable distance, is sufficient to deflect its galvanometer needle. For experiments on radiant heat, this instrument is most important, and now supersedes all others.

A curious effect was observed in 1834 by Peltier, and is sometimes known as the Peltier effect. When a feeble galvanic current is sent through an antimony-bismuth pair, in a direction from bismuth to antimony, and the junction is immersed in water, cooled down to the freezing-point, but not frozen, as much cold will be developed as will make the water freeze. Heat will be produced if we reverse the current, and the water will not then be frozen. In a series of pairs the junctions will be alternately heated and chilled. Only the current must not be too strong, else the whole will be heated.

All these facts have been shewn to be in complete accordance with the modern doctrine of the conservation of energy. If the two faces of a thermo-pile be kept each at a constant temperature, a constant current flows, in the antimony plates, from the warmer junctions to the other; and the energy of the current is an exact equivalent of the excess of heat-energy absorbed at the warmer over that given out at the colder junctions. If the current be not converted into magnetical, mechanical, or chemical force, the heat energy will be entirely recovered as heat in the circuit. But if the current be used to do any work, a corresponding amount of heat will be withdrawn from the circuit.

ANIMAL ELECTRICITY.

The tissues and organs of animals are not only affected by the electric spark and current, but they are themselves also a source of electricity. In general, the strength of their electro-motive power is so feeble that it requires special experiment to detect it. There are, however, some species of fishes which exhibit such a power very readily.

It was long ago known that a certain kind of flat fish, somewhat like a skate, and found on the shores of the Mediterranean, produced a numbing sensation in the arms of the fishermen when they handled it. The Romans called it *torpedo*, from a word meaning to 'benumb,' and this name is now usually given to the whole genus to which it belongs. It has regular electric organs or batteries, placed on each side in the spaces

between the pectoral fins, the head, and gills. Each battery consists of a number (varying according to age) of hexagonal prisms, somewhat like the cells of a honeycomb. The double set of organs is completely under the control of the torpedo; it can give a shock similar to that of a Leyden jar; and Matteucci has even obtained sparks from it.

Among other kinds of fish with a similar power, the most noted is the *Gymnotus electricus*, or electrical eel, found in the rivers of Bengal and Surinam, and common in all the streams flowing into the Orinoco. It is from three to four feet in length usually, though it has been found even six feet long. The whole of its viscera and digestive organs lie near the head, the rest of the body being taken up with the electrical apparatus. This consists of four batteries—two on each side, and placed one above the other, the upper being the larger. The batteries are made up of a number of piles, looking very like galvanic troughs, and numbering from thirty to sixty in the upper, and from eight to fourteen in the lower battery.

Faraday experimented, about 1840, on a specimen of this eel, exhibited in the Adelaide Gallery, in London. The shock which the animal was capable of giving was very great, equal to that of a good-sized Leyden battery. It was strongest when one hand communicated with the head, and the other with the tail, and it was sufficient to stun or even kill fish.

In all such cases we have the extreme of electric development in the animal system. But apart from special organs, living nerve and muscle have an electricity of their own, which fails as life dies out, and is wanting altogether after death. Much attention has been given of late years to this electricity of muscles and nerves; and the discoveries of Du Bois-Reymond, Matteucci, and others, have given the study a title to be regarded as a branch of physical science.

Galvani must, however, be credited with being the father of the science. Frog-limbs, as prepared by him, are still one of the best means of shewing not only the effect of galvanic action on the animal frame, but also the existence of an electro-motive force in the frame itself. Galvani proved that two metals in contact are not required to cause convulsions in the frog-limbs. A single wire joining the spinal nerves with the muscles of the leg causes sensible convulsions, and he argued from this the existence of muscular and nervous currents.

The existence and principal laws of such currents are now beyond a doubt; but we are still in darkness as to their real origin, and their analogy to other known sources of electricity.

In living animals, or in those very recently killed, there is always a current flowing from the interior of a muscle or of a nerve to its surface. These currents cease in warm-blooded animals in a few minutes after death; but in cold-blooded animals, such as the frog, they continue for a much longer period.

That there are natural electricities resident in the nerves and muscles to cause these currents, may be shewn by a delicate galvanometer, or by the quadrant electrometer of Sir W. Thomson. By means of this sensitive electrometer, it is found that the surfaces and the ends of nerve (or muscle) fibres are oppositely charged like the two coatings of a Leyden jar. The sheaths of the fibres are supposed to be such bad conductors that they can act as a dielectric, like the glass of the Leyden jar. A charge is given to the outer surface by oxygenation, or in some other way, and an opposite charge is induced by it on the inside. The current that affects the galvanometer arises from the connecting two oppositely charged parts.

But the curious thing is, that the muscle and nerve fibres are *charged*, while they remain *at rest*, and *action* is accompanied with a disappearance or *discharge* of the electricities. This is like the discharge which occurs when the torpedo puts itself in action. Indeed, the discharge of the torpedo may only be 'the unmasked form of what occurs in a masked form in every case of muscular and nervous action.'

As, then, a natural activity of nerve and muscle coincides with natural electric discharges in their tissues, so an artificial activity is induced by artificial discharges. Mere charge or electrification has no effect, so long as it is constant. It is only a *sudden change of charge* (which is really a discharge) that produces an involuntary and artificial activity.

This explains why the passage of a voltaic current is attended with no artificial production of action so long as it is constant. It is just equivalent to a constant charge of the fibres, and, therefore, to a state of rest. Only at the letting on or taking off of this charge do we have a change of state, which is really a discharge; only then do we feel the *shock;* and only then are the fibres excited. This is easily verified by experiment with the galvanic current, either on the living body, or on the bodies of animals recently dead.

The physiological effects of electricity were among the first observed, and had doubtless a good deal to do with the rapid development of the science. The life-like convulsions excited by it in the limbs of dead animals hinted that nerve-force might be nothing but electricity. Many experiments were made on the bodies of oxen, horses, sheep, and such like, soon after death. Executed criminals were even experimented on, and many of the vital actions were alarmingly induced. All this was to find the connection between vital and electrical force. It was clear there was some relation, and it was thought probable that the two forces might be identical.

Experiment has, however, failed to establish any relation between electricity and life, so definite as it has established between electricity and the physical forces of heat, light, chemical, magnetical, and mechanical force. Man would fain find out the secret of life, and the panacea for all his infirmities. But the problem remains, and will remain, unsolved.

HISTORICAL SKETCH.

Magnetism.—All that the ancients knew of magnetism was the property of the loadstone. Even the compass is comparatively modern. We are not sure of its being known in Europe before the end of the twelfth century, though some say the Chinese had it long before. Columbus, on his famous voyage, first noticed the variation of the compass; and about eighty years after (1576), a London instrument-maker discovered the dip. In the beginning of the seventeenth century,

Gilbert published a treatise on magnetism, in which he first applied the term *poles* to the magnet, and he speculated on the nature of the earth's magnetism, and on magnetism generally. The astronomer-royal, Halley, published the first magnetic charts in 1701. Some twenty years after, Graham, the celebrated instrument-maker of London, discovered the daily variation of the compass. Armatures were not used before 1750, when special attention was given to new processes of increasing and preserving magnetism. In 1770, the magnetism of cobalt and bismuth was first observed. About the beginning of this century, Humboldt inaugurated the system of careful observation of the magnetic elements, and in 1835, stations were established throughout Europe for this purpose. In 1831, Captain Ross discovered the north magnetic pole, and Barlow in the same year suggested an electric theory of the earth's magnetism. Colonel Sabine, in 1837, first published an isodynamical chart of the globe, shewing all places of equal magnetic intensity. In 1845, Faraday discovered diamagnetism; and ten years later, Tyndall shewed that a diamagnetic body assumes a polarity similar in action but transverse to that of a magnetic body when under magnetic influence. More recently, Tyndall has discovered that a close relation exists between the optic axes of crystals and the positions in which they set between the poles of a powerful magnet.

Electricity.—The science of electricity dates from 1600, when Gilbert wrote his celebrated treatise. He has given us the earliest speculations on the subject, and bequeathed to us the name electricity itself. In 1672 was constructed, by Otto von Guericke of Magdeburg, the first electrical machine. It was in the humble form of a globe of sulphur, turned by a handle, and rubbed with a cloth in the hand. This Hawksbee replaced, in 1709, by a glass cylinder; and in 1744 a fixed cushion-rubber was first used by Winkler, a Leipsic professor. Accident led to the discovery of the Leyden jar by Musschenbroeck of Leyden, in 1746. While holding in one hand a glass flask filled with water, which he had just charged from a machine, he happened with the other hand to touch a wire which communicated with the water. He received a very violent shock—so violent, that he declared he would not have another for the kingdom of France. In 1747, Franklin explained the action of the Leyden jar, and in 1752 made his well-known kite experiment. The nature of induced electricity occupied the attention of Wilke, Æpinus, and Canton about this time. In 1768, Ramsden first constructed a plate-machine; and in 1780, Nairne brought his cylinder-machine into notice, its value being that it gave either positive or negative electricity. Volta invented the electrophorus in 1775, and in 1782 his well-known condenser. About 1787, Coulomb investigated the laws of electric attraction and repulsion. After this, the science was thrown in the shade by galvanism, until Faraday, in 1837, made some invaluable researches on statical induction, and shewed its action to be universal. More recently, Reiss, Tœpler, and Holtz have paid special attention to the electricity of friction; and the novel induction-machines of the latter two have rekindled the curiosity of experimenters.

Galvanism, Current Induction, &c.—Little idea could Galvani have had that his accidental discovery, in 1786, was the embryo of one of the grandest sciences which the human mind has developed. It was five years ere he published his researches, and then they were thrown as an apple of discord among the philosophers of the time. Volta next year (1792) discarded Galvani's explanation, and gave in place his now equally famous contact theory; while within the same year another professor, Fabroni, of Florence, *suggested* chemical action as having some share in the phenomenon. With the last year of the century (1799) came Volta's crowning evidence of the truth of his reasoning, his zinc and copper pile, which has proved a boon to science and to man. Volta sent the news of his discovery in 1800 to Sir Joseph Banks, in England, and within a few weeks fresh discoveries commenced. Carlisle and Nicholson decomposed water and several of the salts by means of the pile, and every year saw some new application of this remarkable contrivance. Davy traced the origin of the electricity to chemical action, and Wollaston went farther; he even attributed frictional electricity to chemical action, and proved that it can be made to give chemical effects. The voltaic pile was improved by Cruikshank, who gave it the trough form in 1802, which it subsequently assumed in all experiments. In 1806, Davy discussed fully electro-chemical decomposition; and in 1813, by aid of the enormous battery at the Royal Institution, he discovered the wonders of the electric light. Even as early as 1808, Sömmering proposed to effect telegraphic signalling by an electro-chemical process; but it was not till the Dutch philosopher Œrsted discovered, in 1820, the deflection of a magnetic needle by the current, that the basis of our present system was laid. To the same year belong several remarkable ideas. Schweigger followed up the discovery of Œrsted in a few months with his invention of the galvanometer; Ampere proposed the deflections of its needle as a means of telegraphing through a line of wire, but, strange to say, it was put to no practical test for a dozen years more; and, lastly, Ampere produced his electric theory of magnetism, which has been so remarkably fertile in results.

The immortal Faraday now appears on the field, to surpass by his achievements even Davy, his illustrious master. In 1831–1832, he published, in the *Philosophical Magazine*, his researches on electricity, by which he made known his discovery of volta-electric or current induction, and also of magneto-electric induction. His discovery was embodied in the magneto-electric machines of Pixii, Saxton, and Clarke, which appeared in succession between the years 1832 and 1836. About the same time, Faraday established the definite laws of electro-chemical decomposition, and traced the spark, which appears on breaking a long circuit, to the *extra current*, or its own induction. These years were remarkable in the history of electricity, for, in 1833, Ampere's idea of a telegraph was first put to a practical test. Gauss and Weber, at Göttingen, actually established an electric telegraph, about two miles long, between their magnetical observatory and their physical cabinet. The indicator was a reflecting galvanometer, and they made up an alphabet of right and left deflections of the needle. This, however,

was merely looked on as a scientific curiosity, till 1837, when no less than three practical systems were independently tried. In June of that year, Cooke and Wheatstone patented a five-needle telegraph, which was soon after put in action on the Great Western Railway. Their lines were underground insulated wires, and were undoubtedly the first used for general purposes. Cooke had seen in the lectures of Professor Muncke of Heidelberg, one of Baron Schilling's horizontal needle telegraphs, and had been struck by its practical value. In July of 1837, Steinheil, at Munich, established a system of wires, upwards of seven miles in length, stretching them over the houses of the town. He was thus the first to have an air-line. He also first made use of the earth as 'a return wire.' He had three ways of telegraphing—by the deflections of a needle, by the sounding of two bells, and by printing on a strip of paper dots to right and left with positive and negative currents. In October of the same year, Professor Morse of New York exhibited his printing instrument, which we have already described; but it did not come into practical use till 1844. During these years also appeared new forms of galvanic battery, Daniell's in 1837, Grove's in 1839, and Bunsen's in 1843, the importance of the telegraph having given a stimulus to the study of galvanic action. Faraday, in 1840, by a series of testing experiments, seemed to establish the chemical theory of the galvanic current; yet thirty years later, and the balance of opinion has apparently turned in favour of the contact theory, which Sir W. Thomson may be said to have put beyond dispute. The first successful submarine cable was laid in 1851 between Dover and Calais. In 1858, the first Atlantic cable was completed; but it and a second laid in 1865 were not fortunate; that of 1866 was, however, permanently successful. Now there are not a few Atlantic cables, English, American, or French; and there is telegraphic communication (partly submarine) between Europe and India, China, Australia, and the Cape of Good Hope, as there is between Chili and the United States. The perfection of the telephone about 1876, by which sounds, articulate or other, are communicated at a distance by electricity, marked a new application of electric science. The gradual development of magneto-electric or dynamo-machines and electro-magnetic apparatus led in 1881 to an electric tramway at Berlin, followed by one at Portrush in Ireland. Electric boats have also been successfully used; and amongst most recent developments, tricycles lighted and propelled by special tricycle electro-motors have to be mentioned.

With regard to the modern development of electrical science generally, it is remarkable that it should have taken an almost identical shape both in frictional and in current electricity. The machines of Holtz and Tœpler alongside of those of Wilde and Ladd, shew that induction supplies the link between mechanical force and electric energy of whatever form. Of modern contributions to electricity, we cannot here attempt an outline. They are associated with a host of illustrious names, such as Becquerel, De la Rive, Jacobi, Ohm, Harris, Du Moncel, Ruhmkorff, Wheatstone, Bertin, Siemens, Joule, Jenkin, Varley, Edison, Graham Bell, and Sir William Thomson.

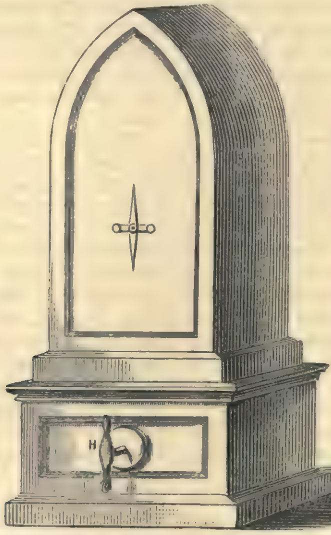

Fig. 45.—Cooke and Wheatstone's Single Needle Instrument.

CHRONOLOGY—HOROLOGY.

THE general relation of events and successive existences to each other we denominate *Time*—a thing of duration, involving the past, the present, and the future. It is evident that for the measurement of time we can have no standard of the same tangible nature with a pound, a yard, or a pint measure. We must have recourse to the space or duration involved in some continued or reiterated *motion*, as to which we have all the proof possible in the nature of the thing, that it requires the same period for its recurrence on one occasion as on every other. The motions of the heavenly bodies are of such a nature, and present the surest standard of reckoning time on a large and comprehensive scale. For periods, however, less in duration than a single day, or day and night, there are no explicit natural standards; hence the utility and necessity of mechanism of human invention, the motions of which, mathematically adjusted and numbered, shall measure and record more brief and arbitrary divisions.

In accordance, therefore, with what is the common practice of mankind in applying such a scale of time to the general routine and business of life, especially in its more civilised condition, we purpose to treat—*first*, of the measurement of time by days, months, years, and cycles, considered with special reference to their respective natural and artificial subdivisions and accumulations; and, *secondly*, of those instruments and machines which have been invented for dividing the leading astronomical unit, or day, into seconds, minutes, and hours. The former of these departments may be termed *Chronology*, or the science of time in general; the latter, *Horology*, or an explanation of the various contrivances which have been devised for marking and measuring its arbitrary subdivisions.

CHRONOLOGY.

Chronology—from *chronos*, time, and *logos*, discourse—is literally the doctrine of time; the science which treats of its various divisions, and of the order and succession of events. The chronologist has thus a threefold duty to perform—namely, to assign a measure to the interval which elapses between successive recurrences of any natural event; to determine certain points or epochs from which to date occurrences, whether preceding or succeeding that epoch; and, lastly, dating from any given epoch, to arrange in due order all facts and phenomena which may be considered of importance. Adopting this course, we shall treat, in the first place, of the division of time into

DAYS AND HOURS.

A day, in the ordinary sense, is one complete alternation of light and darkness, caused by the revolution of the earth on its axis. It takes rather more than a complete revolution of the earth to bring a spot on its surface back into the same position with regard to the sun, because the sun has in the meantime moved forward a little in the sky. The period that thus elapses is a natural or *solar* day. These periods, however, are not of exactly the same length at all seasons of the year, and therefore the mean length is taken as the standard, and is called the *civil* day. It is this civil day, divided into twenty-four equal parts called hours, that our clocks and watches keep. The period of a complete revolution of the earth, which is determined by two successive culminations of a fixed star, is called a sidereal day, and is shorter than the mean day by nearly four seconds (see ASTRONOMY). We have thus three species of day—the sidereal, or that time which elapses between two successive culminations of the same star, and which is now universally adopted by astronomers in their observatories; the solar, natural, or apparent day, being the time that elapses between two consecutive returns of the same terrestrial meridian to the centre of the sun, and which consequently commences at noon; and the civil or mean solar day, which is the mean or average of these meridional returns, and which most modern nations have adopted, placing the commencement and termination at mean midnight.

The succession of day and night would undoubtedly constitute the first great natural period reckoned by the human race—involving, as it does, not only the most familiar and most strikingly contrasted phenomena within the bounds of man's experience, but phenomena peculiarly adapted to the great necessities of his nature—those of vigilance and sleep. Yet the precise point at which the day should be held to begin and terminate, must have been a matter much less easily settled; and accordingly we find, that while amongst ancient nations—the Babylonians, Persians, Syrians, Greeks, and almost all the nations of Asia—the day began at sunrise, and was held to last throughout the whole of the ensuing daylight and darkness—an arrangement better adapted to countries near the tropics than elsewhere, as the sun there rises more nearly about the same time throughout the year—the Jews, Turks, Austrians, and others, with some of the Italians and Germans, have begun their day about sunset; the Arabians theirs at noon, as do astronomers and navigators of all nations; the ancient Egyptians, and most of the modern Europeans and Americans, on the other hand, as well as the modern Chinese, beginning theirs at midnight, which is evidently the most convenient method, since it throws all the waking and active portion of the day under one date.

In the civilised part of the world, it is now customary to divide the day, and reckon the minuter portions of time, by instruments, to be afterwards described, in seconds, sixty of which constitute a minute; in minutes, sixty of which

constitute an hour; and in hours, twenty-four of which constitute a day. Most nations have these instruments marked for only twelve hours, the computation being twofold, like the day itself; but the Italians, Bohemians, and Poles run them on from the first to the twenty-fourth—from one o'clock to twenty-four o'clock. The Chinese, on the other hand, divide the day into twelve hours only, each being, therefore, twice the length of ours.

It is here necessary to observe, that as the earth rotates from west to east, every meridian has its own natural day; and any place east or west of that meridian has a corresponding earlier or later sunrise. The earth, of 360° of longitude, turns in twenty-four hours; consequently every hour is equal to 15°; and every degree equal to four minutes of time. Thus, taking Greenwich as the normal meridian, Alexandria being 30° east, is two hours earlier, or has it twelve o'clock when it is ten at Greenwich; Bengal is 90° east, and it is there twelve at noon when only six in the morning at Greenwich. So New York is 74° west, or 4 hours 56 minutes; and consequently, when noon at Greenwich, it is only four minutes past seven in the morning at New York. As with these large distances, so with every other difference of longitude, however minute; and it is thus that we speak of our clocks being earlier or later than Greenwich time, according as we are situated east or west of that meridian. Ipswich, for example, being east of Greenwich, is about five minutes before, or earlier; Edinburgh, being west, is about twelve and a half minutes behind; and Dublin, being still farther west, is about twenty-five minutes late. Hence the necessity, in these days of rapid transit, of keeping by one uniform standard of time, or at least of having a table of differences for the principal stations throughout the country. In most cases, it would be preferable to have our clocks furnished with two minute-hands—one to indicate Greenwich time, and the other the natural time of the locality.

MONTHS AND WEEKS.

After the day, the next distinct natural measure or division of time marked out by the heavenly bodies in their time-keeping revolutions, is the month. The *lunar month*, or *synodic month*, is the period between two consecutive new or full moons, and is equal to 29 days 12 hours 44 minutes 3 seconds (see ASTRONOMY). The month came ultimately to be disconnected from the lunar and terrestrial revolutions, as will be afterwards more particularly noticed, and civil or *calendar months*, accommodated to the year, were substituted; these also, as well as the names given to them in their annual order, will fall to be noticed while treating of the year itself and its subdivisions.

The subdivision of the month into weeks of seven days is very ancient, but is far from having been universal, as is sometimes assumed. It was probably first instituted as corresponding roughly to the four quarters of the moon. It is found as a civil institution among the Hindus, Assyrians, and Persians from the earliest times; it is only among the Jews that we see a religious signification given to the concluding or seventh day of the period. Whether the Egyptians borrowed it from the Jews, or the Jews from the Egyptians, it is certain that the latter at an early period counted seven periodical days, naming them after the seven planets of the old astronomy. The application of the names of the planets to the days of the week in the order they now stand, originated in this way: It was an astrological notion that each planet in order presided over an hour of the day, the order, according to their distances from the earth, being, on the geocentric system, Saturn, Jupiter, Mars, the sun, Venus, Mercury, the moon. Assuming Saturn to preside over the first hour of Saturday, and assigning to each succeeding hour a planet in order, the 22d hour will fall again to Saturn, the 23d to Jupiter, the 24th to Mars, and the first hour of the next day to the sun; in the same way, the first hour of the following day falls to the moon, and so on. From Alexandria, this seven-days week was imported, together with the names of the individual days, to the Greeks and to the Romans, about the time of Christ. The Greeks had previously divided the civil month into periods of ten days. The Roman month was anciently divided into three periods — *Calends*, *Nones*, and *Ides*. The calends were at the beginning of the month; the ides at the middle of the month, on the 13th or 15th; and the nones (*novem*, nine) were the ninth day before the ides, counting inclusively. From these three terms the days were counted backwards in the following manner: Those days comprised between the calends and the nones were denominated *days before the nones;* those between the nones and ides, *days before the ides;* and those from the ides to the end of the month, *days before the calends*. The Greeks had no calends; hence the Roman phrase, *Græcæ calendæ*, or 'never,' corresponding to the English 'Latter Lammas,' and the Scotch 'Morn come never.'

The Jews, as well as the early Christians, had no special names for the single days, but counted their number from the previous Sabbath, beginning with Sunday, as the first after the Sabbath, and ending with Friday, as the sixth after the previous, or as the eve (*Ereb*) of the next Sabbath. After a very short time, however, Christianity had to fall back again upon the old heathen names, previously introduced in Gaul, Germany, &c. by the heathen Romans. The Sunday, or *dies Solis*, alone was changed in many of the Romanic languages in accordance with the new creed. It was called *Kyriake*, *dies Dominicus* or *Dominica*, the Day of the Lord, a term which in Italian became *Domenica*, in Spanish *Domingo*, and *Dimanche* in French. It is very curious to notice how the names of the five days of the week which followed those named after the sun and moon, became Germanised, as it were, or the names of the originally imported gods translated into those of the Germanic divinities. Thus, the day of Mars became that of Ziu. Mercury became Wodan; and the fourth day was called after the latter, in Dutch, English, and Scandinavian; while in Germany it was simply called the middle of the week—*Mittwoch*. The day of Jupiter became the day of Thor—Thursday, *Donnerstag;* while the *Dies Veneris* was transformed into the day of Freya (Friday). The day of Saturnus, retained under this name in some northern tongues, became a *laugardage*, or bathing-day, in others; while in Upper Germany it remained a Sunday-eve or

Samstag. The Arabs have the seven-days period, and count the individual days instead of naming them, as do the Slavonic nations, and Quakers among ourselves. In England, the Latin names of the days are still retained in legislative and judiciary acts.

YEARS AND SEASONS.

The year, properly so called, or the solar or astronomical year, is that portion of time which elapses while the sun passes through the twelve signs of the zodiac, or rather, while the earth revolves once completely round the sun in its orbit; thus producing an alternation of the seasons (see ASTRONOMY).

The distinction of the seasons would soon be found to depend upon the alternate approach and departure, or elevation and depression, of the sun in the heavens at stated and regularly recurring intervals; but the exact division of time into solar years could not have been effected till astronomy had made some progress; when it would immediately appear, in the endeavours at length made to measure the year by revolutions of the moon, that as an exact number of days, or times of the earth's rotation, is not contained in 'a moon,' or lunar month, so an exact number of moons, or even of days, is not contained in a year, or revolution of the seasons. Such observations as these led to methods of accommodating the one period to the other; or, in other words, to the

ADJUSTMENT OF THE CALENDAR.

Almost all the nations of antiquity originally estimated the year, or the periodical return of summer and winter, by twelve lunations—a period equal to 354 days 8 hours 48 minutes 36 seconds. But the solar year is equal to 365 days 5 hours 48 minutes 49 seconds; or 10 days 21 hours 13 seconds longer than the lunar year, an excess named the *epact;* and, accordingly, the seasons were found rapidly to deviate from the particular months to which they at first corresponded; so that in thirty-four years, the summer months would have become the winter ones, had not this enormous aberration been corrected by the addition or intercalation of an extraordinary month now and then. Thus was the calendar first adjusted, and the solar year estimated to consist of twelve months, comprehending 365 days. But no account was taken of the odd hours until their accumulation forced them into notice; and a nearer approximation to the exact measurement of a year was made about forty-five years before the birth of Christ, when Julius Cæsar, being led by Sosigenes, an astronomer of his time, to believe the error to consist of exactly six hours in the year, ordained that these should be set aside, and accumulated for four years, when of course they would amount to a day of twenty-four hours, to be accordingly added to every fourth year. This was done by doubling or repeating the 24th of February; and, in order to commence aright, he ordained that year, which was called the last 'year of confusion,' to be made up of fifteen months, so as to cover the ninety days which had been then lost. The 'Julian style' and the 'Julian era' were then commenced; and so practically useful and comparatively perfect was this mode of time-reckoning, that it prevailed generally amongst Christian nations, and remained undisturbed till the renewed accumulation of the remaining error of eleven minutes or so had amounted, in 1582 years after the birth of Christ, to ten complete days; the vernal equinox falling on the 11th instead of the 21st of March, as it did at the time of the Council of Nice, 325 years after the birth of Christ.

This shifting of days had caused great disturbances, by unfixing the times of the celebration of Easter, and hence of all the other movable feasts. And accordingly, Pope Gregory XIII. after deep study and calculation, ordained that ten days should be deducted from the year 1582, by calling what, according to the old calendar, would have been reckoned the 5th of October, the 15th of October 1582. The Catholic nations, in general, adopted the *style* ordained by their sovereign pontiff; but the Protestants were then too much inflamed against Catholicism in all its relations, to receive even a purely scientific improvement from such hands. The Lutherans of Germany, Switzerland, and, as already mentioned, of the Low Countries, at length gave way in 1700, when it had become necessary to omit *eleven* instead of ten days. It was not till 1751, and after great inconvenience had been experienced for nearly two centuries, from the difference of the reckoning, that an act was passed (24 Geo. II. 1751) for equalising the style in Great Britain and Ireland with that used in other countries of Europe. It was enacted, in the first place, that eleven days should be omitted after the 2d of September 1752, so that the ensuing day, the 3d, should be called the 14th; and, in order to counteract a certain minute overplus of time, that 'the years 1800, 1900, 2100, 2200, 2300, or any other hundredth year of our Lord which shall happen in time to come, except only every fourth hundredth year of our Lord, whereof the year 2000 shall be the first, shall not be considered as leap-years.' A similar change was about the same time made in Sweden and Tuscany; and Russia and Greece are now the only countries which adhere to the *old style;* an adherence which renders it necessary, when a letter is thence addressed to a person in another country, that the date should be given thus: April $\frac{1}{13}$ or $\frac{\text{June 26}}{\text{July 8}}$; for it will be observed, the year 1800, not being considered by us as a leap-year, has interjected another (or twelfth) day between old and new style.

In the Julian arrangement, the odd months—the first, third, fifth, &c.—were to have thirty-one days, and the even numbers thirty days, except February; but Augustus altered the disposition for that which now holds. The names of the twelve months are strictly Roman; the origin of several of them is obscure.

The commencement of the year, till a comparatively very recent period, was the subject of no general rule. The Athenians commenced it in June, the Macedonians in September, the Romans first in March, and afterwards in January, the Persians on 11th August, the Mexicans on 23d February, the Mohammedans in July, and astronomers at the vernal equinox. Amongst Christians, Christmas-day, the day of the Circumcision, the 1st of January, the day of the Conception, the 15th of March, and Easter-day, have all been used at various times, and by various nations, as the initial

day of the year. Christmas-day was the ecclesiastical beginning of the year, till Pope Gregory XIII. on reforming the calendar, ordered it, in 1582, to begin thenceforward on the 1st of January. In France and England, the same practice commenced about the same time; but in the latter country, it was not till 1752 that legal writs and instruments ceased to consider the 25th of March as the beginning of the year. In Scotland the change was made in 1600. The English plan was found exceedingly inconvenient; for when it was necessary to express a date between the 1st of January, which was the commencement of the historical year, and the 25th of March, which opened the legal one, error and confusion were sure to occur, unless it were given in the following awkward fashion: January 30, 1648–9, or 164$\frac{8}{9}$. Even this was apt to lead to mistakes; and it is perhaps even to this day a matter of doubt with some intelligent persons, whether the execution of Charles I., of which the above is the usual appearance of the date, occurred in the year 1648 or 1649: it in reality occurred in the year which, by our present uniform mode of reckoning, would be called 1649.

The present mode of reckoning time has experienced no interruption in its leading features for many years, except under the French Republic. In September 1793, the French nation having resolved that the foundation of their new system of government should form their era, instead of the birth of Christ, whose religion they had in a great measure shaken off, resolved also that a calendar should be adopted on what was termed philosophical principles. The Convention, therefore, having decreed, on the 24th November 1793, that the common era should be abolished in all civil affairs, and that the new French era should commence from the foundation of the Republic—namely, on the 22d September 1792, on the day of the true autumnal equinox—ordained that each year henceforth should begin at the midnight of the day on which the true autumnal equinox falls. This year they divided into twelve months of thirty days each, to which they gave descriptive names as follows: From the 22d of September to the 21st of October was *Vendémiaire* (Vintage Month); to the 20th November was *Brumaire* (Foggy Month), and so of the rest. In ordinary years there were in this scheme five extra days—namely, from the 17th to the 21st of our September inclusive: these the French called *Jours Complémentaires*, or *Sans-culottides*, and held as festivals; the first being dedicated to Virtue, the second to Genius, the third to Labour, the fourth to Opinion, and the fifth to Rewards. At the end of every four years, forming what they called a Franciade, occurred a leap-year, which gave a sixth complementary day, styled *Le Jour de la Révolution*, and employed in renewing the national oath to live free or die.

The *week*, though not exclusively a Christian or Jewish period of time, they also abjured. The thirty days of the month were divided into three parts, of ten days each, called *Décades;* of which the first nine—called Primidi, Duodi, Tridi, Quartidi, Quintidi, Sextidi, Septidi, Octidi, Nonidi—were working or common days, while the tenth, styled Décadi, was observed as a kind of Sabbath, though not exactly in the Jewish sense of the word. The French, however, in indicating any particular day, either by word or writing, generally mentioned only the number of the day of the month. The Republican Calendar was first used on the 26th of November 1793, and was discontinued on the 31st of December 1805, when the calendar used throughout the rest of Europe was resumed.

CYCLES.

A cycle, from a Greek word signifying *circle*, is a circulating period of time, on the completion of which, certain phenomena return in the same order.

The *Solar Cycle* is a period of twenty-eight years, during which the day of the month, in every succeeding year, falls on a different day of the week, from the first, till the cycle is completed; when the days of the month and week meet as at first, one cycle corresponding to another. By this cycle, which has no relation to the sun's course, we find 'the Dominical letters,' or those letters amongst the first seven in the alphabet—used to represent the days of the week—which point out the days of the month on which the Sundays fall during each year of the cycle. If there were 364 days in the year, the Sundays would happen every year on the same days of the month; if 365 exactly, every seventh year; but because the additional fractional period contained in the year makes an alteration of a day in every fourth year, the cycle extends to four times seven, or twenty-eight years.

The first solar cycle in the Christian era having begun nine years before the commencement of that era, to discover what year of the cycle the year 1872 forms, we must add 9, and divide the sum 1881 by 28, the period of the cycle, and the quotient 67 is the number of solar cycles that have passed during that era, the remaining 5 being the year of the cycle corresponding to 1872.

The *Lunar Cycle*—also called the 'Golden Number,' from its having been written in letters of gold by the Greeks, and the 'Metonic Cycle,' from its having been discovered by Meton, an Athenian astronomer—is a period of nineteen years, at the end of which the phases of the moon occur on the same days of the civil month as in a previous lunar cycle, and within an hour and a half of the same precise moment of time.

The first lunar cycle in the Christian era having begun one year before the commencement of that era, to discover what year of the cycle 1872 forms, we must add 1, and divide the sum 1873 by 19, the period of the cycle, and the quotient 98 is the number of lunar cycles that have passed during that era: the remainder, 11, shewing that 1872 is the eleventh year of the next lunar cycle.

The *Dionysian Period* is a combination of the solar and lunar cycles, forming, by the multiplication of 28 by 19, a period of 532 years, at the expiration of which it is again new moon on the same days of the week and month as before: chronological events are compared and tested by such a calculation.

The *Indiction* may here also be noticed; though, were it not for severing it from the other cycles with which it is connected in the Julian period, it might perhaps more properly appear under the head of epochs and eras. This was a Roman period of fifteen years, the first of which commenced in the year 312 after the birth of Christ.

It was appointed merely for the regulation of certain payments by the subjects of the empire; but it came to be observed by the Greek Church and the Venetian senate, as well as the court of Rome.

The *Julian Period* is a combination of the solar and lunar cycles with the Indiction; the respective periods of 28, 19, and 15 years are multiplied by each other, and the product, 7980 years, is what is called the Julian period, during which there cannot be two years having the same numbers for the three cycles; but at the termination of this period they return in the former order.

The year 1872 is the 6585th of the Julian period; hence it began about 700 years previous to the date vulgarly assigned to the creation of the world, and has been used instead of that era, to obviate the disputes of chronologers, and to reconcile their systems; for all agree as to the year in which the Julian period began.

EPOCHS AND ERAS.

In early times, when there was little mutual intercourse between different countries, it was natural for each nation to take as a starting-point in their annals some event of signal importance in their eyes. This event would form *an epoch*, so named from a Greek word signifying to stop. The enumeration and series of years computed from an epoch is called *an era;* and accordingly of epochs and eras there have been almost as many as there have been of nations. As the eras of ancient nations, however, have become obsolete, it would be useless, as it is here impossible, to enumerate all that we know of, or even any great number of them. But we shall notice a few of the most important in the meantime, reserving the names of all the other principal eras to be afterwards presented together in a tabular form.

The *Era of the Olympiads* is the first on record, and it also became the most celebrated of the ancient methods of computing lengthened periods of time. It took its rise amongst the Greeks 776 years before the birth of Christ. Public games had been instituted at Olympia, a city in Elis, which took place every fourth year, at the recurrence of the full moon after the summer solstice—namely, about the beginning of our July. As this festival made a great impression on the public mind, the people began to reckon by Olympiads, or recurrences of the Olympic games—an Olympiad comprising four years. The computation by Olympiads ceased after the 364th Olympiad, in the 440th year after the birth of Christ, as usually computed. The Greeks latterly adopted a new era, called

The *Era of Seleucus*, or the *Seleucidæ*, sometimes also called the era of Alexandria. This era commenced twelve years after the death of Alexander the Great, at the first conquest (312 B.C.), by Seleucus Nicator, of that part of the east which afterwards formed the immense empire of Syria. This era has also prevailed, and still exists, amongst the people inhabiting the Levant. The Jews reckoned by it till the fifteenth century of the Christian era, when they substituted the supposed era of the Creation, to be afterwards noticed; and they still begin their year according to it, in the month of September or October.

The *Roman Era* was reckoned by the Romans from the epoch of the foundation of their famous city Rome, an epoch taken to correspond to the 753d year before the birth of Christ. The computation of time by the Roman era ceased in the sixth century of the Christian era.

The *Christian Era*, of which we now live in the 1872d year, was not adopted as a mode of time-reckoning immediately after the commencement of Christianity. The era of the Olympiads, the Roman era, the era of Seleucus, and the dates of ecclesiastical councils, and other events then considered of importance, were the common modes of reckoning, and continued partially to be so till a period less remote than many people suppose. Even in Italy, and its celebrated capital, Rome, which became the chief seat of Christianity at a very early period, this era was not used till the sixth century. It was introduced into France in the seventh, but not fully established till the eighth century. In Spain, though occasionally adopted in the eleventh, it was not uniformly used in public instruments till after the middle of the fourteenth century, nor in Portugal till about the year 1415. Now, however, all nations professing Christianity have abandoned other eras, and confined themselves to this; using the Latin words *Anno Domini*, 'the year of our Lord,' or their initial letters A.D. to distinguish it; while, for all dates previous to the generally received epoch of the era, the words *Anno ante Christum*, 'the year before Christ,' their abbreviation A.A.C. or more usually the letters B.C. signifying 'before Christ,' are used. The birth of Christ is now believed to have actually taken place four years earlier than the date fixed for it when this mode of reckoning was introduced.

The *Era of the Hegira* commences at the epoch of the flight of Mohammed from Mecca to Medina, which took place on the 16th day of July 622 A.D. The Mohammedan year is regulated by this event; hence it is used by the Turks, Arabs, and other Mohammedans, comprising a large portion of the modern population of the world.

The *Mundane Era*, or era of the creation of the world, has been the subject of much controversy. As many as 300 different opinions, according to Kennedy, in his *Scriptural Chronology*, have been entertained regarding the period which elapsed between the creation and the incarnation. Some have made it 3616 years; others 6484. From the creation to the deluge, the computation of the Hebrew text makes a lapse of 1656 years; the Samaritan version only 1307; the Septuagint 2262. No ancient chronologist attempted to fix the epoch of the creation: some conceived it impious to do so. In modern times, the impiety has been supposed to lie all the other way. But some enlightened commentators have been bold enough to return to the ancient orthodox idea, so far at least as to maintain that the Scriptural epoch of the creation is indefinite, being merely cursorily alluded to in the words, 'In the beginning God created the heavens and the earth.' Geologists, in general, also adopt this wide interpretation. In the authorised version of the Bible, however, the chronology usually given places the epoch of the creation in the year 4004 B.C. Thus, 1 A.D. is 4004 A.M.; the letters A.M. being used as an abbreviation of *Anno Mundi*, 'year of the world.'

YEARS OF PRINCIPAL ERAS CORRESPONDENT TO 1872.

	Years.	Abbrev.
Era of Creation (Constantinopolitan account)	7381	A.M. Const.
Era of Creation (Alexandrian account)	7364	A.M. Alex.
Era of Creation (Jewish account), 23d Thebet	5632	A.M.
Julian Period	6585	Jul. Per.
Caliyug (Hindu)..Poos or Margaly,	4973	Cal.
Olympiads...7th month 1st year of	663	Olymp.
Era of Rome	2625	A.U.C.
Era of Nabonassar...8th month of	2620	Ær. Nab.
Era of Death of Alexander—3d month,	2197	A. Mort. Alex.
Diocletian, or era of Martyrs—25th Cohiac,	1588	Ær. Diocl.
Hegira.................22d Rabiu II.	1295	A.H.

MISCELLANEOUS PERIODS.

Besides these major periods, we have others of less significance, but still useful to be known, as they are frequently alluded to in works of a historical nature. Thus, a *lustre* (Lat. *lustrum*) is a period of five years; or, more properly, the completion of fifty months, at the end of which term a census was taken of the Roman population. A *generation* is the interval of time elapsed between the birth of a father and the birth of his son, and is generally used in computing considerable periods of time both in sacred and profane history. The interval of a generation is consequently of uncertain length, and depends on the standard of human life, and whether the generations are reckoned by eldest, middle, or youngest sons. Thirty years are usually allowed as the mean length of a generation, or three generations for every hundred years. A *reign* is the interval that elapses between the accession and demise of a monarch or supreme governor, and is a term in frequent use by historians. It is a period, however, of very uncertain duration, and differs in different countries, according as the sovereign may be liable to assassination, deposition, and the like. Dr Hales has, however, shewn that the average standard of reigns is about twenty-three years, reckoning from a series of 454 kings in 10,105 years. A *century* (*centum*, a hundred) is a period of one hundred years, reckoning from the commencement of the first year in any given century; thus the current century is the nineteenth of the Christian era.

TABULAR CHRONOLOGY.

Under this head the leading events, phenomena, or facts recorded in history, are arranged in the order of time in which they have occurred—that is, in chronological order. Referring the reader to the systematic chronologies of Newton, Blair, Playfair, Sir Harris Nicolas, and others, we shall merely remark, that the best mode of tabulating events is that which exhibits the dates in bold characters, and endeavours to arrange in juxtaposition the leading occurrences in the principal countries of the world. By these means, reference is greatly facilitated, and a notion of civil progress more intelligibly conveyed. The language of tabular chronology should always be concise, elliptical rather than expletive—a mere indication rather than an account of the event recorded.

HOROLOGY.

Reference has already been made to the heavenly bodies and their motions as the most primitive and natural, as well as most perfect time-keepers. Our attention here, therefore, must be confined to those artificial machines which have been invented chiefly for the purpose of adding to the convenience of these, by dividing the unit of astronomical time-keeping—namely, the day—into fractional parts, such as hours, minutes, and seconds; there being no such convenient and desirable measurement obvious in nature. The science which explains the methods of so measuring and marking the fractional parts of the day is termed *horology*, from two Greek words, signifying *hour* and *discourse*—a term comprehensive of every time-keeping contrivance, from the simplest sand-glass to the most perfect chronometer. The instruments to which we shall here advert are dials, depending upon the shifting shadow of an object illuminated by the sun; clepsydræ, depending upon the equable flow of a liquid; and clocks and watches,* whose movements are determined by weights and springs.

SUN-DIALS.

Long before the invention of any artificial time-keeper, the interval between sunrise and sunset was really divided, with no little accuracy, even amongst the rudest nations, simply by the shortening, turning, and lengthening of the shadows of trees, rocks, and mountains; and it was this primitive mode of dividing the day which no doubt naturally suggested the first idea of sun-dials. The earliest time-measurer of this description of which we have any historical notice, is the dial of King Ahaz, who lived about 742 years before the birth of Christ. According to Herodotus, the Greeks learned the use of them from the Chaldeans, probably through the Babylonian priest and astronomer Berosus. Mention is made of the hemisphere or dial of this philosopher; and the octagonal Temple of the Winds, which is still standing, shews on each side the lines of a vertical dial, and the centres where the gnomons were placed. In Rome, sun-dials were not known till 293 B.C., when one was erected near the Temple of Quirinus—the rising and setting of the great luminary being the only standards of reckoning previous to this period. The Romans at this time were not aware that a dial made for Rome is not suited to other places. The ancients used hemispherical dial-plates, constructed to shew equal divisions of the time between sunrise and sunset, or *temporary* hours, which varied in length with the seasons. The correct theory and practice of dialling belong to modern times. Vertical plain dials were at one time prevalent, as may be seen

* Although modern machines for measuring time are designated by the general appellation of clocks and watches, they are also distinguished by peculiar names arising from certain modifications in their construction, or from certain particular purposes they are intended to serve. By the term *clock* is understood an instrument which not only shews, but also strikes the hours; a *time-piece* is one which shews the hours without striking them; a *quarter-clock* is one which strikes the quarters as well as the hours; an *astronomical clock* is one which shews sidereal time; a *watch* is a portable or pocket time-piece; a *repeater* is one having a contrivance, by means of which it can be made to repeat the hours; a *chronometer* is a watch of the best kind, or one fit to be employed for astronomical purposes.—*Brande's Dictionary of Science.*

on the fronts and gables of many of our old mansions. At present, the most common construction is the horizontal dial, or that in which the plane of the dial-plate is parallel to the horizon. In this form the style or *gnomon* G, the edge of the shadow of which determines the hour-line, runs in the plane of the meridian—that is, due north and south; while its sloping edge forms an angle with the horizon, or plane of the dial, equal to the latitude of the place in which the instrument is situated, and hence parallel to the earth's axis.

Although a sun-dial may certainly be adjusted so as to point out the time of day within a few minutes, it is needless here to dwell further on the details of an instrument now of little use. The most perfect of sun-dials being only available in sunshine, and not at all through the night—in which, by the way, moon-dials were sometimes used—they were partly superseded, even at a very remote period, by

CLEPSYDRÆ AND SAND-GLASSES.

It has been thought that the regular motion of the dropping of water, and the simpler forms of clepsydræ, or water-clocks, were used for the measurement of time even previous to the invention of sun-dials. They certainly were known in very remote antiquity, and were then used in various parts of Asia and Europe; in China, India, Chaldea, Egypt, Italy, and Greece; into the last of which countries they were introduced by Plato. Julius Cæsar found them even in Britain. The Romans themselves had clepsydræ 100 years before Cæsar's invasion; and it is supposed that the Phœnicians had introduced them into Britain through Cornwall, where they traded for tin. The clepsydra invented by Ctesibius of Alexandria, 250 B.C. consisted of a jar containing water, which slowly escaped by a hole at the bottom, while the oar of a miniature boat on the surface, as it sank with the fall of the water, pointed out the hours, which were marked on the side of the jar. It is even alleged that toothed-wheels were applied to clepsydræ by Ctesibius. Such instruments, however, though brought to great perfection in the ninth and tenth centuries, and indeed still used in India, have never been made to measure time with great accuracy. The principal defect is the unequal dropping of the water, caused by the varying depth or weight of the liquid in the containing vessel, increase or decrease of temperature, and change of barometric pressure. As time-keepers, clepsydræ may therefore be considered as superseded by ordinary clocks and watches.

The running of fine well-dried sand through a tube, or from an orifice in a containing vessel, was another obvious species of regular motion, very analogous to the flowing or dropping of water. Accordingly, sand-glasses, still in use in this and other countries, were of very early invention. We have evidence of their employment in the East about a couple of centuries before the Christian era. Though now used only for rude and trivial purposes—the half-minute glass being still employed on shipboard, and the three-and-a-half minute egg-glass by the housemaid—some centuries ago, in Western Europe, they were the almost universal measurers of brief intervals; and hence the numerous allusions of our poets, and the symbolical representations on our monuments and sculptures.

PLANETARIUMS OR ORRERIES.

It is rather a curious circumstance, that, long before the invention of clocks or watches, artificial machines were constructed, imitative of the motions of the sun, moon, and planets—the natural time-keepers.

Of the planetariums of modern times, the first in England was one made for Lord Orrery, whose name has since been given to such machines. The talented and self-taught astronomer, Ferguson, who was originally a poor Scottish herd-boy, made several orreries, and used chronometers to keep them in motion. But though the accuracy with which wheels and pinions can be made to represent different revolutions is beautifully illustrated by the best of these machines, they can give no just conception of the relative size, distance, or velocity of the planets, or hence of the periods of their revolution. 'As to getting correct notions on this subject (the magnitude and distances of the planets),' says Sir John Herschel, 'by drawing circles on paper, or, still worse, from those very childish toys called orreries, it is out of the question.' A verdict so decided, and from such a source, renders any attempt at description or illustration unmeaning and superfluous.

CLOCKS.

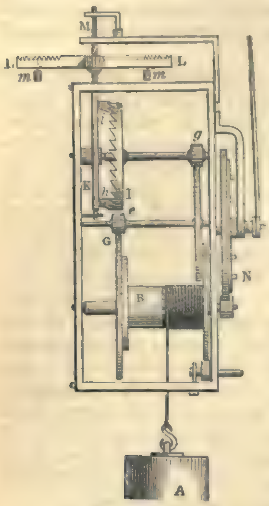
The strong hold which the planetary motions appear to have taken on the minds of our forefathers, as the great antetypes of all true time-keepers, is also curiously manifested in the fact, that even when a more detailed measurement of time became necessary, in the intellectual progress of nations, these motions still continued to be represented, so that the first clock of which we have any perfectly authentic account—that, namely, invented by Wallingford, abbot of St Albans, in 1326—not only shewed the hours, but the apparent motion of the sun, the changes of the moon, the ebb and flow of the tides, &c. This, however, was by no means the first clock ever constructed; instruments with weights, wheels, pinions, and a balance, for the measurement of time, having been long previously known, though by whom invented, appears to be a subject of much controversy. Doubtless, they required more than the intellect of a single mind. Be this as it may, the most ancient clock of which we have any description is that of Henry Vic or De Wyck, a German, erected in the tower of the palace of Charles V. king of France, in 1379; and rude and imperfect as it was, the analogy of modern invention, especially in watches, would lead us to think that it must have been the fruit of several centuries of thought and improvement.

A portrait of this parent of modern time-keepers may be interesting to our readers; and, from its comparative simplicity, will be well adapted as a ground-work for further explanation of the mechanism of clocks and watches in their more complex

and intricate forms. It will, moreover, shew the general mode of construction adopted in the fourteenth century, including the balance with weights, by which the motion was then regulated, instead of as now by a pendulum.

General Movement and Regulation of Clock-work.

Without requiring to enter into any very minute detail of the manner in which motion in a clock or watch is successively communicated from one toothed-wheel G or I, or pinion *e* or *g*, to another, it will be readily understood that the weight A below the clock-work, wound up by a cord on the cylinder B, in its constant tendency to fall to the ground, will cause the cylinder to turn round on its axis; and thus one toothed wheel or pinion will set another in motion, till the movement be communicated to the crown-wheel, escapement-wheel, or wheel of rencounter (I), the teeth of which so act on the two small levers or pallets (*i*, *h*) projecting from, and forming part of, the suspended upright spindle or vertical axis (KM), on which is fixed the regulator or balance (LL), that an alternating or vibratory instead of a circular motion of the balance itself will be the result. The rotatory motion of the wheel-work, in short, will be converted into a vibratory motion by the alternate catching of the levers by the teeth of the crown or escapement wheel, and their alternate escape from them.



De Wyck's Clock.

Were it not for some such check, it is manifest that the weight would go on descending with a rapidly increasing speed till it reached the ground. It is this rapid accelerated motion which begins in a *modern* clock whenever the *pendulum* is taken away. To prevent this rapid unwinding of the clock-work, then, and to adjust it to the more deliberate measurement of time, we have, in De Wyck's clock, the balance *loaded with two weights* (*m*, *m*); and the further these are removed from the axis or spindle (KM), the more heavily will they resist and counteract the escapement of the levers and the rapidity of the rotation of the escapement-wheel, till the clock be brought to go neither too quick nor too slow. The want of a regulation spring, however, must have rendered these machines very imperfect.

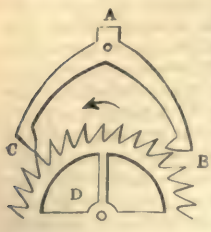
Pendulum and Escapement.

What the balance and the weights attached to it were to clocks of an ancient date, the pendulum is, in general, to modern clocks. The measurement of time being thus regulated by the oscillations of the pendulum, this part of the mechanism of a clock, including the escapement, is of primary interest and importance.

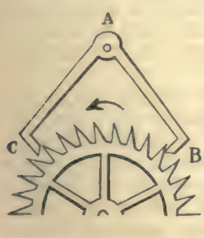
Galileo, the great astronomer, when a student at Pisa, happened to discover, while engaged in the cathedral there—not in meditating on the imposing ceremonial of the Catholic Church, which was then in progress, but in what, to many a good Catholic, would undoubtedly have seemed the vacant, idle, and profane contemplation of the lamps which swung from the roof—that the oscillations of a pendulum, whether great or small, are performed in equal times in the same pendulum—an important fact, the truth of which he tested, not by the beats of his watch (for no such instrument then existed), but by the beats of a natural time-keeper to which we have not yet alluded—namely, the pulse. The law that the time of vibration of a pendulum increases, not as the length, but as the square root of the length—in other words, that a pendulum to beat seconds must be four times the length of one that beats half-seconds—as also the variation of the length with the latitude of the place, are fully described in the number on MATTER AND MOTION. The greatest possible nicety, indeed, is required in the adjustment of the length; for a difference, if in extent amounting to the 1000th part of an inch, would cause an error of about one second a day; therefore, to make a pendulum go slower by one second a day, it must be lengthened by the 1000th part of an inch; and to make it go quicker, it must be shortened in the same proportion.

It does not appear that Galileo ever applied the pendulum to the regulation of time-keepers. Who was the first to do so, is disputed; but as Hüygens, an ingenious Dutchman, about 1657, made a more scientific and efficient application of it than had been done before, he is generally held to be the inventor of the pendulum-clock. Hüygens, in adapting the pendulum to the mechanism previously invented, had little more to do than simply to add a new wheel to the movement, so as to enable him to place the crown-wheel and spindle in a horizontal instead of a perpendicular position, that the lower arm of the balance—then, of course, perpendicular, instead of horizontal, as in De Wyck's clock—might be extended, as it were, downwards, and thus, in fact, be converted into a pendulum. The principle of construction adopted by Hüygens, from the peculiar action of the levers and spindle, required a light pendulum and great arcs of oscillation; and although, to secure isochronous vibration in these large arcs, the ingenious device of constraining the motion in a cycloidal curve was resorted to, yet the consequence was, as has been remarked, that 'Hüygens's clock governed the pendulum, whereas the pendulum ought to govern the clock.' About ten years afterwards, the celebrated Dr Hooke invented an escapement, which enabled a less maintaining power to carry a heavier pendulum. The pendulum, too, making smaller arcs of vibration, was less resisted by the air, and therefore performed its motion with greater regularity. This device is called the *crutch* or *anchor escapement*. It was brought by Hooke before the notice of the Royal Society in 1666; and was practically introduced into the art of clockmaking by Clement, a London clockmaker, in 1680. It is the form still most usually employed in ordinary clocks. It regulates the motion as follows: The pendulum is fixed at A,

and hangs down behind the pallet-wheel (the last of the train of wheel-work), which revolves in the direction of BC, under the action of the weight; B and C are the pallets. When the pendulum swings to the left, AC rises, and a tooth escapes from C, while another falls on the outside of B, and, owing to the form of the pallet B, this latter recoils during the remainder of the swing. The same thing occurs on the pendulum's return; the arm AB rises, a tooth escapes from B, and another falls on the inside of C, and is pushed backwards by it during the remainder of the swing. The revolution of D is thus regularly retarded, one tooth being allowed to escape for every two oscillations—that is, every two seconds—and as the wheel contains 30 teeth, it performs one revolution per minute (the seconds hand is fixed on the extremity of the axle of this wheel). During a portion of each contact between the pallets and teeth, the onward pressure of the wheel gives an additional impetus to the pendulum, so as to counteract the retarding effects of the resistance of the air and friction, which would otherwise bring it to a stand.



The only defect of this escapement is the recoil, and various modifications have been devised to obviate this. The first and most successful was made by George Graham, an English watchmaker in the beginning of the 18th century, and his improved form is called the *dead 'scapement* or *dead-beat escapement*. Here the outer surface of B and inner of C are arcs of circles, whose centre is A, and a little consideration will shew that there can be no recoil. This escapement is adopted in time-keepers when great accuracy is required. Other inventions, as the *detached escapement*, the *pin-wheel escapement* in various forms, and the *gravity escapement* (described below), though very efficient, have not come into general use.

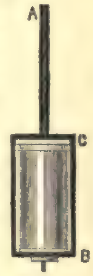


In the great clock in the new Houses of Parliament at Westminster, the pendulum is upwards of 13 feet long, to beat 2 seconds, and its bob weighs 6 cwts. The motion is kept up by a *remontoir* or *gravity escapement*. On each side of the pendulum-rod a small metallic hammer is hung upon a peg. 'The swinging of the pendulum first draws out a little bolt, that stopped the turning of a wheel; the wheel then goes round, under the influence of the weight, lifting one of the little hammers as it does so, until it is caught by another bolt. The hammer-head next falls by its own gravity, and strikes the pendulum-rod just as it is in the act of descending, communicating the force of its blow to quicken the movement; the same thing is afterwards repeated on the opposite side of the vibration, and then again on the same side; so going on alternately.' The push thus given is evidently unvarying. The wheel has three stops and cogs on it, and goes once round in three beats of the pendulum, or in six seconds. With this contrivance 'it is found that all the teeth of the several wheels may be rough, just as turned out from the casting, and the clock will nevertheless keep better time than it would have done with the most perfectly finished teeth under other arrangements.'

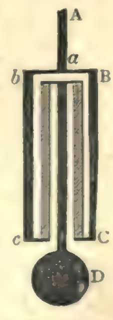
The gradual perfection of the clock required also improvements in the pendulum. No simple pendulum, however, can be depended on for an accurate time-keeper, for the isochronism of vibration of the pendulum depends on its being always the same length; now a cord contracts or expands with changes in the moisture of the atmosphere, and a rod with cold or heat. To overcome these defects in the pendulum, compensating pendulums were invented, of which Graham's *mercurial compensation pendulum*, invented in 1715, and Harrison's *gridiron pendulum*, in 1726, are the two principal forms.

Compensation Pendulums.

In the mercurial pendulum represented in the fig., the rod A, and the framework CB, are of steel. Inside the framework is placed a cylindrical glass jar, nearly full of mercury, which can be raised or depressed by turning a nut at B. By increase of temperature, the steel portion AB is lengthened by an amount proportional to its length, its coefficient of linear dilatation, and the change of temperature, conjointly—and thus the jar of mercury is removed from the axis of suspension. But neglecting the expansion of the glass, which is very small, the mercury rises in the jar by an amount proportional to its bulk, its coefficient of cubical dilatation, and the change of temperature, conjointly. Now, by increasing or diminishing the quantity of mercury, it is obvious that we may so adjust the instrument that the length of the equivalent simple pendulum shall be unaltered by the change of temperature. The screw at B has nothing to do with the *compensation;* its use is to adjust the length of the pendulum so that it shall vibrate in one second.



The construction of the *gridiron* pendulum will be easily understood from the cut. The black bars are steel, the shaded ones are brass, copper, or some substance whose coefficient of linear dilatation is more than double that of steel. It is obvious from the figure that the horizontal bars are merely connectors, and that their expansion has nothing to do with the vibration of the pendulum, so they may be made of any substance. It is easily seen that an increase of temperature lowers the bob by expanding the steel rods, whose effective length consists of the sum of the lengths of A*a*, BC, and the steel bar to which the bob is attached; while it raises the bob by expanding the brass bars, whose effective length is that of one of them only; the other, as well as the steel rod *bc*, being added to the instrument for the sake of symmetry, strength, and stiffness only. If the effective lengths of steel and brass be inversely as their respective dilatation coefficients, the position of the bob is unaltered by temperature; and therefore the pendulum will vibrate in the same



period as before heating. Practically, it is found that a strip of dry fir-wood, carefully varnished, to prevent the absorption of moisture, is very little affected by change of temperature; and, in many excellent clocks, this is used as a very effective substitute for the more elaborate forms just described.

Other Improvements.

While improvements were effecting in the escapement and pendulum of clocks, the ingenuity of artists was not confined to these alone. Till the beginning of the sixteenth century, clocks were of great bulk, and only fit for turrets or large buildings; and although after this period they were made small enough to be introduced into apartments, there could be no such thing as a really portable clock, far less a watch, till weights and pendulums were got rid of altogether. The substitution of a mainspring for a weight, therefore, constituted a great era in horology, or the science of time-keeping; and this took place about the middle of the sixteenth century, and was shortly afterwards followed by the invention of the *fusee*, a very necessary appendage to the mainspring. But as these inventions, together with the balance-spring, rather constitute peculiar features of the watch than of the clock, we shall reserve the explanation of these ingenious pieces of mechanism till we come to treat of watches. Meantime, there is another part of the works which requires to be here noticed—namely, the

Mechanism for Striking the Hours.

It is not known when the alarm or when the striking-mechanism of the clock was first applied. The alarm was adopted for the use of the Romish priesthood, to arouse them to their morning devotions. The first striking-clock probably announced the hour by a single blow, as they still do, to avoid noise, in most of the Scottish churches. In De Wyck's clock, the wheel N, with its projecting pins, served to discharge the striking part, which it has not been thought necessary to illustrate. Like other old clocks, it locked against an interrupted hoop, fixed on what was called the *hoop-wheel;* and the eleven notches on the edge of the plate-wheel determined the hours, or particular number of blows which the hammer should give. During the seventeenth century there existed a great taste for striking-clocks, and hence a great variety of them. Several of Tompion's clocks not only struck the quarters on eight bells, but also the hour after each quarter; at twelve o'clock, 44 blows were struck; and between twelve and one, no less than 113! Many struck the hour twice, like that of St Clement Danes, in the Strand, London, first on a large bell, and then on a small one. Others, again, were invented so as to tell the hours with the least possible noise.

The striking part of a clock is rather a peculiar and intricate piece of mechanism. In ordinary clocks, the impelling power is a weight similar to that which moves the time-measuring mechanism itself; but the pressure of this weight on the striking-machinery is only permitted to come into play at stated periods in course of the workings of the time-keeping apparatus—namely, at the completion of every hour; when the minute-wheel, which revolves once in an hour, and carries the minute-hand of the clock along with it, brings it into action by the temporary release of a catch or detent, permitting the weight wound up on the cylinder of the striking-apparatus to run down for a little, in doing which, the hammer is forced into action, so as to strike the bell. Whether the strokes shall be one or many, is determined principally by two pieces of mechanism, one called a *snail*, from its form or outline, with twelve steps, and the other a *rack*, with twelve teeth; but the intricate action of the whole it would be in vain here to attempt to explain. Suffice it to say, that the time during which the striking-weight is *allowed* to descend, varies according to the turning of the twelve steps of the snail on its axis, and the position of the twelve teeth of the rack, at different hours of the day; being sometimes only long enough to permit one blow to be given by the hammer on the bell, and at another time long enough for twelve such blows.

The lifting piece of the rack-hook, in some clocks, may be raised by pulling a string attached to a small additional piece of mechanism, and thus the clock is made to repeat the hour last struck at any time required—an addition useful through the night, or to the blind. The modes, however, by which clocks as well as watches have been made repeaters, have been very various. Repeating-clocks were first invented by Barlow, an English clergyman, and executed by Tompion in 1676. Some have been made to repeat both hours and quarters at any time, and to indicate the time by blows which might be felt but not heard.

The bells connected with clocks, especially those of churches and other public buildings, are often worthy of notice, either on account of their gigantic size, or on account of the arrangements by which they are made to perform a variety of musical chimes. The largest bell in the world is the 'Monarch' of Moscow, which is above 21 feet in diameter and in height, and weighs 193 tons. It was cast in 1734, but fell down during a fire in 1737—was injured, and remained sunk in the earth till 1837, when it was raised, and now forms the dome of a chapel, made by excavating the space below it. Another bell in Moscow weighs 80 tons. The great bell of Peking, 13 feet in diameter, and 14 feet high, weighs 53½ tons; those of Olmütz, Rouen, and Vienna weigh nearly 18 tons. The most noted bells in Britain are—'Great Peter,' placed in York Minster in 1845, whose weight is nearly 11 tons; 'Great Tom' of Lincoln, 5½ tons; and the great bell of St Paul's, 5 tons. The bell cast for the New Palace of Westminster, but afterwards cracked, weighed 14 tons; that of the Roman Catholic Cathedral of Montreal, 13½ tons. The metal of which bells are made is generally an alloy of 80 parts copper and 20 tin.

The illumination of clocks was a favourite idea in the seventeenth and eighteenth centuries, and is equally useful in a public way as the striking of hours or the ringing of bells. It was only during the current century, however, that any plan was adopted for public clocks; the first notion being to light them from without, by reflecting the light of a common lamp or gas-jet on their dials. This simple method is still employed, but is vastly inferior to the employment of a translucent dial, with a strongly reflected light from behind.

Curious Clocks.

Various and ingenious, as well as often highly curious, have been the forms and purposes displayed in the construction of clocks, even from their earlier epochs down to the present day. We have already instanced some of an ancient date which pointed out the motions of the sun and moon, the ebb and flow of the tides, &c. Others of a more fanciful description followed. The famous astronomical clock of Strasburg, completed by Isaac Habrecht about the end of the sixteenth century, deserves a prominent place in our catalogue. It was renovated by a M. Schwitgue in 1842, and probably suffered more or less injury in the bombardment of 1870; but its original movements are thus described in Morrison's *Itinerary:* 'Before the clock stands a globe on the ground, shewing the motions of the heavens, stars, and planets. The heavens are carried about by the first mover in twenty-four hours. Saturn, by his proper motion, is carried about in thirty years; Jupiter, in twelve; Mars, in two; the Sun, Mercury, and Venus, in one year; and the Moon in one month. In the clock itself there are two tables on the right and left hand, shewing the eclipses of the sun and moon from the year 1573 to the year 1624. The third table, in the middle, is divided into three parts. In the first part, the statues of Apollo and Diana shew the course of the year, and the day thereof, being carried about in one year; the second part shews the year of our Lord, and the equinoctial days, the hours of each day, the minutes of each hour, Easter-day, and all other feasts, and the Dominical letter; and the third part hath the geographical description of all Germany, and particularly of Strasburg, and the names of the inventor and all the workmen. In the middle frame of the clock is an astrolabe, shewing the sign in which each planet is every day; and there are the statues of the seven planets upon a circular plate of iron; so that every day the planet that rules the day comes forth, the rest being hid within the frames, till they come out, of course, at their day—as the sun upon Sunday; and so for all the week. There is also a terrestrial globe, which shews the quarter, the half-hour, and the minutes. There is also the figure of a human skull, and the statues of two boys, whereof one turns the hour-glass, when the clock hath struck, and the other puts forth the rod in his hand at each stroke of the clock. Moreover, there are the statues of Spring, Summer, Autumn, and Winter, and many observations of the moon. In the upper part of the clock are four old men's statues, which strike the quarters of the hour. The statue of Death comes out at each quarter to strike, but is driven back by the statue of Christ, with a spear in his hand, for three quarters; but in the fourth quarter that of Christ goes back, and that of Death strikes the hour with a bone in his hand, and then the chimes sound. On the top of the clock is an image of a cock, which twice in the day crows aloud, and claps his wings. Besides, this clock is decked with many rare pictures; and being on the inside of the church, carries another frame to the outside of the walls, whereon the hours of the sun, the courses of the moon, the length of the day, and such other things, are set out with great art.'

Other ancient clocks displayed processions of saints, with obeisance to the Virgin and Child, &c.; and scarcely a town of any importance was without some curiosity of this sort peculiar to itself. Many curious specimens were invented in the seventeenth century; amongst which were a variety measuring time, or at least moved, by balls running down inclined planes, swallowed up by, and traversing the bodies of, brazen serpents, or descending in metallic grooves, to be again thrown up by Archimedean screws: some were made to go by their own weight, descending inclined planes, and thus avoiding the casualties to which mainsprings and weight-lines are liable; others, by means of springs, were even made to ascend such planes. One clock was simply and ingeniously hung like a lamp from the ceiling, and was kept going by its own descent, the winding up consisting merely in pushing it again towards the ceiling. In another, the dial formed the brim of a plate, filled with water, in which swam a tortoise, turning marvellously with the hour, and ever pointing towards it—by magnetic attraction, as every one would now readily conceive; and this favourite idea was varied by many other simple contrivances.

The improvements above described in the escapement and the pendulum bring the mechanical perfection of the clock, as a time-keeping instrument, to the point which it has attained at the present day. But the art of horology would be incomplete unless there were some standard, independent of individual mechanical contrivances, to which all may be referred, and by which the errors of each—which must exist in the most perfect human contrivances—may be corrected. The movements of the heavenly bodies are still, as of old, the only standard for a general measurement of time, affording as they do marks of unvarying certainty. These marks or signals can, however, only be accurately read by persons furnished with the proper apparatus, and instructed sufficiently in its use. This is done in observatories, and there are in most parts of this country now sufficient opportunities of setting clocks by a communication more or less direct with these establishments. For the more ready transmission of correct time to the public, there is at Greenwich Observatory, as well as some others, a ball which is dropped by means of electricity precisely at one o'clock. Within the last few years, however, there has been invented a most ingenious device by which public clocks in a town can be kept at every instant in perfect agreement with the mean-time clock in the observatory. This is effected by an electric connection, and a modification of Bain's electric pendulum, invented by Mr R. L. Jones of Chester.

In the electric clock or pendulum invented by Mr Bain, about 1844, electricity, or rather electro-magnetism, was the moving power. The clock consisted of the pendulum and two or three small wheels connecting its oscillations with the motion of the hands. There were neither weights nor spring, and nothing to wind up. The bob of the pendulum, in oscillating, was made alternately to break and remake an electric circuit which converted it, from time to time, into a temporary magnet; and thus the attraction and repulsion of two permanent magnets, one on each side, kept up its motion. Clocks, however, moved directly by electricity were found unsatisfactory; and a modification was introduced about 1851, in which the

electricity, instead of maintaining the pendulum-motion immediately, draws up a weight which discharges that function, on the principle of the gravity escapement.

But more important is the device of Mr Jones mentioned above. It consists in making a standard clock of the usual construction to regulate the flow of a galvanic current, and thus control the action of any number of secondary clocks, also of the ordinary construction. The pendulums are not intrusted solely to the stimulus of the electricity, but are moved by their own weights, as in ordinary clocks, so that if the electricity ceased to be sent to them, they would go on without it. It might be supposed that a confusion of the two forces, electricity and gravity, would ensue; such, however, is not the case. While the motion of the clock is intrusted to its own weight, the pendulum submits docilely to the controlling action of the electricity; and thus a secondary clock of little value may be invested with all the perfection of the most costly observatory clock. The success of Jones's pendulum has been severely tested in the arrangement employed by Professor Smyth for firing the one o'clock time-gun at Edinburgh. A clock in the Castle of Edinburgh is made to liberate the trigger of the gun exactly at one o'clock. This clock is regulated on Jones's principle, by a clock at the Observatory on the Calton Hill, nearly a mile distant. The Observatory clock, by means of electricity, sets off a time-ball on a neighbouring monument at the same instant. The fall of the ball, and the flash of the gun, though occasioned each by its own clock, are perfectly simultaneous.

Miscellaneous Clock-work.

The applications of clock-work to other purposes than that of measuring time are numerous and important. In all of them, however, the principle is the same—namely, the indication of space, or, what is equivalent, the indication of time or number by mechanical motion. All our *meters*, by which the discharge of gases and liquids is now measured, are but combinations of clock-work; as are also those numerous inventions for *registering* events connected with atmospheric temperature, rise and fall of barometric pressure, direction and force of wind, vigilance of sentinels, and the like.

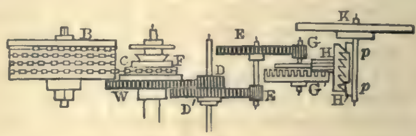
Thus, by a properly constructed *anemometer* (literally, wind-measurer), not only may the force and direction of the wind be ascertained at any given moment, but the instrument may be made to trace or register the direction from which, and the force with which, the aërial current has swept during every minute of the day—all that is necessary being, to place under the tracing-pencils a clean sheet of paper every twenty-four hours. A curious time-keeping method of insuring the presence and attention of night-watchmen has been successfully tried. It consists of a clock with pins projecting round the dial, which can only be pushed inwards at a certain interval, when the watchman's presence and attention are required to unlock the case, and do so; otherwise, his neglect, and the exact quarter of an hour at which he was absent, are shewn by the *tell-tale*.

Closely allied to these varieties of clock-work, but evincing a greater degree of scientific skill, are the various machines which have from time to time been invented to lessen the drudgery of long and continuous calculation. The most ambitious of those contrivances were those projected by the late Mr Babbage, but none of them, we believe, were so far perfected as to do actual work. The Arithmometer of M. Thomas of Colmar executes all ordinary arithmetical operations, and is in actual use. Opinions, however, are divided as to possible advantages derivable from such machines. In the *Journal of the Institute of Actuaries* for July 1871, two writers uphold their utility on the ground of actual experience; another, after pointing out their drawbacks, and the limits of their use, concludes that 'arithmeticians have not much to expect from the aid of calculating machines. A few tables, otherwise easily made, comprise the whole extent of our expected benefits.'

WATCHES.

Clocks and watches are certainly amongst the most perfect, as, in the civilised world, they are the most indispensable machines ever produced by human ingenuity. 'To become a good watch-maker,' says Berthoud, 'it is necessary to be an arithmetician, in order to find the revolutions of each wheel; a geometrician, to determine the curve of the teeth; a mechanician, to find the forces that must be applied; and an artist, to be able to put into execution the principles and rules which these sciences prescribe. He must know how fluids resist bodies in motion; the effects of heat and cold on different metals; and, in addition to these acquirements, he must be endowed by nature with a happy genius.' No one who has not closely attended to the matter, can conceive the difficulty which has been experienced even in dividing circles for the wheels of a watch into the requisite number of rigorously equal parts, and in 'pitching' them in, or adjusting them one with another. All the resources of art shewn by Ramsden, Troughton, and other eminent mathematical instrument-makers, have been here called into requisition. And as to the delicacy of touch and adjustment necessary in the mere regulation of the mechanism, after being thus accurately made and 'pitched in,' some slight idea may be formed from the fact, which we give in the words of Mr Thomson, that 'a second (a mere pulsation) is divided into four or five parts, marked by the vibrations of a watch-balance, and each of these divisions is frequently required to be lessened an exact 2880th part of its momentary duration!'

Before entering upon a description of the various parts, we here present the general arrangement of the wheel-work of a common vertical watch—the frame-plates being omitted, and the dial being supposed to be turned downwards. B is the *barrel* or drum, containing the spring which produces the motion. F is the *fusee*, connected with



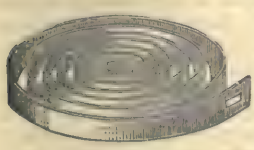
the barrel by the chain *c*. W is the *fusee-wheel*, called also the first or great wheel, which turns with the fusee, and works into the pinion D, called

the *centre-wheel pinion:* this centre pinion, with the centre wheel or second wheel D′, turns once in an hour. The centre wheel D′ works into the *third-wheel pinion* E; and on the same arbor is E′, the *third wheel,* which gives motion to the fourth or *centrate-wheel pinion* G, and along with it the centrate-wheel G′. The teeth of this wheel are placed at right angles to its plane, and act on the pinion H, called the *balance-wheel pinion;* H′ being the balance-wheel, or *scape*-wheel, or crown-wheel, attached to the same arbor. The balance-wheel acts on the two *pallets, p, p,* attached to the *verge* or arbor of the *balance* K; and these being placed at a distance from each other, equal to the diameter of the balance-wheel, and in different places, receive alternately from the scape-wheel an impetus in opposite directions, which keeps up the vibratory motion of the balance. Such is the general arrangement of the powers and motions; we shall now proceed to the analysis.

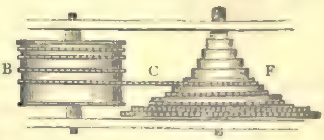
Mainspring and Fusee.

The invention of the mainspring, in place of the weight, was the first pre-requisite to the formation of the watch. But although the mainspring was applied as the maintaining power to time-pieces of a very imperfect description, called watches, about the middle of the sixteenth century, and although the balance had, in such instruments as these, assumed its present form of a vibrating ring, with the greatest weight of course accumulated round a circumference, it was not until the spiral hair-spring was applied to the balance, some time after the invention of the pendulum, as a substitute in clocks for the balance itself, that a comparatively useless machine was converted into a time-measurer nearly as accurate, even in its ordinary form, as the pendulum-clock. Though the invention of the balance-spring, however, was comparatively an early improvement, and the greatest the watch has ever received, we must pass it over in the meantime, till we briefly describe those parts of the mechanism which first rendered the existence of the watch possible at all.

The *mainspring* consists of a coil of thin elastic steel ribbon, inclosed in a miniature barrel or 'drum,' to the inner side of which the outer end of the coil is fixed, while the inner is fixed to an axis at the centre of the drum, round which it may be wound or twisted, so as, by its elasticity and recoil, to cause the drum to make as many revolutions as it makes turns itself while it unwinds. Here, then, we have the main power which sets the whole mechanism of the watch in motion. But it is evident that this power, if thus at once applied to the wheels, would cause them to move with less and less rapidity as it became uncoiled, and as its springing power of course became exhausted; so that unless the wheels were so constructed that only the middle turns were required to be in action, and not those in which it is at its greatest or its least power, a force sufficiently equal even for ordinary purposes could not be thus obtained. French spring-clocks, strange to say, are still, in general, made on this defective principle; but English watches and spring-clocks are supplied with a 'fusee,' which corrects the inequalities of the mainspring with a simplicity only equalled by its ingenuity.



The *fusee,* F, is a cone with a spiral groove, attached to the side of the first wheel of the watch,

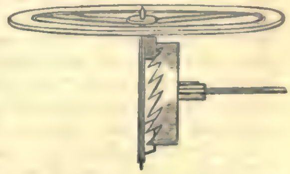


and connected with the barrel or drum B, containing the mainspring, by a chain C, hooked, at its ends, to both.

In winding a watch, the key is placed on the axis of the fusee, and the chain is wound off the barrel on to the cone of the fusee. When fully so wound, the spring is at its greatest power of recoil; but the chain being then round the smallest part of the cone, the influence of the spring on the wheels is at its least amount; while, just as the power of the spring relaxes and diminishes, the cone enlarges, and its lever-influence hence increases. The fusee, in short, is a variable lever, worked by the mainspring, with more purchase when it has less power, and with less purchase when it has more power. It is a very beautiful contrivance, completely answering the intended purpose, when properly made. By means of a spring contained in the interior of the fusee-wheel, the watch is maintained in motion, while the fusee itself is turned by the watch-key in winding up the mainspring. This is called the *going fusee.* When the watch or spring-clock has no fusee at all—and in very flat watches no fusee *can* be introduced—the barrel is immediately attached to the first wheel. In every case, however, the power of the spring is conveyed through the wheels, by nearly the same arrangement in all watches and clocks, to

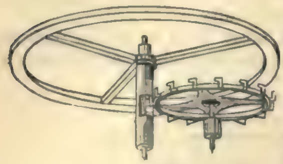
The Escapement.

On the peculiar construction of this part of the mechanism, so as best to keep up the vibrations of the balance, the superiority of one watch over another principally depends. The *vertical* escapement, represented in the adjoining figure, is liable, though in a less degree, to the same objection as the old crown-wheel and the crutch or anchor escapements in clocks. There is a recoil of the scape-wheel after one of its teeth has been stopped by a pallet, which interferes more or less with the accuracy and uniformity of the motion of the train.

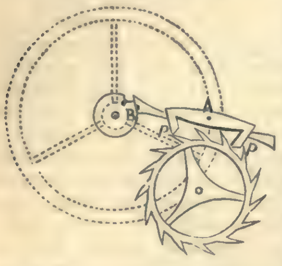


Almost immediately after the invention of the balance-spring, attempts began to be made to introduce an escapement which would produce greater accuracy than the vertical escapement. Hooke, Hüygens, Hautefeuille, and Tompion introduced new principles, each of which has since been successfully applied, though they all, from imperfect execution, failed at the time. The first

real improvement was made by George Graham, the inventor of the dead escapement in clocks. This is called the horizontal escapement; it was introduced in the beginning of the last century, and it is still the escapement used



in most foreign watches. The impulse is given to a hollow cut in the cylindrical axis of the balance, by teeth of a peculiar form projecting from a horizontal crown-wheel. Other forms of escapement in high estimation are the lever escapement, originally invented by Berthoud, improved by Mudge; the duplex escapement, the principle invented by Hooke, the construction perfected by Tyrer; and the detached escapement of Berthoud, improved by Arnold and Earnshaw. The last-mentioned is that which is employed in marine chronometers and in pocket-chronometers, as watches made in all respects like chronometers are called. The lever escapement is that which is used in most English watches. In it the scape-wheel and pallets are exactly the same as in the dead escapement in clocks. The pallets, *p*, *p*, are set on a lever which turns on their arbor, A; and there is a pin, B, in a small disc on the verge or arbor of the balance, which works into a notch at the end of



the lever. The pin and notch are so adjusted, that when a tooth of the scape-wheel has got free, the pin slips out of the notch, and the balance is detached from the lever during the remainder of its swing; whence the name *detached* lever escapement, originally applied to this arrangement. On the balance returning, the pin again enters the notch, moving the lever just enough to send the tooth next in order to escape from the dead face of the pallet on to the impulse face; then the scape-wheel acts upon the lever and balance; the tooth escapes, and another drops upon the dead face of the pallet, the pin at the same time passing out of the notch in the other direction, leaving the balance again free. This arrangement is found to give great accuracy and steadiness of performance. To prevent the teeth from slipping away while the balance is free, the faces of the pallets are slightly undercut, and this makes them secure while at rest; moreover, there is a pin on the lever which moves through a notch on the balance disc, while the pin, B, moves through the notch in the lever, which is so adjusted as to guard against the lever moving and the teeth escaping, while the balance is free.

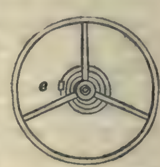
Balance and Balance-spring.

These are the only other parts of the mechanism of the watch of which it is necessary here to treat.

The balance, as may be seen from the representations of it in connection with the different escapements just noticed, is a wheel finely poised on its axis; the pivot-holes in which it turns being frequently—in chronometers and clocks, as well as in watches—jewelled, or made of small rubies, diamonds, &c.; as those of other of the wheels also are, for the sake of durability. The natural effect of an impulse given to such a wheel would be a complete rotation on its axis. This, however, as we have already seen, is convertible, by various escapements, into a vibratory motion. But as in clocks the pendulum was found to be a most invaluable adjunct, absorbing, as it were, in its own more or less extended oscillation, every inequality in the rotation of the wheel-work, or the vibration of the balance, something of precisely the same nature for watch-escapements was the great desideratum, when the balance-spring or hair-spring was invented; and, from this analogy, it even acquired, improperly, the name of the pendulum-spring.*

Simple and obvious as the suggestion of the regulative influence of a spring, applied to the vibrating mechanism of the watch-balance, in place of either weight or pendulum, may now appear—especially after the idea of the mainspring, as a substitute for the maintaining weight, had been suggested—this has been held to be a crowning invention in the mechanism of the watch; and the honour of its first suggestion has been claimed by no less than three very eminent men—by Dr Hooke; by Abbé Hautefeuille, a Frenchman; and by Hüygens, the Dutch astronomer. It was ultimately proved, that although Hüygens had applied for a patent at Paris in 1674, Hautefeuille had done so several years before; while Hooke had made a similar application in England in 1658. To Hooke, therefore, must be attributed the first idea of the balance-spring.

In its application to the balance of a watch, one of the extremities (*e*) of the spring is fastened to a point independent of the balance, while the other is attached near its axis. When the balance is at rest, the spring is inclined neither way, this position being called the point of rest; but when the impulse is given to the balance



by the crown-wheel of the escapement, it is clear that now a rotatory motion of the balance cannot take place, even though there should be nothing in the form of the escapement to prevent it; the balance will now only move round so far as the impulse given is able to overcome the elastic resistance of the spring; and when that resistance becomes equal to the impulse given, the balance will stop for a moment, and then be driven back by the elastic recoil of the spring, continuing thus to vibrate so long as the impulse is repeated or the watch is in motion.

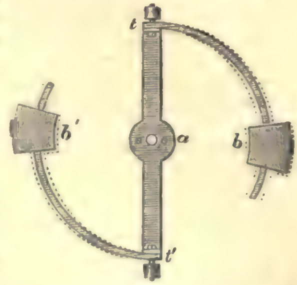
The recoil of the spring is sufficient to drive back the balance to a distance nearly double the length of its first motion; this is therefore called the long arc of vibration. But when the motion of the balance is free, with a certain length of spring, the *long* arc of vibration is made in less time than

* This little instrument, the hair-spring, is no less remarkable for the extreme delicacy of its construction, than for the great value which it shews the possibility of giving to a piece of steel, of exceedingly small and insignificant appearance, by manual labour. Four thousand hair-springs scarcely weigh more than a single ounce, but cost often more than £1000!

the short one, to which the impulse is given: with a spring of greater length this principle is reversed; whence it was concluded by Le Roy and Berthoud, that equality of time, or *isochronism*, in unequal vibrations, could be more easily obtained by lengthening the spring than by tapering it. In principle, too, the stronger and shorter the spring, the quicker will be its vibrations. Thus effects of an extremely varied description can be produced on the motions of a watch by the slightest difference of length and taper in a hair-spring. And it is thus that the correctness of the time-keeping is essentially dependent on the principle adopted in the formation of this apparently most insignificant little appendage. So much is this the case, that if the hair-spring be isochronal in a free or detached escapement, the time shewn will be the same, notwithstanding changes in the motion of the wheels, or even in the power of the mainspring. In England, where time-keepers have been brought to their greatest perfection, it is considered that isochronism is most easily attainable by using the cylindrical helical spring, which is applied to all marine chronometers.

Compensation.

In watches, even more than in clocks, variations of temperature, unless provided for, produce variations in the rate of going, the increase or diminution of the temperature affecting to some extent the moment of inertia of the balance, and to a great extent the elastic force of the balance-spring. A rise in the temperature makes the balance expand, and therefore augments its moment of inertia; it adds to the length of the spring, and thereby diminishes its elasticity, the elastic force of a spring varying inversely as the length; and the time of vibration of the balance, which depends upon the moment of inertia directly, and upon the elastic force of the spring inversely, is increased—the watch, that is, goes more slowly—in consequence both of the increase of the inertia and of the diminution of the elastic force of the spring. A fall in the temperature is attended by opposite results, the watch going more rapidly than before. A watch without a compensated balance would vary very much more than a clock without a compensation pendulum, but that being usually carried in the waistcoat pocket, it is kept at a pretty uniform temperature. To invent a satisfactory compensation, was at one time the great problem for watchmakers. The compensation can obviously be made in either of two ways—by an expedient for shortening the effective length of the balance-spring as the temperature rises, so as to increase the elastic force of the spring; or by an expedient for diminishing the moment of inertia of the balance as the temperature rises, so as to correspond to the diminution of the force of the spring. The first method was that made use of by John Harrison, who first succeeded in making a chronometer capable of measuring time accurately in different temperatures; but an adaptation of the other method, invented by Earnshaw, is that which is always employed now: $t\ a\ t'$ is the main bar of the balance; and $t\ b$, $t'\ b'$ are two compound bars, of which the outer part is of brass, and the inner part of steel, carrying weights, b, b', which may be screwed on at different places. The brass bar expands more with heat, and contracts more with cold than the steel bar; therefore, as the temperature rises, the bars, with their weights, bend inwards, and so the moment of inertia of the balance is diminished; as it falls, they bend outwards, and the moment of inertia is increased; and of course the diminution or the increase must be made exactly to correspond to the diminution or increase in the force of the spring.



CHRONOMETERS.

The chronometer is just a large watch fitted with all the contrivances which experience has shewn to be conducive to accurate time-keeping—for example, the cylindrical balance-spring, the detached escapement, and the compensation-balance. As a watch which will keep time in one position will often not do so equally well in another, marine chronometers are always set horizontally in a box in *gimbals*, an arrangement which keeps the chronometer horizontal, whatever the motion of the vessel.

The great importance of an accurate portable time-keeper at sea is for determining the longitude. From what has been already said on the subject of time, it will be readily understood that if the captain of a ship, leaving a port in Great Britain with a chronometer set to Greenwich time, shall, after sailing westward for a time, observe when the sun is at his highest point, or on the meridian, and find that his chronometer at that instant marks one o'clock, he must be 15° west of Greenwich. This use was first distinctly pointed out by Sir Isaac Newton. A committee of the House of Commons, of whom this philosopher formed one, having been appointed, on the 11th June 1714, to consider the question of encouragement for the invention of means for finding the longitude, the result of their meetings was a memorial containing an explanation of the different means proper for ascertaining the longitude, and recommending encouragement for the construction of chronometers as the best means of ascertaining it. An act of parliament was then passed, offering a reward for this purpose.

The first chronometer used at sea was invented by John Harrison. After many years of study, it was completed in 1736. After several further trials and improvements, and two trial voyages to America, undertaken for the satisfaction of the commissioners, the last of which was completed on the 18th September 1764, the reward of £20,000 was finally awarded to Harrison.

Somewhat later than this, several excellent chronometers were produced in France by Berthoud and Le Roy, to the latter of whom was awarded the prize by the Académie Royale des Sciences. Progress was still made in England by Arnold, Earnshaw (the inventor of the compensation still in use), and Mudge, to whom prizes were awarded by the Board of Longitude, and

under whom a perfection nearly equal to that of the present day was obtained. The subsequent progress of watch-making has been chiefly directed to the construction of pocket-watches on the principle of marine chronometers, or to the combination of accuracy with convenient portability. The adjusted lever watch is now made in Clerkenwell with a degree of accuracy which enables the performance to be warranted within an error of one second a day.

USEFUL HINTS.

For the attainment of habits of punctuality, for the regulation of the usual routine of business and of everyday life, much often depends on the judicious selection of a time-keeper. Although, therefore, none but a workman possessing a thorough knowledge of his art is capable of forming a certain judgment regarding the merits of a particular watch or clock, yet a few general hints may not be without use. With this view we select the following remarks from an excellent little work published some years ago—Thomson's *Time and Time-keepers.*

And first of clocks: These, in general, measure time more accurately than watches, especially eight-day weight or long clocks, which are also cheapest. Long and heavy pendulums are to be preferred. A light pendulum shews a clock to be badly constructed, or deficient in power. Steel rods are better than brass, well-seasoned and varnished wood than steel, and compensation-rods than either. The clock should be steadily fixed to the wall, or firmly placed on *three* feet sufficiently far apart, so that the mechanism may be uninfluenced by the oscillations of the pendulum. Clocks are regulated by lengthening the pendulum, to make them lose, and by shortening it, to make them gain; this is very generally done by turning a nut or screw *below* the weight or *bob* of the pendulum, *to the right to gain*, or *to the left to lose;* or, if the screw is *above* the weight, the rule is *reversed.* Many French clocks, and a few old English ones, are liable to derangement in striking, unless the hands are moved rapidly *forward.* The hands of English clocks, in general, may be turned either way without injury, and the same with a watch, unless it has an alarm.

An intelligent, careful man may be safely trusted with the cleaning, adjusting, or repairing of clocks, while a diversity of talent and experience is necessary to qualify him for the manipulation of watches. 'The possessor of a good picture would doubtless inquire into the ability of the artist before he intrusted him to retouch it; and this caution is equally necessary for a watch, as many of the best construction have sustained irreparable injury from the hands of unskilful workmen. Even bad watches—which are by far the greatest number—require the aid of better hands than those which constructed them.' A clever artist may enable even a bad watch to perform tolerably well. Watches should ordinarily be cleaned every second or third year; small, flat, or complicated ones oftener. All require care in handling. They should be regularly wound as nearly at the same hour as possible; and while being wound, should be held steadily in the hand, so as to have no circular motion themselves. When hung up, let the watch have support, and be perfectly at rest; or when laid horizontally, let it be placed on a soft substance for more general support, otherwise the motion of the balance will generate a pendulous motion of the watch, causing much variation in time. Should a watch vary by heat or cold, as when worn or not worn in the pocket, the hands may be set to time; but the regulator should not be altered, if set to the ordinary temperature of the season. Compensation watches, if properly constructed, do not so vary. A trial even of a year or two is no proof of the substantial worth of a watch. Dealers themselves may be deceived. A duplex watch may be very bad, while a vertical one may be very good, so that workmanship is as important as principle. Many low-priced and bad watches have eight or even ten holes jewelled, while many good and costly ones have but four: a hole can be jewelled for three shillings. 'The high-sounding description, the handsome exterior, the offered trial, and enticing cheapness, are effective baits to the short-sighted.' External ornament forms but a small item of expense, and the prices therefore will, in general, point out the comparative qualities of the work in the shop of an artist of known integrity and ability.

The large thick old watch is less absurd than some of the more recent kind, little thicker than half-a-crown, or even much smaller. The lever watch is capable of great accuracy, and is preferable to the vertical, though the principle of the latter is more generally understood, and more easily repaired; lever watches, however, are neither expensive to repair nor liable to derangement. The horizontal or cylinder watch is liable to great tear and wear, but performs with considerable accuracy. The duplex watch, with a compensation-balance, when well constructed, and treated with ordinary care, will keep time with the greatest accuracy; but being delicate, it does not stand violent exercise: a bad duplex watch is most expensive to repair. The detached watch, the escapement of which is the only one used in marine chronometers, is the most perfect, but requires care. Repeaters are expensive to repair as well as to purchase, but may be as accurate as others. Watches shewing seconds are often useful, and, if well made, are neither expensive nor easily deranged. A watch may be handsome, yet bad; but a good watch is seldom unsightly. The spring for shutting the shells is not so good as the snap; it often allows dust to penetrate to the works. The covers of hunting-watches will not protect the glass when the hunters are very flat. The extreme accuracy of marine chronometers is partly produced by their being kept constantly in a horizontal position. They are only required to shew *equal* time; whether they gain or lose is of little consequence, provided they are regular, and *keep* their known rate.

CHEMISTRY.

CHEMISTRY is a department of physical science, and therefore treats of the properties and changes of matter.

As the division of physical science into various departments depends more upon the various methods which we use in observing the phenomena of nature, than upon any real natural distinction, it is impossible to give a logically complete definition of any of these departments; and what now belongs to one, it may be found, at some future time, more convenient to transfer to another. We shall, therefore, neither quote any of the numerous definitions of chemistry already given, nor add one to the number, but leave the reader to form an idea of its scope and purpose from the outline of the facts and principles of the science contained in the present paper.

Matter, whether as it occurs in nature, or as modified by art, is obviously of various kinds, and any specimen of matter that we may examine is either all of one kind, or a mixture of several different kinds. There are various means by which we can determine whether a specimen of matter is pure (that is, all of one kind) or not.

We can often prove that a substance is a mixture by simple inspection. Thus, any one who looks at a piece of granite at once sees that it consists, not of one substance, but of a mixture of several, the particles of each being large enough to be distinctly visible. The smaller the particles, and the more intimate the mixture, the more difficult does it become to distinguish it, by simply looking at it, from a pure, single substance. Where the eye cannot settle the question, we must resort to other means. These may be described generally as ways of 'taking samples.' If samples taken in many different ways agree with one another, and with the original substance, we conclude that we have to deal with a pure body; if, on the contrary, the samples differ from one another, we learn that the substance is a mixture, and, further, find out how to separate it into its several ingredients. We shall describe a few of these 'tests of purity,' or ways of taking samples.

1. *Elutriation.*—In the first case, we shall suppose that we have a substance, no part of which dissolves in water, and which consists of very small particles of two or more bodies of different specific gravity. The substance is reduced to a fine powder, and stirred up with water. This is left for a time at rest, and gradually a part of the powder separates—if heavier than water, as a sediment at the bottom; if lighter than water, as a scum at the top. The scum is then removed, or the muddy water poured off from the sediment and again left at rest, when a further portion separates; and by repeating this process, we obtain a series of samples differing from one another in the rate of deposition. If the substance were all of one kind, these samples would only differ from one another in the *size* of the particles, the largest separating most rapidly; but if we have a mixture, we find that (supposing the particles of the different ingredients to be of the same average size) the particles which are denser than water go down the faster the denser they are, and the particles lighter than water rise to the surface the faster the lighter they are, so that the first sample differs in kind from the last. This method of 'elutriation' is exemplified in the washing of ores; the lighter clay or earth with which the ore is mixed, falling slowly through the water, is washed away as mud, while the heavier ore falls quickly to the bottom of the vessel in which the washing is performed, and is thus retained.

2. *Solution.*—Some substances, such as sugar, salt, &c. dissolve in water; others, such as sand, charcoal, &c. do not. We can therefore detect a mixture of a soluble and an insoluble substance, and separate them from one another, by treating the mixture with water until no more will dissolve: we have then the insoluble substance left, and can recover the soluble one from the liquid by evaporating away the water. This process, sometimes called 'lixiviation,' is used in extracting saltpetre from earth containing it, in obtaining potash from wood-ashes, and in many other important operations. Other liquids besides water may be used for similar purposes, a liquid being selected which will dissolve some of the ingredients in the mixture and leave others undissolved. The solution is separated from the insoluble residue, either by allowing the latter to settle and then decanting, or by filtration.

3. *Crystallisation.*—Substances soluble in water require very various proportions of water to dissolve them; thus 100 parts of water will, at the ordinary temperature, dissolve 33 parts of Epsom salts, 20 parts of washing-soda, 10 parts of bicarbonate of soda (common 'baking-soda'), and about one-third part of plaster of Paris. If, then, a mixture of soluble substances be dissolved in water, and the water gradually evaporated, the least soluble of these substances will separate first; and by collecting separately the successive crops of crystals, we shall have a series of samples, the first consisting almost exclusively of the least soluble, the last of the most soluble. Such a method of separation is seldom perfect, each crop generally containing some admixture of the ingredients prevailing in the crop before and in that after it. It is in this way that common salt is obtained from sea-water. Sea-water contains, besides common salt, smaller quantities of various other salts. Of these the least soluble is sulphate of lime, and this is the first to appear on evaporating the water; the common salt crystallises next; and the 'mother-liquor,' as the solution left after the common salt has been removed is called, contains salts of magnesia, which are very soluble.

4. *Dialysis.*—If a solution of common salt be securely tied up in a bladder, and the bladder be hung in a vessel filled with pure water, it will be found after a time that the water outside the

bladder is as salt as that within; and if the water outside be frequently renewed, the whole of the salt can be removed from the bladder. If, instead of a solution of salt, we take a solution of glue (weak enough to prevent its *setting* as a jelly), we find that practically none of the glue escapes into the outer vessel. If a mixture of salt and glue be treated in this way, the two substances will be separated—the salt passing through the bladder, and the glue remaining behind. Many substances, especially those which crystallise, behave like salt, and pass through the bladder; while many other substances, especially those which, like glue, do not crystallise, but form jellies, and, when dried, appear as horny masses, pass extremely slowly through the bladder. The late Mr Graham, Master of the Mint, who discovered this method, called the first set of bodies 'crystalloid'—that is, crystal-like; and the second, 'colloid'—that is, glue-like bodies. Dialysis is used in detecting poisons in animal fluids, such as the contents of the stomach. Most of the important poisons are crystalloid; while most of the animal fluids that interfere with the detection of poisons are colloid, so that the two can be separated by this means. Dialysis has also been applied to remove the salt from the brine in which meat has been salted. Such brine contains much nutritious matter dissolved out of the meat, but is far too salt to be used as food; by dialysis the salt can be removed, while the nutritious matter, being colloid, remains in the bladder.

5. *Fusion.*—A mixture of a fusible and an infusible substance may be resolved into its ingredients by heating it till the fusible body melts, and then pressing it, or allowing it to drain away from the infusible residue. The same method may be employed to separate from one another two substances of different degrees of fusibility, by heating the mixture to a temperature higher than the fusing-point of the one, and below the fusing-point of the other.

6. *Distillation.*—Some substances are *volatile*—that is, can be converted by the action of heat into vapour, which, when cooled, is condensed, or restored to the liquid or solid state. By distillation we can separate volatile from non-volatile bodies. The mixture is heated in a vessel (retort or still), to which a tube is adapted, to convey the vapour to the 'condenser,' where it is cooled. The

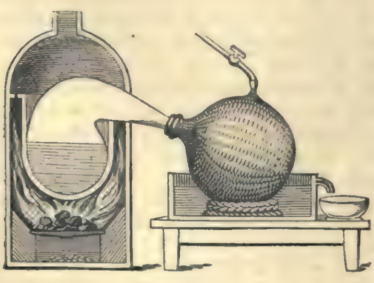


Fig. 1.

volatile substance distils over, while the non-volatile ingredient remains in the retort or still. By what is called *fractional distillation*, it is possible to separate, more or less completely, substances of different degrees of volatility; the first portion of the distillate contains a larger proportion of the more volatile ingredient, and the last a larger proportion of the less volatile. Thus, when the 'wash,' or liquid formed by the fermentation of malt, is distilled, the first portion consists of a very volatile product called the 'foreshot;' then alcohol mixed with water distils over; and lastly, a substance less volatile than alcohol, the 'fousel oil.'

7. *Diffusion of Gases.*—If a heavy gas and a light gas are placed together in a vessel, the heavy gas below and the light above, they slowly mix, even when left at rest; but, when once mixed, they shew no tendency to separate; and however long the mixture is kept, the mixture at the top will be found to have the same composition as that at the bottom. It is, therefore, often necessary to apply a test, in order to determine whether a given specimen is a single gas or a mixture. Some of the methods already mentioned may sometimes be employed for this purpose. Thus, gases differ in their solubility, and in this way it may be shewn that atmospheric air is a mixture, one of its ingredients (oxygen) being considerably more soluble in water than the other (nitrogen). Again, some gases can be condensed into liquids by cold and pressure, and thus partially separated from those which cannot be so condensed. By this means Faraday discovered in oil-gas the gas now known as butylene.

There is, however, a special method by which, in almost all cases, mixtures can be distinguished from single gases.

The slow mixing of two gases, of which we have just spoken, and which is known as 'diffusion' of gases, takes place not only when the two gases are in immediate contact, but also when they are separated by a porous septum (such as a plate of unglazed earthenware), and in this case it is easy to measure the 'rate of diffusion' by observing what quantity of gas passes through the septum in a given time. Now, different gases have different rates of diffusion—the lighter the gas the faster does it diffuse.* If, then, a mixture of two gases of different density be allowed to diffuse through a porous plate, more of the lighter gas will pass out, and proof will be obtained that the specimen was a mixture, and not a single gas.

The various methods of which we have given a general description are physical or mechanical modes of separating completely or partially the ingredients of a mixture, and thus, more or less perfectly, obtaining pure substances. Let us now consider some of the properties of these pure substances. For this purpose, it is necessary to classify them, or arrange them in groups. This may be done in several different ways. We may, for instance, distinguish them as, first, simple; and second, compound. A compound substance is one which we can, by the application of some process, separate into two or more pure substances, different from each other and from the original substance. We shall give an instance, and shew how a compound differs from a mixture. White statuary marble is a pure body; it cannot, by any mechanical process, such as we have described above, be separated into ingredients—any such mechanical mode of sampling

* Experiment has shewn, in complete accordance with theory, that the rate of diffusion is inversely proportional to the square root of the density of the gas.

it yields samples identical with one another. But if we weigh a piece of marble in a crucible, the weight of which is known, and then raise it to a bright red-heat, we find that, upon cooling, it weighs less than it did before. If we continue the heating until no further change of weight is produced, we find that one hundred parts of marble are reduced to fifty-six. Something must have been lost in this process, and we are able, by methods—the details of which we cannot at present describe—to shew that this something is a gas, or kind of air, which the marble gives off when strongly heated. By appropriate means we can catch this air, and shew that one hundred parts of marble give off exactly forty-four parts of it by weight. What is left in the crucible is not marble—it differs entirely from it in appearance and properties—it is quicklime. We have thus decomposed marble into two substances, quicklime, and a gas, which its discoverer, Dr Black, called 'fixed air,' because it had been in a fixed or solid condition in the marble. We shall afterwards see what this gas is—in the meantime we shall call it fixed air. By heating marble we have then obtained from it two different substances, lime and fixed air : but it will be at once seen that this *decomposition* is quite another thing from the separation of a mixture into ingredients. Marble is not a *mixture* of lime and fixed air ; it is a pure substance, having properties of its own ; thus, lime and fixed air are both soluble in water, marble is not ; marble is tasteless, while both of the bodies formed from it have well-marked tastes. The space occupied by a piece of marble is not the same as that occupied by the lime and fixed air which can be obtained from it. On the other hand, the properties of the ingredients of a *mixture* remain unchanged—that is, are the same in the separate and in the mixed state ; and the space occupied by the mixture is the same as that occupied by the ingredients unmixed.

A large number of substances can be *directly* decomposed by the action of heat, light, or electricity, and thus proved to be compounds, as we have seen is the case with marble ; and in many cases we can reverse the process, and prove that a substance is compound by forming it from its components ; thus, quicklime and fixed air unite and form a substance identical in chemical characters with marble.*

By this process of 'synthesis' (or *putting together*) we can often prove that substances which we are unable to decompose directly are really compounds. Thus, quicklime cannot be decomposed without the addition of some other substance, but we can prove it to be a compound by effecting its synthesis. The metal calcium, which can be obtained from lime by a series of processes which will be described in a later part of this paper, unites with oxygen gas, and the resulting compound is quicklime. The compound character of quicklime, and the nature of its components, are as clearly proved by this synthesis as they could be by the direct decomposition of quicklime into calcium and oxygen. There are, however, a considerable number of substances (sixty-three are at present known) which chemists have not as yet been able either to decompose, or to produce by synthesis. Such substances have, therefore, not been proved to be compound, and are provisionally styled 'elements,' or simple bodies. All compounds are composed of two or more of these *elements* united together ; and compounds are sometimes classified as binary, ternary, quaternary, &c. according as they consist of two, three, four, &c. elements.

A more generally useful system of classification of pure substances is to arrange them in groups or natural families according to their resemblances in chemical action. This system will be best illustrated by means of examples, and for this purpose we shall select five groups, which include the most important and useful substances, and the relations of which exhibit most strikingly the nature of chemical action. These five groups are (1) Acids, (2) Bases, (3) Salts, (4) Metals, and (5) Salt-radicals.

As particular examples of these groups, we may here mention the following substances—(1) Acids : Sulphuric Acid (oil of vitriol), Nitric Acid (aquafortis), Hydrochloric Acid (spirit of salt), Acetic Acid (vinegar). (2) Bases : Caustic Potash, Caustic Soda, Lime, Magnesia, Oxide of Lead (litharge), Ammonia (spirit of hartshorn). (3) Salts : Sulphate of Soda (Glauber's salt), Sulphate of Magnesia (Epsom salt), Chloride of Sodium (common salt), Chloride of Ammonium (sal-ammoniac), Acetate of Lead (sugar of lead), Nitrate of Potash (saltpetre). (4) Metals : Potassium, Sodium, Calcium, Magnesium, Zinc, Iron, Copper, Silver. (5) Salt-radicals : Chlorine and Iodine.

If we examine the acids above mentioned, we find that they possess certain well-marked characters in common. They have all a sour taste ; they all act in the same way upon blue and purple vegetable colours (such as the colouring-matter of the violet, or of the red cabbage, or the colouring-matter called *litmus*, obtained from certain lichens), turning them red. These two characters —the sour taste, and the 'acid reaction,' as the reddening of vegetable blue colouring-matters is called—belong to most acids which are soluble in water. The taste of the soluble bases is not so generally characteristic, although many of them have a peculiar so-called 'alkaline' taste—resembling that of soap—well marked in potash, soda, and lime. The change which they produce upon the above-mentioned vegetable colouring-matters is exactly the reverse of that of the acids, and is called the 'alkaline reaction.' Thus, if we take a purple infusion of red cabbage, and add potash, soda, lime, or ammonia to it, it becomes green ; if to this green liquid we cautiously add an acid, it becomes purple, and then red ; an addition of a soluble base (alkali) to this red liquid renders it first purple, then green. Similarly, blue litmus is reddened by acids, and reddened litmus has its blue colour restored by the addition of an alkali. Another substance which is used as a test for the alkaline reaction is the yellow colouring-matter of the turmeric root—this is rendered brown by alkalies, and the yellow colour is restored on adding an acid. These characters (taste and reaction) belong to well-marked acids and bases which are soluble in water ; they do not belong to *all* acids and bases. The distinguishing character of these groups is *their action upon each other*.

* Sir James Hall has shewn that if this substance (*amorphous* or *uncrystallised carbonate of lime*) is heated under great pressure, it does not decompose, but fuses, and, on cooling, forms a substance in all respects the same as white marble.

When an acid and a base are mixed, a salt is produced. Thus, if we gradually add a solution (in water) of hydrochloric acid to a solution (in water) of caustic soda, a point will be reached where the mixed solution has neither the alkaline reaction of the soda nor the acid reaction of the hydrochloric acid. Such a solution is said to be *neutral*, and, on examination, is found to contain neither acid nor base, but a new substance, different from either of them. In the case which we have taken, this neutral substance is common salt. A similar action takes place between every acid and every base, and the fact that salts are formed in this way has given rise to the nomenclature of salts which was till lately in almost universal use, and is still very frequently employed. This nomenclature will be best explained by a series of examples. Thus,

Sulphuric Acid	acts on	Soda,	producing	Sulphate of Soda.
Nitric Acid	"	Soda,	"	Nitrate of Soda.
Hydrochloric or Muriatic Acid	"	Soda,	"	Hydrochlorate or Muriate of Soda.
Sulphuric Acid	"	Ammonia	"	Sulphate of Ammonia.
Acetic Acid	"	Oxide of Lead	"	Acetate of Oxide of Lead.
		&c. &c.		

In all these cases, the name of the acid ends in *-ic* (sulphur*ic*, nitr*ic*, &c.). There are, however, acids the names of which end in *-ous*, such as sulphur*ous* acid, nitr*ous* acid. In such cases,

Sulphurous Acid	acts on	Soda,	and produces	Sulph*ite* of Soda.
Nitrous Acid	"	Potash,	"	Nitr*ite* of Potash.
		And so on.		

Sulphur*ic* Acid produces sulph*ates*; Sulphur*ous*, sulph*ites*, &c.

When this characteristic action of an acid upon a base takes place, water is in most cases produced as well as the salt. This formation of water is of great theoretical importance, and will be adverted to again further on.

What we have now seen enables us to define acids and bases as substances opposed to one another in chemical character, and capable of acting upon one another, so that both the acid and basic properties are neutralised, and salts produced. It is necessary, however, to note that this distinction between acids and bases is one rather of degree than of kind, some acids possessing the acid character, and some bases possessing the basic character, in a much more strongly marked manner than others. Thus, some substances behave as acids with strong or well-marked bases, and as bases with the stronger acids; for instance, white arsenic has decidedly acid properties, and forms salts with most bases, but acts like a base when treated with hydrochloric or tartaric acid. Alumina and green oxide of chromium are bases to most acids, but acids to some of the stronger bases, such as potash and lime. The salts formed from a strong acid and a weak base have, generally speaking, when soluble, an acid reaction; those formed from a weak acid and a strong base have, under similar conditions, an alkaline reaction. Thus, sulphate of alumina has an acid reaction; carbonate of potash has an alkaline reaction.

The next point which we shall consider is the relation between the *quantity* of acid and the *quantity* of base required to form a salt. This is most easily investigated in the case of strong acids and bases which form with one another salts neutral to vegetable colours, although the same principles apply equally to all other cases. To illustrate these principles, we shall examine the relations of the acids and bases mentioned above—namely, sulphuric, nitric, hydrochloric, and acetic acids; and the bases, caustic potash, caustic soda, lime, magnesia, oxide of lead, and ammonia. Let us first take a certain weighed quantity of pure caustic potash (for reasons to be explained afterwards, we select the quantity 56 grains*), and find out how much of each of these acids is required to neutralise it and form a salt. The results are as follow:

56 grains of Caustic Potash are neutralised by—

49	grains of	Sulphuric Acid.
63	"	Nitric Acid.
36½	"	Hydrochloric Acid.
60	"	Acetic Acid.

These quantities—49 parts of sulphuric acid, 63 of nitric acid, 36½ of hydrochloric acid, and 60 of acetic acid—are said to be 'equivalent' to one another—that is, they are equivalent as far as neutralising potash is concerned; and these numbers are called the 'equivalents' of the acids. We further find that

49 grains of Sulphuric Acid neutralise—

56	grains of	Caustic Potash.
40	"	Caustic Soda.
28	"	Quicklime.
20	"	Calcined Magnesia.
111½	"	Oxide of Lead.
17	"	Ammonia.

Similarly, these quantities of the various bases are said to be 'equivalent' to one another, and these numbers are called the equivalents of the bases. Now, the remarkable fact in connection with these numbers (the first discovered of a series of similar facts, upon which the modern system of chemistry is based) is, that *an 'equivalent' of any acid is precisely the quantity required to act upon an 'equivalent' of any base in order to produce a salt.* Thus, 63 grains of nitric acid neutralise 56 grains of potash, 40 of soda, and so on; 60 grains of acetic acid act upon 111½ of oxide of lead to produce sugar of lead, &c. It is thus only necessary to ascertain by experiment the proportion in which a new base unites with *one* known acid, in order to know in what proportion it will unite with any other acid the equivalent of which is known.

The salts thus formed are often called 'neutral salts,' because, when an equivalent of a *strong* acid acts upon an equivalent of a *strong* base, the resulting salt has neither an acid nor an alkaline reaction; it is, however, better to call them 'normal salts,' because, as already mentioned, such of them as have a weak acid and a strong base are often alkaline, and those with a strong acid and weak base are often acid in reaction upon vegetable colours. They are called 'neutral' or 'normal' salts, to distinguish them from two classes of salts which we shall next, shortly, advert to. If we mix 49 grains (one equivalent) of sulphuric acid with water, and add 56 grains (one equivalent) of caustic potash, we already know that the 'normal' sulphate of potash will be produced. If, however, we add only 28 grains (½ equivalent) of caustic potash, and then dry off the water, we find, not, as we might expect, a mixture of neutral sulphate of potash and unacted-on sulphuric acid, but a salt, called the 'bisulphate of potash,' or 'acid' sulphate of potash, which has been formed by the action of one equivalent of

* Instead of grains, it need scarcely be said, any other unit (ounces, pounds, or tons) may be used.

sulphuric acid upon half an equivalent of caustic potash (or, what is the same thing, by the action of two equivalents of sulphuric acid upon one of caustic potash). It is in the case of only some acids that we obtain acid salts: thus, sulphuric, oxalic, tartaric, phosphoric, citric acids form acid salts; nitric and hydrochloric acids do not. As examples of acid salts, we may mention cream of tartar (acid tartrate of potash), salt of sorrel (acid oxalate of potash), baking-soda (bicarbonate of soda), super-phosphate of lime (acid phosphate of lime). In these, we have salts formed from one equivalent of potash, and two of tartaric acid; one of potash, and two of oxalic acid; one of soda, and two of carbonic acid; one of lime, and three of phosphoric acid. It will be noted that here also we have the proportion of acid and base occurring according to equivalents; and it will be well to remember, what will be more fully explained afterwards, that it is the acid which determines the formation of acid salts, some acids forming them, others not.* Most acid salts have an acid reaction; but where the acid is weak, the reaction may be neutral, or even alkaline.

Again, we have seen, that if 60 grains (one equivalent) of acetic acid be treated with $111\frac{1}{2}$ (one equivalent) of oxide of lead, a normal salt (acetate of lead, or sugar of lead) is produced. If this be dissolved in water, and the solution be shaken up with finely divided oxide of lead, it will dissolve 223 grains (two equivalents) more, and form a salt, which is called 'basic' acetate of lead. A basic salt is formed by the action of one equivalent of an acid upon more than one equivalent of base; just as an acid salt is formed by the action of more than one equivalent of acid upon one of base; and as it is the acid which determines the formation of acid salts (some acids forming them, others not), so it is the base which determines the formation of basic salts; some bases, such as oxide of lead, oxide of bismuth, red oxide of iron, forming them; others, such as caustic potash, soda, oxide of silver, not.

Another class of salts deserves mention here —namely, the 'double salts.' These may be regarded as compounds of two salts with one another. As examples, we may mention common alum, consisting of sulphate of potash, and sulphate of alumina; Rochelle salt, tartrate of potash, and tartrate of soda; dolomite, carbonate of lime, and carbonate of magnesia.

We have now considered, pretty fully, the action of acids upon bases; let us specially turn to the action of acids upon salts, of bases upon salts, and of different salts upon one another.

In order to understand the action of acids upon salts, we shall first examine what takes place when an equivalent of a base is mixed with an equivalent of each of two acids. It is obvious that one or other of two things may occur— First, the base may form a salt with *one* of the acids, the remaining acid being left as it was; or second, the base may be divided into two parts, one forming a salt with part of the one acid, the other with part of the other acid, the rest of both acids being left unacted on. In the first case, we shall have a mixture of *one* salt and *one* acid; in the second, a mixture of *two* salts and *two* acids. Thus if one equivalent ($111\frac{1}{2}$ grains) of oxide of lead be mixed with one equivalent (49 grains) of sulphuric acid, and one equivalent (63 grains) of nitric acid, the whole of the oxide of lead acts on the sulphuric acid, and the nitric acid is left altogether unacted on. Again, if one equivalent (40 grains) of caustic soda be mixed with one equivalent of sulphuric, and one equivalent of nitric acid, the soda acts on both acids, producing sulphate of soda and nitrate of soda, while a part of both acids is left unacted on. Now, the same final result is produced whether the two acids are added at once (as in the cases we have just mentioned) or successively. In the first case, we might add to the oxide of lead, first, nitric acid, and obtain nitrate of lead; and then to the nitrate of lead add sulphuric acid, when we should obtain sulphate of lead and nitric acid—the sulphuric acid turning out (if we may use the phrase) the nitric acid. If, on the other hand, we add the sulphuric acid first, we obtain sulphate of lead, and nitric acid does not act on this; so that in either case we obtain the same final result—sulphate of lead and nitric acid. In the second case, sulphuric acid will *partially* (at ordinary temperatures) drive out nitric acid from nitrate of soda, and nitric acid will also *partially* drive out sulphuric acid from sulphate of soda; in either case, producing a mixture of sulphate of soda and nitrate of soda, sulphuric acid and nitric acid. We have said 'at ordinary temperatures,' and this leads us to a point of great theoretical and practical importance. It is obvious that the balance of the mixture will be destroyed, that is, the proportion in which the base is divided between the acids will be changed, if a part of one of the acids be taken away. Thus, if, in the last-mentioned case of a mixture of sulphate of soda, nitrate of soda, sulphuric acid, and nitric acid, we take away some of the nitric acid, a rearrangement will take place; the soda will be divided between the two acids in proportion to the quantities of them *now* present, a new quantity of nitric acid will be driven out by sulphuric; so that, if we continue to remove the nitric acid as it is formed, the nitrate of soda will be *entirely* decomposed, and nothing but sulphate of soda will be left. Now, nitric acid is much more volatile than sulphuric acid; therefore, by heating the mixture, we can remove the nitric acid as vapour, leaving the sulphuric acid in the mixture; and thus, although at ordinary temperatures, below the boiling-point of nitric acid, sulphuric acid only partially decomposes nitrate of soda, at higher temperatures the decomposition is complete, the nitric acid passing off as vapour. It is, of course, not necessary that one of the acids should be removed *as vapour;* the same result follows, in whatever way it is taken out of the mixture; thus, it may separate as a solid out of an aqueous solution—as, for instance, is the case when an aqueous solution of borax (borate of soda, the salt formed by the action of soda on boracic acid) is treated with sulphuric acid. Here the sulphuric acid drives out the boracic acid, and as the latter is only sparingly soluble in cold water, a large part of it crystallises out, and the borax is almost wholly decomposed. The consideration of the fact, that, as a general rule, a base is shared between the acids which, so to speak, compete for it; and that when one acid is partially removed,

* There are some bases which seldom or never form acid salts, even with those acids which have the greatest tendencies to form them; thus, there are no acid salts of oxide of silver.

the one which is left gets a larger share, enables us to explain some apparently anomalous cases of decomposition. Thus, as we have seen, in a cold aqueous solution sulphuric acid decomposes borate of soda, driving out boracic acid, and forming sulphate of soda ; but if we mix sulphate of soda and boracic acid, and heat the mixture strongly in a crucible, we find that the boracic acid drives out the sulphuric acid, and forms borate of soda : in the first case, the boracic acid is removed by becoming solid ; in the second, the sulphuric acid is removed by being converted into a vapour.

The balance in such a mixture as we have been considering may be disturbed, and a rearrangement necessitated, by the removal of one of the salts, as well as by the removal of one of the acids. Thus, if we mix an equivalent of nitrate of lime* with one equivalent of sulphuric acid, and a sufficient quantity of water to retain the whole in solution, the lime is divided between the nitric and sulphuric acids, so that we have a mixture of sulphate of lime, nitrate of lime, sulphuric acid, and nitric acid. If to this mixture we add alcohol (spirit of wine), a change of conditions is produced, for sulphate of lime is insoluble in dilute alcohol. The result is, that the sulphate of lime is precipitated,† and the sulphuric acid in the liquid acts upon the nitrate of lime, producing more sulphate of lime, which is also precipitated, and so on until the whole of the nitrate of lime is decomposed, and nothing is left but sulphate of lime as a precipitate, and nitric acid in solution.

The action of acids upon salts is taken advantage of in the preparation of many acids. Thus, nitric acid is prepared by the action of sulphuric acid on nitrate of soda ; hydrochloric or muriatic acid, by the action of sulphuric acid on common salt (which we may call muriate of soda) ;‡ tartaric acid, by the action of sulphuric acid on tartrate of lime, &c. It is also used in analysis, as will be explained when we come to that branch of the subject.

The action of bases upon salts will be easily understood from what has just been said of the action of acids upon salts. The new base may—first, totally decompose the salt, driving out the original base ; second, partially decompose it, the acid being shared between the two bases ; or, third, produce no change ; and as in the case of the acids, so here, a partial decomposition may be made complete by removing the base as it separates, or by removing the newly produced salt. It sometimes happens that the new base, taking part of the acid of the salt, leaves a basic salt ; thus, when ammonia is added to nitrate of lead, nitrate of ammonia is produced, and basic nitrate of lead. The latter being nearly insoluble in water, is precipitated.

The action of bases upon salts is taken advantage of in the preparation of bases ; thus, ammonia is prepared by the action of lime upon hydrochlorate of ammonia; caustic potash and caustic soda, by the action of lime upon carbonate of potash or carbonate of soda; oxide of silver, by the action of caustic potash upon nitrate of silver, &c.

* By an equivalent of a *salt* we mean the quantity formed by the action of an equivalent of acid upon an equivalent of base.

† When the mixture of two liquids causes the separation of an insoluble solid substance, the solid is said to be 'precipitated,' and is called a 'precipitate.'

‡ This nomenclature will be more fully explained farther on.

The action of salts upon salts.—Some salts may be mixed together without any action taking place. In the case of others, especially when one or both are in solution, an exchange of acids and bases takes place, which may be, as in the actions just described, either complete or partial. Thus, if we mix one equivalent of nitrate of lead and one equivalent of sulphate of soda, both dissolved in water, we obtain an equivalent of sulphate of lead and an equivalent of nitrate of soda. Such an action is called double decomposition. In this case one of the salts produced (sulphate of lead) is insoluble in water, and is therefore precipitated. When all four salts—namely, the two which are originally mixed, and the two which are or may be produced—are soluble in water, it is often difficult to make out whether double decomposition has taken place or not, and still more difficult to determine the exact extent of the change. As previously pointed out, a partial change may be rendered complete by the removal of one of the products, either as a precipitate or in the form of vapour. Thus, in the example given above, the double decomposition is complete, the sulphate of lead being precipitated ; and when carbonate of lime and muriate of ammonia are mixed, carbonate of ammonia and muriate of lime are produced, and the action is complete if the mixture be heated, because carbonate of ammonia is volatile, and is driven off as vapour.

Double decomposition is taken advantage of in the preparation of many salts, and also in chemical analysis.

In the sketch of the characters of acids, bases, and salts, and their relations to one another just given, we have omitted a very important point which we must now advert to ; this is, the relation of *water* to these classes of bodies.

Water enters into combination with a great variety of substances, and in different ways. Thus, many substances dissolve in water, and the solutions so formed are weak compounds of water and the substances dissolved ; weak compounds, because the components are easily separated, moderate heat driving off the water.* Again, many crystalline substances contain water as an essential constituent, without which they would either not crystallise at all, or crystallise in a different form ; hence called 'water of crystallisation.' This water also is feebly held in combination, and is easily driven off. Many crystalline substances containing water of crystallisation, lose it on exposure to dry air, losing at the same time their crystalline form. This change is called 'efflorescence,' and crystalline substances which undergo this change are said to be 'efflorescent.' Washing-soda is a familiar instance. The clear, transparent crystals of washing-soda contain nearly 63 per cent. of water of crystallisation. On exposure to dry air, they lose water, and become white and powdery. All substances containing water of crystallisation do not lose it so readily, but a temperature a few degrees above the boiling-point of water is sufficient to drive it off in every case. Now, there are soluble acids and soluble bases, there are crystalline acids and crystalline bases containing water of crystallisa-

* Although solutions may be said to be *weak* compounds because easily decomposed, many soluble substances have such a strong attraction for water, that they can remove it from moist air, and unite with it to form a solution ; such substances are said to be 'deliquescent,' and are used for the purpose of drying gases.

tion, but acids and bases enter into combination with water in another and special way. We have pointed out before that there are substances which may be said to be intermediate between acids and bases, which act as bases to strong acids, and as acids to strong bases. Now, water is such a substance. Water unites with many bases, forming substances called 'hydrates,' or 'hydrated bases' (thus, 'hydrate of lime,' 'hydrated oxide of lead,' &c.); it also unites with many acids, forming substances called 'hydric salts,' or 'hydrated acids' (thus, 'hydric sulphate,' or 'hydrated sulphuric acid,' &c.). This kind of combination of water with acids and bases was long confounded with one or other of the two kinds mentioned just before, and from this there has arisen a confusion in the nomenclature of acids, bases, hydrates, and hydric salts, which is very likely to prove perplexing to the beginner.

Thus, the term 'sulphuric acid' is used to express two different things—1. Oil of vitriol, which, when as strong as it can be made, consists of nearly pure 'hydric sulphate,' or 'sulphate of water;' and 2. A white, solid substance, which is oil of vitriol without the water. This white solid, when put into water, unites with it, giving out a great deal of heat, and forming oil of vitriol, or 'hydric sulphate.'

In the case of many other acids, we have the same double meaning of the word; we have the 'anhydrous' (that is, waterless) acid, and the compound of that with water—the hydrated acid, or hydric salt. Some chemists restrict the word *acid* to the hydric salt, and call the anhydrous acid the 'anhydride;' others restrict the name acid to the anhydrous substance, and call the hydrated acid a hydric salt. Thus, we have the name sulphuric acid applied to two substances—anhydrous sulphuric acid, or sulphuric anhydride; and hydrated sulphuric acid, or hydric sulphate. And these differ from one another in that the latter is a compound of the former with water.

As all the processes described in the preceding pages in illustration of the action of acids on other substances, were assumed to take place in water, it was not necessary to allude to this ambiguity, and the acids taken as examples (sulphuric, nitric, hydrochloric, and acetic) were supposed to be in the state of hydric salts. The question, indeed, would be one of only theoretical interest, if every acid existed in both forms. But there are some acids which occur *only* as hydric salts, others which occur *only* as anhydrous acids. Thus, carbonic acid gas dissolves in water, but does not combine with it to form a hydrated acid, or hydric carbonate. Again, oxalic acid cannot be obtained in the anhydrous form. If we try to drive off the water from hydrated oxalic acid (hydric oxalate), we find that the acid itself decomposes and breaks up into other substances. We shall return to the consideration of these relations when we come to speak of salt-radicals.

As acids (that is, anhydrous acids) unite with water to form hydrated acids, or hydric salts, compounds in which water acts as a base, so anhydrous bases unite with water also, forming hydrated bases or hydrates in which water acts as an acid; and here also we are apt to get into confusion with the names. Thus, the word lime is generally used to mean quicklime—the anhydrous base, but not unfrequently for what is properly called slaked lime, the compound of lime and water (hydrate of lime).

Having considered in a general way the characters of acids and bases, we shall now shortly examine their composition, for they are all compounds—that is, they can all be produced by the union of elements, and can all be decomposed or broken up by separating these elements from each other. And first, we shall investigate the composition of water, which is, as we have seen, both an acid and a base—an acid in relation to the strong bases; a base in relation to the strong acids.

Water, as is well known, was long regarded as a simple or elementary substance. It is one of the four 'elements' of the ancients—fire, air, earth, and water; and although we now know that water is decomposed in a great many chemical changes constantly taking place, and produced from its elements in some of the most familiar and frequent cases of chemical action, the real nature of these changes escaped the observation of chemists until a comparatively recent time. The discovery of the composition of water was made by Cavendish about the year 1781. He shewed that when hydrogen gas is burned in the air, water is formed; and that if, instead of common air (which contains about 20 per cent. of oxygen), pure oxygen is used, the hydrogen and oxygen disappear, and water is produced, and *that the weight of the water formed is the same as that of the hydrogen and oxygen which have disappeared.* He thus proved that water is formed by the union of hydrogen and oxygen—that it is a compound of these two gases. By measuring the quantity of each gas,* he ascertained the proportion in which they unite, and shewed that one volume of oxygen unites with two volumes of hydrogen. As oxygen weighs bulk for bulk 16 times as much as hydrogen, the proportion by *weight* is 8 parts of oxygen to 1 of hydrogen; that is, 1 oz. of hydrogen in burning will use up and unite with 8 oz. of oxygen, and produce 9 oz. of water; or 9 oz. of water can be decomposed into 8 oz. of oxygen and 1 oz. of hydrogen; and the 1 oz. of hydrogen will occupy a space twice as great as the 8 oz. of oxygen. The composition of water was discovered by the method of *synthesis*—that is, by forming it from its constituents. We can also prove it by analysis—that is, by decomposing it into its constituents. This may be done by passing through water a current of electricity, from a galvanic battery for instance, when the hydrogen will bubble up from the one wire (that connected with the zinc of the battery), and the oxygen from the other (that connected with the copper of the battery). The two gases can thus be collected separately, and measured, when it will be found that the hydrogen produced fills just twice the space filled by the oxygen.

Water is thus a compound of hydrogen and oxygen, or, in chemical language, an *oxide* of hydrogen; the compounds of oxygen with other elements being termed 'oxides.' Now, a very

* When the bulks of two or more gases have to be compared, they must be measured under the same pressure and at the same temperature, as a change of pressure or of temperature produces a change in the bulk of a gas.

large number of the anhydrous acids and anhydrous bases are oxides, and the anhydrous bases which are oxides are all oxides of metals.

This brings us to the consideration of the fourth group or family of substances mentioned in p. 307—namely, Metals.

Like all the other groups which we have examined, the metals possess certain characters in common, by which they may be recognised as belonging to the group; some of these characters are physical, some are chemical. The most marked physical characters of the metals are, the 'metallic lustre,' and the readiness with which they conduct heat and electricity. The metallic lustre is the name given to the peculiar brilliancy of a polished metallic surface. All metals, when polished, shew this lustre; but some substances which are not metals shew it also. Thus, 'black-lead,' or plumbago, which is not a metal, and is in no way related to lead, but is a form of carbon, has a brilliant metallic lustre; and a considerable number of compounds shew it also, such as iron pyrites and galena. The power of conducting heat and electricity is possessed to a greater or less extent by all substances; by some, however, to such a small extent, that they are usually called 'non-conductors;' as instances, we may mention glass, resin, gutta-percha. The metals differ greatly from one another in 'conductivity,' or the power of conducting heat and electricity; but they are, as a rule, much better conductors than non-metallic substances. In other physical properties, metals shew great variety—in fusibility, ranging from mercury, which is liquid at ordinary temperatures, and only freezes at about $-40°$ Fahr. to platinum, which requires the highest temperature we can produce for its fusion; and osmium, which has not yet been fused. Metals differ greatly in density; the lightest known simple solid and the heaviest—lithium and osmium—being both metals. Some metals are malleable and ductile—that is, they can be beaten into thin plates or leaves, and drawn into wire, as is the case with gold, silver, copper, and iron; others are brittle, and can be pounded into a powder in a mortar. This is the case with antimony and bismuth. Most metals are white or gray, but we have yellow gold and red copper. Some are very hard, others very soft. As examples among common metals, we may compare the hardness of iron with that of silver, and that of lead.

Let us now turn to the chemical characters of metals. We have just mentioned that all the anhydrous bases which are oxides are oxides of metals. We may now add further, that every metal has an oxide which is a base. It is possible, directly or indirectly, to obtain a compound of each metal with oxygen. Some metals, such as zinc, aluminium, and magnesium, unite with oxygen in only one proportion; others, such as iron, copper, lead, mercury, form each more than one oxide, the various oxides containing the metal and oxygen in different proportions. In the former case, the oxide is a base; in the latter case, at least one of the oxides is a base. Thus, the oxide of zinc, the oxide of aluminium, and the oxide of magnesium, are bases; two of the three oxides of iron, both of the oxides of copper, one of the three oxides of lead, and both of the oxides of mercury, are bases. We may therefore define a metal as an element which forms in combination with oxygen at least one base. There are two general principles which may be mentioned here: 1. The more readily a metal unites with oxygen, the more basic is the oxide; thus, sodium is more easily oxidised than magnesium, magnesium than zinc, zinc than copper, copper than silver; and soda (oxide of sodium) is a stronger base than magnesia (oxide of magnesium), magnesia than oxide of zinc; and so on. 2. When a metal forms two basic oxides, we usually find that that which contains the least oxygen is the stronger base. Thus, two of the oxides of iron are bases; one (ferrous oxide) contains iron and oxygen in the proportion of 7 to 2; the other (ferric oxide) in the proportion of 7 to 3; and the former is the stronger base.

We shall now examine the action of acids and salts upon metals. The anhydrous acids, as a rule, do not act at all upon metals. There are some exceptions to this rule, which we may have occasion to allude to farther on. The action of the hydrated acids or hydric salts on metals is quite analogous to that of other salts. We shall illustrate this action by one or two examples. If we take a clear colourless solution of nitrate of silver, and place in it a piece of bright clean copper, we see in a few minutes that the copper is covered over with a growth of what looks like soft white moss; this gradually increases, the liquid at the same time becoming blue. The white covering on the copper consists of small scales of silver, and the blue colour of the liquid is due to nitrate of copper. If we take enough copper, we can in this way decompose the whole of the nitrate of silver, separating the silver in the metallic state. Again, if we place a piece of clean iron in a solution of nitrate (or sulphate) of copper, metallic copper is deposited on the iron, the blue colour of the solution disappears, and we have a solution of nitrate (or sulphate) of iron.* Again, if we place a piece of iron in a solution of hydrated sulphuric acid (oil of vitriol), that is, hydric sulphate, we have hydrogen gas given off, and sulphate of iron remains in solution. In each of these cases we have one metal driving out another, and taking its place.† Copper drives out silver, iron drives out copper, and iron drives out hydrogen. In each such case, the metal which drives the other out is said to be 'positive;' that which is driven out is said to be 'negative.' Thus, silver is negative to copper; copper is positive to silver, but negative to iron; iron is positive to copper; and so on. By means of a number of experiments of this kind, we can arrange the metals in a series, beginning with the most negative, and ending with the most positive. If we examine this series, we find that the more 'positive' a metal is, the more basic is its most basic oxide. So that just as a strong base drives out a weak one, so the metal of a strong base drives out the metal of a weak one.

We have hitherto looked upon salts as compounds of acids and bases, but the reader will now see that they may also be represented in another

* This action may be taken advantage of to detect copper in a solution; thus, a steel fork is covered with a red deposit of copper when it is dipped in a jar of pickles which have been coloured green by means of copper.

† We here speak of hydrogen as a *metal*. Chemically it is so, for water (the oxide of hydrogen) acts as a base, and substances have been obtained which may be regarded as *alloys* of hydrogen.

way. Thus, we have spoken of sulphate of copper as a compound of

$$\underbrace{\text{Oxide of Copper, that is, Copper and Oxygen,}}_{\text{Base.}} \quad \text{and} \quad \underbrace{\text{Anhydrous Sulphuric Acid.}}_{\text{Acid.}}$$

But just as a strong base, such as potash, will decompose this salt, driving out the oxide of copper, and forming sulphate of potash, so a more positive metal than copper—for instance, zinc—drives out the copper, and forms sulphate of zinc, in which the base is oxide of zinc. Here it is the *metal* which is changed; all the rest remains as it was. We may therefore represent the salt as a compound of metal with all the rest of the salt, thus:

$$\underbrace{\text{Copper}}_{\text{Metal.}} \quad \text{and} \quad \underbrace{\text{Oxygen and Anhydrous Sulphuric Acid.}}_{\text{Salt-radical.}}$$

The *rest of the salt*, that which in union with metal forms the salt, is called the 'salt-radical.' In the case of the sulphates, and indeed of the majority of salts, the salt-radical has not been obtained *in the free state*—that is, by itself, and is only known *in combination* with metals, forming salts, and with hydrogen, forming the hydric salt or hydrated acid, thus:

$$\overbrace{\text{Hydrogen and Oxygen}}^{\text{Water.}} \quad \text{and} \quad \overbrace{\text{Anhydrous Sulphuric Acid.}}^{\text{Acid.}}$$

Salt-radical.

There are, however, a number of substances known, which, *in combination*, play exactly the part of the salt-radicals we have just been considering—that is, they unite with metals to form salts, and with hydrogen to form hydric salts, corresponding exactly in general properties to the hydrated acids. These substances are called 'halogens' (that is, salt-producers). We shall illustrate their characters by means of an example, and for this purpose we shall select the most important of them—namely, chlorine. Chlorine is a simple substance—in other words, it has not been decomposed—and thus differs entirely from the salt-radicals of the sulphates, nitrates, &c. which consist of anhydrous acid and oxygen, and have not been obtained in the free state. Chlorine, in the free state, is a greenish yellow gas with an acrid smell. It readily unites with hydrogen, forming the substance known as muriatic acid gas, or, from its composition, hydrochloric acid gas. This is a true hydric salt, possessing all the general properties of the hydrated acids. It acts upon bases, producing salts and water; it drives out weaker acids (in the hydrated form—that is, as hydric salts) from their salts. The salts thus formed we have in the former pages called 'muriates,' or hydrochlorates;' but we now see what they are; they are compounds of metals and chlorine, the oxygen of the metallic oxide (or base) uniting with the hydrogen of the hydrochloric acid to form water. They are hence called 'chlorides.' Thus, instead of 'muriate of soda,' we say 'chloride of sodium;' and so on. They are, however, true salts, undergoing all the changes and reactions common to salts. It will be noticed that *all* salts can be represented as compounds of metal and salt-radical, while some salts (such as the chlorides) cannot be represented as compounds of acid and base. This has led to a modification of the old names of many salts; thus, we often use the names sulphate of sodium (or sodium sulphate) instead of the old sulphate of soda. It must not be supposed that sulphate of sodium means a compound of sodium and sulphuric acid; it is a compound of sodium *and oxygen* and sulphuric acid (anhydrous).

We may now place side by side the various names given to the same salt:

Sulphate of Soda	Sodic Sulphate	Sulphate of Sodium.
Hydrated Sulphuric Acid	Hydric Sulphate	Sulphate of Hydrogen.
Muriate of Soda	Sodic Chloride	Chloride of Sodium.
Hydrochloric Acid	Hydric Chloride	Chloride of Hydrogen.
Nitrate of Oxide of Lead	Plumbic Nitrate	Nitrate of Lead.
&c.	&c.	&c.

Sulphate of soda means the salt formed by the action of sulphuric acid on soda; sulphate of sodium means the compound of sodium and the salt-radical of the sulphates; while sodic sulphate may be used to indicate the same substance without referring to either view of its constitution. For this, as well as for other reasons, the names in the middle column are to be preferred, although this system sometimes involves us in the use of novel and awkward adjectives, such as zincic, or bismuthous.

We have seen that many bases are oxides of metals, and we must now attend to the relation of the metals to their oxides. When a metal (or other substance) is made to unite with oxygen, it is said to be 'oxidised;' when the oxygen is taken away from an oxide, and the original substance (whether metal or not) is reproduced, the oxide is said to be 'reduced.' We have thus two processes inverse to one another—that is, the one undoing what the other does, oxidation and reduction. Thus, there is an important ore of iron called the magnetic oxide of iron; when this is smelted, the oxygen is taken from it, and we obtain metallic iron—this is a process of reduction. If we heat iron strongly in the air, it becomes covered with a crust or scale of a black, brittle substance, which breaks off when the iron is hammered—this is an oxide of iron, and is identical in composition with the magnetic iron ore—this is a process of oxidation. It is obvious that these two processes go in opposite directions.

Most processes of oxidation are accompanied by the giving out of heat, sometimes in a very marked degree; thus, when charcoal is strongly heated in air or oxygen (and it must be remembered that about one-fifth of the atmospheric air consists of oxygen), it unites with oxygen, forming an oxide (carbonic acid, Black's fixed air), and in doing so, gives out much heat. Such an oxidation we call a combustion, or burning. And although different processes of oxidation are accompanied by the giving out of very different quantities of heat, we may generalise the term, and call all such processes cases of 'burning.' Similarly, all processes of reduction may be grouped together as cases of unburning.*

As in a case of 'burning' or 'oxidation,' heat is given out, so in a case of 'unburning' or 'reduction,' heat disappears, or is used up; and we find that exactly as much heat is used in effecting the unburning of an oxide as was given out in producing it. It will thus be seen that the greater

* This is here stated generally; some of the few exceptions will be mentioned among the compounds of Chlorine and Oxygen.

the quantity of heat given out during an oxidation, the greater is the amount of *work* required to be done, in order to effect the corresponding reduction. Now, the difficulty of undoing a union, or of breaking up a combination, may be taken as a measure of its stability, so that the most stable oxides are those during the formation of which the most heat is given out.

Many oxidations can be effected directly by the action of oxygen, and some reductions can be effected directly by means of heat or electricity; thus, hydrogen unites with oxygen, or is burnt, producing water; and water can be decomposed by heat or by electricity into hydrogen and oxygen. There are, however, many oxidations which cannot be effected by the direct action of oxygen, but require the use of an 'oxidising agent'—that is, a substance or mixture containing oxygen in combination, and ready to part with it to a body capable of being oxidised. Thus, nitric acid contains a large quantity of oxygen, and readily gives up part or all of this oxygen to oxidisable substances; accordingly, nitric acid is a powerful oxidising agent, and is used to oxidise bodies in cases where the action can either not be produced at all, or not so conveniently by oxygen alone. As an instance of an oxidising agent which is a mixture, we mention the mixture of chlorine and water. This mixture will oxidise in many cases in which water alone would be without action—the tendency of chlorine to unite with the hydrogen of the water increasing the readiness of the oxygen to leave the hydrogen, and unite with the substance to be oxidised.

Just as we have oxidising agents, so we have also reducing agents—that is, substances or mixtures which remove oxygen: these are generally bodies having a tendency to combine with oxygen, in other words, they are oxidisable; and the most powerful reducing agents are, as might be expected, those which give out most heat in uniting with oxygen. By far the most practically important reducing agents are hydrogen and carbon, either singly as hydrogen gas, and as charcoal or coke, or combined, as they are in coals, coal-gas, wood, and other ordinary combustibles. A large number of metallurgical operations are cases of reduction, in which coal, or coke or charcoal, is used to take away the oxygen of a metallic oxide, and leave the metal uncombined. It is in this way, as is more fully explained in the article METALLURGY, that iron, tin, zinc, and some other metals are reduced from such of their ores as contain the metals as oxides.

THE DOCTRINE OF EQUIVALENTS, AND THE ATOMIC THEORY AND NOTATION.

We have already seen what is meant by an 'equivalent' of an acid, or of a base; we shall now consider the question of 'equivalence' somewhat more fully. As has been already stated, zinc can turn copper out of a salt, such as sulphate of copper, and take its place; this is technically called 'replacement,' and zinc is said to 'replace' copper.* As the salts may be considered as compounds of sulphuric acid (anhydrous) with oxide of copper and with oxide of zinc respectively, it is evident that equivalents of these oxides contain the same quantity of oxygen, for the oxygen remains as it was, thus:

$$\begin{array}{l} \overbrace{\text{Before......Copper}}^{\text{Oxide of Copper.}} \\ \underbrace{\text{After.........Zinc}}_{\text{Oxide of Zinc.}} \end{array}\Big\}\ \text{and Oxygen and Sulphuric Acid.}$$

And in the same way it may be shewn, by means of other replacements, that an equivalent of any basic oxide contains the same quantity of oxygen. By an extension of the meaning of the word equivalent, this quantity of oxygen is called an equivalent of oxygen, and the quantity of metal united to it is called an equivalent of the metal. Those metals which form more than one basic oxide have, of course, more than one equivalent; and when we speak of *the* equivalent of a metal of this kind, we must state *which* basic oxide or which set of salts we are referring to. Thus, the black oxide of mercury contains twice as much mercury as the red oxide for the same quantity of oxygen; and therefore the equivalent of mercury in the black oxide and its salts is twice as great as the equivalent of mercury in the red oxide and its salts. The phenomena of 'electrolysis' furnish an excellent illustration of the equivalence of metals in their salts. When an electric current from a galvanic battery is passed through a solution of a salt, the salt is decomposed, the *metal* being deposited at the end of the wire coming from the zinc of the battery, and the *salt-radical* at the end of the wire coming from the copper of the battery.* This decomposition, by means of an electric current, is called 'electrolysis.' Now, a very remarkable law of electrolysis is, that *a given amount of electricity decomposes (or electrolyses) equivalent quantities of different salts.* Thus, if a current from a battery be made to pass through a series of vessels, each vessel containing a solution of a salt, the quantity decomposed of any one salt will be equivalent to the quantity decomposed of any other. If, now, one of these vessels contain a solution of a salt of the red oxide of mercury, and another a solution of a salt of the black oxide of mercury, we shall find that twice as much mercury is separated in the second as in the first.

In order to express these equivalent quantities in numbers, it is necessary, in the first place, to fix upon a number which shall, by convention, represent one of them, and then, by experiment, find out the relation between the equivalent of that substance and the equivalent of every other element, radical, or substance. For this purpose, it has been found most convenient to select hydrogen as the element with which to compare all others, and to fix the equivalent of hydrogen as unity. The equivalent of hydrogen is thus settled by convention to be 1, and by experiment we determine the equivalents of other elements or radicals. Thus, when hydric sulphate (hydrated sulphuric acid) acts on metallic zinc, for every

* 'Replace' is here used in the sense of the French *remplacer*, and not in its ordinary English sense; but as we have no one English word which can be used to mean 'to be a substitute for,' it seems better to keep the word at present in use, than to try another, such as 'displace' (as has been suggested), which expresses the meaning no better.

* Where the metal is one which acts on water (such as sodium), we have, of course, not the metal itself separated, but the products of its action on water; and similarly if the salt-radical is incapable of separate existence, we obtain the products of its decomposition.

grain of hydrogen set free we find that 32·5 grains of zinc are dissolved, and that, therefore, the *equivalent* of zinc is 32·5. Again, when sulphate of copper acts on metallic zinc, for every 32·5 grains of zinc dissolved we find that 31·75 grains of copper are separated—therefore, the equivalent of copper is 31·75. Once more, when nitrate of silver acts on metallic copper, for every 31·75 grains of copper dissolved we find that 108 grains of silver are separated; therefore, 108 is the equivalent of silver. Now, one grain of hydrogen unites with 8 grains of oxygen to form 9 grains of water; 32·5 grains of zinc unite with 8 grains of oxygen to form 40·5 grains of oxide of zinc; 31·75 grains of copper and 108 grains of silver unite each with 8 grains of oxygen to form respectively 39·75 grains of black oxide of copper and 116 grains of oxide of silver; therefore, the equivalent of oxygen is 8. In the same way, 1 grain of hydrogen, 32·5 grains of zinc, 31·75 grains of copper, and 108 grains of silver unite with 35·5 grains of chlorine to form respectively hydrochloric acid (hydric chloride), chloride of zinc (zincic chloride), chloride of copper (cupric chloride), and chloride of silver (argentic chloride); therefore, the equivalent of chlorine is 35·5.

In a similar way, the equivalent of any element or radical may be determined, it being always recollected that an element or radical has as many different equivalents as it forms series of compounds. Now, if we compare the different equivalents of the same element or radical, we find that they have a simple arithmetical relation to one another. Thus (taking the equivalent of hydrogen as 1), the equivalent of mercury in the red oxide of mercury and in its salts is 100; in the black oxide of mercury and in its salts, 200—that is, twice 100: the equivalent of copper in the black oxide of copper and in its salts is 31·75; in the red oxide of copper and in its salts, 63·5—that is, twice 35·75: the equivalent of iron in the ferrous salts is 28; in the ferric salts, 18·6—that is, two-thirds of 28.

These two facts—1st, that the equivalent of an element remains the same through a series of compounds; and 2d, that the different equivalents of the same element have a simple arithmetical relation to each other—enable us to form a system of chemical notation by means of which the composition of compounds may be fully and distinctly expressed.

In this system of notation, which is known as the ATOMIC NOTATION, certain symbols are used, each of which represents a definite quantity of a particular element. The subjoined table contains the names of the elements with the symbol of each, and the quantity of the element which the symbol represents. This quantity is called the 'atomic weight' of the element, for reasons which will be afterwards stated.

TABLE OF ELEMENTS WITH THEIR SYMBOLS AND ATOMIC WEIGHTS.

Aluminium	Al	27·5
Antimony or Stibium	Sb	122
Arsenicum	As	75
Barium	Ba	137
Beryllium or Glucinum	G	9·3
Bismuth	Bi	210
Boron	B	11
Bromine	Br	80
Cadmium	Cd	112
Cæsium	Cs	133
Calcium	Ca	40
Carbon	C	12
Cerium	Ce	92
Chlorine	Cl	35·5
Chromium	Cr	52
Cobalt	Co	59
Copper (*Cuprum*)	Cu	63·5
Didymium	Di	96
Erbium	Er	112·6
Fluorine	F	19
Gallium	Ga	68
Gold (*Aurum*)	Au	196
Hydrogen	H	1
Indium	In	113
Iodine	I	127
Iridium	Ir	197
Iron (*Ferrum*)	Fe	56
Lanthanum	La	92
Lead (*Plumbum*)	Pb	207
Lithium	Li	7
Magnesium	Mg	24
Manganese	Mn	55
Mercury (*Hydrargyrum*)	Hg	200
Molybdenum	Mo	96
Nickel	Ni	59
Niobium	Nb	97·5
Nitrogen	N	14
Osmium	Os	199
Oxygen	O	16
Palladium	Pd	106·5
Phosphorus	P	31
Platinum	Pt	197
Potassium or Kalium	K	39
Rhodium	Ro	104·3
Rubidium	Rb	85
Ruthenium	Ru	104·2
Selenium	Se	79·5
Silicon	Si	28
Silver (*Argentum*)	Ag	108
Sodium or Natrium	Na	23
Strontium	Sr	87·5
Sulphur	S	32
Tantalum	Ta	138
Tellurium	Te	129
Thallium	Tl	204
Thorium	Th	119
Tin (*Stannum*)	Sn	118
Titanium	Ti	50
Tungsten or Wolfram	W	184
Uranium	U	120
Vanadium	V	51·2
Yttrium	Y	61·5
Zinc	Zn	65
Zirconium	Zr	89·5

If we compare the *atomic weights* as given in this table with the *equivalents* of the elements, we shall find that, even in the cases where each element has only one equivalent, that number has not always been chosen as the atomic weight of the element. Thus, the equivalent is the same as the atomic weight in the case of hydrogen, of potassium, of sodium, of rubidium, of cæsium, and of lithium. But the atomic weight is twice the equivalent in the case of barium, of beryllium, of cadmium, of calcium, of magnesium, of oxygen, of strontium, and of zinc. Aluminium has only one equivalent, and the atomic weight of aluminium is three times its equivalent. Where an element has more than one equivalent, the atomic weight is sometimes equal to one of these equivalents, and sometimes not. Thus, the atomic weight of copper is equal to the equivalent of copper in the cuprous compounds (red oxide of copper and its

salts); the atomic weight of mercury is equal to the equivalent of mercury in the mercurous compounds (black oxide of mercury and its salts); the atomic weight of silver is equal to the equivalent of silver in all its compounds except the peroxide, and the suboxide and the few salts derived from it, &c. The atomic weight of iron is twice the equivalent of iron in the ferrous salts, and three times the equivalent of iron in the ferric salts. In all cases, however, the atomic weight stands in a simple arithmetical relation to each of the equivalents.

The way in which this notation is used will be most easily explained by a few examples. Compound substances are represented by formulæ expressing the proportions by weight of their elementary constituents—thus, HCl means the compound of 1 part by weight* of hydrogen and 35·5 parts by weight of chlorine—that is, 36·5 parts of hydrochloric acid. Here the proportion in which the two elements combine is that of their atomic weights, and the symbols are simply placed one after the other. Again, H_2O means the compound of 2 parts by weight of hydrogen and 16 parts by weight of oxygen—that is, 18 parts of water. Here H_2 represents twice the quantity of hydrogen represented by H, so that as H stands for 1 part of hydrogen, H_2 stands for 2 parts of hydrogen. Again, sulphurous acid gas contains equal weights of sulphur and oxygen, and is represented by the formula SO_2, by which we mean the compound of 32 parts of sulphur and twice 16 parts of oxygen—that is, 64 parts of sulphurous acid gas. In the same way, SO_3 means the compound of 32 parts of sulphur and three times 16 parts of oxygen, and this is 80 parts of anhydrous sulphuric acid. CuO means the compound of 63·5 parts of copper and 16 parts of oxygen—that is, 79·5 parts of black oxide of copper, or cupric oxide. Now, 18 parts of water unite with 80 parts of anhydrous sulphuric acid to form 98 parts of hydrated sulphuric acid (hydric sulphate). Similarly, 79·5 parts of black oxide of copper unite with 80 parts of anhydrous sulphuric acid to form 159·5 parts of cupric sulphate. These compounds may therefore be represented by the complex formulæ H_2O,SO_3 and CuO,SO_3 respectively; the comma placed between the formulæ indicating that the compounds may be regarded as composed, the one of water and anhydrous sulphuric acid, the other of cupric oxide and anhydrous sulphuric acid. Further, if we place cupric sulphate, which is a white powder, in water, 159·5 parts of it at once unite with 18 parts of water, forming a blue powder, which may be represented by the formula CuO,SO_3,H_2O. This blue powder dissolves readily in water, forming a blue solution; and if we evaporate the water carefully, we obtain blue crystals, containing, in addition to the water previously in the blue powder, four times 18 parts of water—the crystalline substance (crystallised cupric sulphate, or blue vitriol) has therefore the formula $CuO,SO_3,H_2O,4H_2O$. Here $4H_2O$ means four times 18 parts of water (a large figure placed *before* a formula multiplying the whole formula up to the first comma). The water present in this salt occurs in two different forms of combination—1. Water of crystallisation, easily driven off by heat; of this there are four molecules. 2. Water retained with great force, requiring a high temperature to expel it, and called 'water of halhydration;' of this there is one molecule. In the same way, hydrated nitric acid, nitrate of potash, and nitrate of copper are represented by the formulæ H_2O,N_2O_5; K_2O,N_2O_5; CuO,N_2O_5 respectively, and crystallised nitrate of copper by $CuO,N_2O_5,3H_2O$. Again, 1 part of hydrogen unites with 35·5 parts of chlorine to form 36·5 parts of hydrochloric acid (or hydric chloride), and this is represented by the formula HCl; and similarly, chloride of sodium (sodic chloride, common salt) and cupric chloride have the formulæ NaCl and $CuCl_2$ respectively. Looking over these formulæ,

Hydrated Sulphuric Acid	or	Hydric Sulphate	H_2O,SO_3,
Sulphate of Soda	"	Sodic Sulphate	Na_2O,SO_3,
Sulphate of Copper	"	Cupric Sulphate	CuO,SO_3,
Hydrated Nitric Acid	"	Hydric Nitrate	H_2O,N_2O_5,
Nitrate of Potash	"	Potassic Nitrate	K_2O,N_2O_5,
Nitrate of Copper	"	Cupric Nitrate	CuO,N_2O_5,
Hydrochloric Acid	"	Hydric Chloride	HCl,
Chloride of Sodium	"	Sodic Chloride	NaCl,
Chloride of Copper	"	Cupric Chloride	$CuCl_2$,

we at once see that 2 parts of hydrogen (H_2), twice 23—that is, 46 parts of sodium (Na_2), 63·5 parts of copper (Cu), and twice 39—that is, 78 parts of potassium (K_2), are equivalent to one another—that is, are capable of playing the same part in a compound.

The reader will remember that salts can be represented not only, as has been done above in the case of the sulphates and nitrates, as compounds of base and acid (anhydrous), but also as compounds of metal and salt-radical, the salt-radical consisting of the anhydrous acid and the oxygen of the base. A glance at the formulæ of the sulphates and nitrates given in the preceding table will shew how this view can be represented by formulæ. Thus:

Hydric Sulphate	H_2O,SO_3	or	H_2,SO_4.
Sodic Sulphate	Na_2O,SO_3	"	Na_2,SO_4.
Cupric Sulphate	CuO,SO_3	"	Cu,SO_4.

Here SO_4 represents the salt-radical of the sulphates—that is, the group of elements which is united with a metal to form a sulphate. This, like many other radicals, cannot be (or at least has not as yet been) obtained as a separate substance, but may still be spoken of and reasoned about as *that which is common to all the sulphates*, that group which remains unchanged when we pass from one sulphate to another. Similarly, we may represent the nitrates thus:

Hydric Nitrate	H_2O,N_2O_5	or	H_2,N_2O_6.
Potassic Nitrate	K_2O,N_2O_5	"	K_2,N_2O_6.
Cupric Nitrate	CuO,N_2O_5	"	Cu,N_2O_6.

Here N_2O_6 is the salt-radical of the nitrates. But it will be at once observed that N_2O_6 can be divided by two, or that N_2O_6 is the same as $2NO_3$; we can therefore simplify the above formulæ thus: Hydric Nitrate, H,NO_3; Potassic Nitrate, K,NO_3; and Cupric Nitrate, $Cu,2NO_3$ or $Cu,(NO_3)_2$ (the group NO_3 between the brackets being multiplied as a whole by the small figure placed after it; in other words, a group of symbols placed within brackets is treated as a single symbol).

* Instead of 'part by weight' or 'part,' we may here and throughout read 'grain,' or 'ounce,' or 'pound,' or any other unit we please; we must, however, remember that, having once adopted a particular unit, we must adhere to it through all the formulæ which we wish to compare together.

We can now compare the formulæ of the sulphates and nitrates with those of the chlorides:

Hydric Sulphate, H_2,SO_4; Hydric Nitrate, H,NO_3; Hydric Chloride, H,Cl.
Sodic Sulphate, Na_2,SO_4; Sodic Nitrate, Na,NO_3; Sodic Chloride, Na,Cl.
Cupric Sulphate, Cu,SO_4; Cupric Nitrate, $Cu,(NO_3)_2$; Cupric Chloride, Cu,Cl_2.

This comparison shews that NO_3 is equivalent to Cl, while SO_4 is equivalent to Cl_2, just as K is equivalent to H, and Cu equivalent to H_2, or that there is a difference in the *value* of the symbols of the salt-radicals in our system of notation, similar to the difference in the *value* of the symbols of the metals. We shall see by-and-by why the atomic weights have been fixed so as to give rise to these differences; our object at present is to explain the use of the system as it is, not to give reasons why it has been made so. It is also obvious that the quantities of the salts above mentioned represented by the last formulæ are not equivalent to one another; the *equivalent* quantities being H_2,SO_4; Na_2SO_4; Cu,SO_4; $2[H,NO_3]$; $2[Na,NO_3]$; $Cu,(NO_3)_2$; $2[H,Cl]$; $2[Na,Cl]$; Cu,Cl_2.

It is of the utmost importance that symbols or formulæ should *always* be used as representing definite *quantities* of the substances, and that the slovenly habit should be avoided of using them as contractions or synonyms for the *names* of the substances. When we use the words 'water,' 'common salt,' or 'sulphate of potash,' we do not indicate any particular quantities of these bodies; but when we write H_2O, NaCl, or K_2SO_4, we mean 18 parts of water, 58·5 parts of common salt, or 174 parts of sulphate of potash. Just as the quantity of an element represented by its symbol is called its atomic weight, so the quantity of a substance represented by its formula is called its molecular weight.

Acids such as hydrochloric and nitric, which contain in one molecule *one* atom of hydrogen capable of being replaced by metal, are called 'monobasic acids;' those that, like sulphuric acid, contain in one molecule *two* such hydrogen atoms, are called 'dibasic acids.' There are also 'tribasic' and 'tetrabasic' acids, containing respectively three and four atoms of replaceable hydrogen. All acids containing in one molecule more than one atom of replaceable hydrogen are called 'polybasic;' and this polybasic character explains the occurrence of acid and double salts of such acids. Thus, in bisulphate of potash, K_2O,SO_3, H_2O,SO_3, or $HKSO_4$, we have *one* of the hydrogen atoms of sulphuric acid, H_2SO_4, replaced by potassium. Again, common phosphoric acid (p. 326) has the formula $3H_2O,P_2O_5$, or H_3PO_4, and is tribasic, so that we have such salts as Ag_3PO_4, Na_2HPO_4, NaH_2PO_4, $NaNH_4HPO_4$, &c.

We can use formulæ not only to express the quantitative composition of substances, but also the action of substances upon each other, or generally, chemical changes. We do this by means of what are called 'chemical equations.' Let us take as an instance the action of sulphate of potash upon chloride of barium. Here we have 174 parts of sulphate of potash and 208 parts of chloride of barium before the change, and after it we have 233 parts of sulphate of baryta and 149 parts of chloride of potassium. We represent the change by the following equation:

$$K_2SO_4 + BaCl_2 = BaSO_4 + 2KCl.$$

The formulæ representing the quantities of the substances before the change are written first, connected by the sign + (which here is the same as '*and*'); then we write = which here stands for '*become*,' or '*are changed into;*' and lastly, the formulæ representing the quantities of the substances produced by the change, also connected by the sign +.

The above equation may then be read as follows: 174 parts of sulphate of potash and 208 parts of chloride of barium are changed into 233 parts of sulphate of baryta and 149 parts of chloride of potassium. We shall have frequent occasion to use such equations farther on in this paper.

The system of atomic or symbolic notation, which we have just explained, originated in the Atomic Theory of Dalton. According to this theory, matter is composed of exceedingly minute ultimate particles or atoms which are incapable of being divided. All the atoms of a given element are precisely similar to one another, but the atoms of one element differ not only in properties, but also in weight, from those of the others; and although we cannot discover the actual weight of an individual atom, the theory assumes that we can discover the proportion existing between the weights of the atoms of different elements, and that these proportions are represented by the atomic weights. Thus, we do not know the weight of an atom of iron, but, if this assumption is correct, it is four times the weight of an atom of nitrogen—that is, in the proportion 56 : 14. In the same way, an atom of mercury is two hundred times as heavy as an atom of hydrogen; and so on.

The theory further supposes that when combination takes place, the atoms of the constituents go together to form groups or molecules; thus, when copper is heated in oxygen, each atom of copper attaches itself to one atom of oxygen to form a molecule of cupric oxide. The formula of a compound may thus be considered as a list of the number and kind of the atoms forming the molecule of the compound.

So far we have considered the proportions *by weight* in which constituents occur in compounds; we shall now look for a little at another way of measuring them—namely, by volume or bulk. We can measure the volume or bulk of a quantity of matter, whether it be solid, liquid, or gaseous, and express it by means of units; and just as we used the word 'part' to indicate a unit of *mass* (which may be a grain, or a pound, or a ton), so now we use the word 'volume' to indicate a unit of bulk (which may be a cubic inch, or a cubic foot, or a gallon), only reminding the reader that here, as before, having once fixed *which* of these is to be our unit, we must adhere to it throughout.

Chemists have made some progress towards finding out the laws of combination according to volume in the cases of solids and liquids; but this part of the subject is at present both too complicated and too speculative to be profitably discussed here. We shall therefore confine ourselves to the laws of combination of gases according to volume. The first step towards the discovery of these laws was made by Gay-Lussac, soon after the publication of Dalton's Atomic Theory; and it is a remarkable fact in the history of chemistry that Dalton, who had thrown so

much light on the laws of combination according to weight, was inclined to doubt the accuracy of Gay-Lussac's views. These views were afterwards greatly extended and simplified by Avogadro; and subsequent investigation and comparison have established what we may call 'Avogadro's law' so fully, that it may be said to be as important a corner-stone of the chemical edifice as the Atomic Theory itself. Without entering into historical questions, which are beyond the scope of this paper, we shall state this law, as it is at present held by the great majority of chemists, thus: *A volume of any gas contains the same number of* molecules *as the same volume of any other gas, the two volumes being measured at the same temperature and pressure.* (See foot-note, p. 311.)* It follows at once from this law that the specific gravities of two gases (taken at the same temperature and pressure) are in the same proportion as their molecular weights; and we have thus a means of determining the molecular weight of any substance which either is a gas at ordinary temperatures, or can be, without chemical change, converted into one by the action of heat, by comparing its specific gravity in the gaseous state with the specific gravity (at the same temperature and pressure) of some gas the molecular weight of which is known.

By applying this method, we find that the molecular formula of a substance is not always the formula which most simply represents its composition.

Thus, let us assume that the formula of hydrochloric acid gas is HCl, and therefore its molecular weight 36·5, and from this let us deduce the molecular weight of some other gases. The specific gravity of hydrogen is to the specific gravity of hydrochloric acid almost exactly as 1 : 18·25, or as 2 : 36·5; therefore, if the molecular weight of hydrochloric acid is 36·5, that of hydrogen must be 2, and its formula H_2. Again, the specific gravity of hydrochloric acid is to that of nitrogen almost exactly as 36·5 : 28; therefore, the molecular weight of nitrogen is 28, and its formula N_2. In these cases, then (and the same is true of many other gases), the theory leads us to believe that the atoms are united in pairs, each pair being a molecule, and that, just as in hydrochloric acid each hydrogen atom is united with an atom of chlorine, so in hydrogen gas each atom of hydrogen is united with another atom of hydrogen. Again, the well-known substance benzol is a compound of carbon and hydrogen in the proportion of 12 parts of carbon to 1 of hydrogen; the simplest formula by which its composition could be represented is obviously CH. If this were its true formula, the specific gravity of its vapour should stand to that of hydrochloric acid gas (at the same temperature and pressure) as 13 : 36·5, but we find the proportion almost exactly 78 : 36·5—that is, 6 times 13 : 36·5. The molecular weight of benzol is therefore 6 times 13, and its formula C_6H_6. In considering individual substances, we shall meet many such cases, and need not, therefore, dwell longer on the subject here.

THE DOCTRINE OF ATOMICITY.

In order to illustrate what is called 'the Doctrine of Atomicity,' we shall give in a tabular form the molecular formulæ of a number of substances, selected so as to place this 'doctrine' before the reader in the way in which it may be most easily understood:

Hydrochloric Acid	HCl.	Water	H_2O.	Ammonia	NH_3.	Marsh Gas	CH_4.
Hydrobromic Acid	HBr.	Sulphuretted Hydrogen	H_2S.	Phosphuretted Hydrogen	PH_3.	Siliciuretted Hydrogen	SiH_4.
Hydriodic Acid	HI.	Seleniuretted Hydrogen	H_2Se.	Arseniuretted Hydrogen	AsH_3.	Perchloride of Tellurium	$TeCl_4$.
Chloride of Sodium	NaCl.	Chloride of Calcium	$CaCl_2$.	Chloride of Gold	$AuCl_3$.	Perchloride of Tin	$SnCl_4$.
Bromide of Potassium	KBr.	Bromide of Zinc	$ZnBr_2$.	Terbromide of Phosphorus	PBr_3.	Bromide of Platinum	$PtBr_4$.

Looking at these formulæ, the reader will easily see that there are some elements, such as hydrogen, chlorine, bromine, iodine, sodium, and potassium, which unite with one another two and two to form compounds containing two atoms in the molecule, one of the one, the other of the other element. Such elements are called 'monads.' Again, there are elements, such as oxygen, sulphur, selenium, calcium, and zinc, which unite with monads to form compounds containing three atoms in the molecule, one atom of the element in question uniting with two monad atoms (as in the second column). Such elements are called dyads. Further, we have elements, such as nitrogen, phosphorus, arsenic, and gold, each atom of which unites with three monad atoms to form a molecule. Such elements are called triads. In the same way there are elements, such as carbon, silicon, tin, and platinum, which are called tetrads, each atom uniting with four monad atoms to form a molecule. These different modes of combination can be represented graphically by drawing lines uniting the symbols of the atoms forming the molecule, thus:

Hydrochloric Acid. Water. Ammonia. Marsh Gas.

Bromide of Sodium. Chloride of Calcium. Terchloride of Phosphorus. Stannic Chloride.

In these *graphic formulæ* it will be observed that a monad atom is represented by its symbol with *one* line proceeding from it; similarly, *two* lines proceed from the symbol of a dyad atom; *three*, from that of a triad; and so on.

The property of combining with a definite number

* This law is in complete accordance with the 'Dynamical Theory of Gases,' as at present held by physicists.

of monad atoms is termed 'atomicity;' thus, the atomicity of hydrogen is one; of oxygen, two; of nitrogen, three; of carbon, four. More complex compounds can be represented in a similar way, thus:

Lime.	Carbonic Acid.	Carbonate of Lime.
$Ca{=}O$	$O{=}C{=}O$	$Ca\begin{matrix}\text{—O—}\\ \text{—O—}\end{matrix}C{=}O$

Chemists are divided in opinion, as to whether an element always has the same atomicity—some holding that this is the case; while others consider that an element may have one atomicity in one set of compounds, and another in another set. The latter school regard, for instance, sulphur as dyad in sulphuretted hydrogen ($H{-}S{-}H$) and analogous compounds, tetrad in anhydrous sulphurous acid (SO_2; $O{=}S{=}O$), and hexad in anhydrous sulphuric acid (SO_3; $O{=}\overset{\overset{\displaystyle O}{\|}}{S}{=}O$) and the sulphates, such as sulphate of potash (K_2SO_4; $K{-}O{-}\underset{\underset{\displaystyle O}{\|}}{\overset{\overset{\displaystyle O}{\|}}{S}}{-}O{-}K$). For further developments of the *Theory of Atomicity*, the reader is referred to any of the larger treatises on chemistry.

DULONG AND PETIT'S LAW.

We have hitherto considered the *atomic weight* of an element as a number adopted merely with a view to the simple, consistent, and convenient representation of the composition of the compounds of that element by means of formulæ. It has been found, however, that the atomic weights so selected have an important relation to some of the physical properties of the elements. The relation of the atomic weight to the *specific heat* (see NATURAL PHILOSOPHY, p. 205) of the elements has been most fully worked out, and will alone be considered here. This relation is expressed by means of a proposition, called, from its discoverers, *Dulong and Petit's Law.* This is, that the specific heat of an element in the solid state is inversely proportional to its atomic weight; or, that the product of the atomic weight and specific heat in the solid state of an element is constant. This law is not absolutely true. The specific heat in the solid state of an element multiplied by its atomic weight is a number which, in the case of the great majority of elements, is 6·6, or very nearly this number, and this enables us in some cases to fix the atomic weight of an element where purely chemical evidence is doubtful; but as there are a few exceptional cases, and as even in those in which the product approximates to 6·6 the divergence is considerable, this law can only be regarded as an indication of a relation, not as an exact statement of it; it is, however, too important to be altogether passed over in such a sketch of chemical principles as we have here endeavoured to give.

We have now gone over the main points of chemical principle: in order to give the reader a general view of the science, it is now necessary that we should append a short statement of chemical *facts*, to supplement what has necessarily been interwoven into the preceding parts of this paper.

SHORT STATEMENT OF THE PROPERTIES OF THE ELEMENTS AND THEIR COMPOUNDS, OF THE METHODS OF PREPARING THEM, AND THEIR ACTION UPON EACH OTHER.

OXYGEN.—Oxygen is a colourless, tasteless, odourless gas; its specific gravity (that of air being taken as unity*) is 1·1056. It is slightly soluble in water, 100 volumes of water, at ordinary temperatures and pressure, dissolving about 3 volumes of oxygen. It has not been reduced to the liquid state by any amount of pressure even at the lowest temperature hitherto attained.

It exists *free* in atmospheric air, of which it constitutes, by volume, about 20·9 per cent. It may be obtained pure—

1. By heating certain metallic oxides, such as oxide of silver (Ag_2O), oxide of mercury (HgO), which simply decompose into oxygen and metal; or peroxide of manganese (MnO_2), peroxide of barium (BaO_2), anhydrous chromic acid (CrO_3), which decompose into oxygen and an oxide of the metal containing less oxygen than the original substance—peroxide of manganese yielding oxygen and an oxide having the formula Mn_3O_4, containing two-thirds of the oxygen in the peroxide—peroxide of barium and anhydrous chromic acid losing half their oxygen, and leaving oxides having the composition expressed by the formulæ BaO and Cr_2O_3 respectively.

2. By the decomposition by heat of certain salts containing oxygen. The most practically important of these are: (*a*) *Chlorate of potash*, K_2O,Cl_2O_5 or $KClO_3$—this salt, when *strongly* heated alone (or by the action of a more moderate heat when mixed with a small quantity of peroxide of manganese, red oxide of iron, or black oxide of copper), decomposing into oxygen and chloride of potassium (KCl), thus yielding all its oxygen as oxygen gas; (*b*) *Sulphate of zinc*, ZnO,SO_3 or $ZnSO_4$, which, when heated, yields oxide of zinc (ZnO), sulphurous acid gas (SO_2), and oxygen gas. As sulphurous acid gas is readily soluble in water, we can obtain the oxygen pure by washing the mixed gas.

3. By the *electrolysis* of water. See p. 311.

4. By the action of the green parts of living plants upon carbonic acid gas and water, under the influence of sunlight. This action cannot be conveniently used for the preparation of pure oxygen, but it plays a most important part in the economy of nature. See VEGETABLE PHYSIOLOGY.

Oxygen is a *supporter of combustion;* that is, it enters into combination with combustible substances, and in doing so produces a great deal of heat. The conditions under which such combustions take place, and the products formed, will be given under the heads of the combustible substances themselves.

Oxygen is essential for the support of *animal life.* In the process of respiration, oxygen is absorbed by air-breathing animals in the lungs, by water-breathing animals in the gills from the oxygen dissolved in the water, in both cases the red colouring-matter of the blood entering into a feeble combination with oxygen. Oxygen is thus carried by the blood to all parts of the body, where

* Throughout this paper, when it is not otherwise stated, the specific gravity of a gas is referred to that of air as unity.

it combines with the carbon and hydrogen of the tissues, producing carbonic acid and water. This combination is attended by the evolution of heat, and is thus the source of animal heat. See HUMAN PHYSIOLOGY.

The compounds of oxygen have already been to some extent described, and will be further treated of under the elements of which they are oxides. Most common rocks, such as quartz, granite, limestone, trap, basalt, &c. are compounds of oxygen.

Ozone is a remarkable modification of oxygen. It has hitherto been obtained only mixed with a large proportion of common oxygen. Oxygen can be ozonised—that is, part of it converted into ozone —in various ways; for instance, by passing electric sparks through it, or by the slow combustion of various substances, as phosphorus. Oxygen prepared by electrolysis contains ozone. Ozone can be converted into common oxygen by heat, and also by contact with a great variety of substances. Ozonised oxygen occupies less space than the common oxygen from which it was prepared, and expansion takes place when ozone is reconverted into common oxygen, thus proving that ozone is denser than common oxygen. Experiments seem to prove that the density of ozone is to that of common oxygen as 3 : 2. If this is the case, the molecular formula of ozone is O_3, as that of common oxygen is O_2. Ozonised oxygen has a strong and peculiar odour, and acts as a bleaching and oxidising agent. It is generally present in small quantity in the air, and probably is of use in oxidising offensive and injurious organic matters.

HYDROGEN is a colourless, tasteless, odourless gas. Its specific gravity is 0·0693; in other words, 14½ volumes of hydrogen have the same weight as one volume of air. Light balloons filled with hydrogen, therefore, rise in the air. Hydrogen is very slightly soluble in water, 100 volumes of water dissolving less than two volumes of the gas. It has not been reduced to the liquid state.

Hydrogen does not occur free in this planet, but spectroscopic observations (see ASTRONOMY) prove that it exists in large quantity in the atmosphere of the sun. It forms one-ninth part, by weight, of water, and is an essential constituent of all animal and vegetable tissues. It may be obtained—1. By the electrolysis of water, or dilute acids (see p. 311). 2. By the action of water on certain metals —as sodium, at ordinary temperatures, iron or zinc at a red-heat, the metal uniting with the oxygen, and setting the hydrogen free. 3. By the action of some hydrated acids (hydric salts) upon metals—as hydrochloric acid on zinc, iron, or tin; dilute sulphuric acid on zinc or iron; the metal simply replacing the hydrogen (see p. 312).

Hydrogen is inflammable—that is, it can be set fire to in air or oxygen. In order to set fire to it, the contact of a red-hot body is necessary. If a piece of spongy platinum is placed in a mixture of oxygen and hydrogen, the two gases condense in the pores of the platinum, unite there, and produce sufficient heat to render the metal red-hot, and this sets fire to the hydrogen. As already stated (p. 311), two volumes of hydrogen unite with one volume of oxygen to form water. If the two gases are mixed in this proportion, an explosive mixture is formed. When a flame or a red-hot body is applied to such a mixture, very rapid combination takes place, with violent explosion, caused by the sudden evolution of heat. Hydrogen at a high temperature is a powerful reducing agent. By far the most important compound of hydrogen and oxygen is water; its chief chemical properties have already been described.

The only other known compound of these two elements is the *peroxide of hydrogen.* This substance is formed when acids act on peroxide of sodium or peroxide of barium; thus, $BaO_2 + 2HCl = H_2O_2 + BaCl_2$. Its formula is H_2O_2, and it contains hydrogen and oxygen in the proportion of 1 : 16. It decomposes very readily into water and oxygen gas; a very slight rise of temperature is sufficient to effect this decomposition. In many cases it acts as an oxidising agent, because of the readiness with which it gives up half of its oxygen; but, curiously enough, it sometimes acts as a *reducing* agent. Thus, when brought in contact with oxide of silver, it not only gives off its own superfluous oxygen, and is reduced to water, but also, if we may use the expression, induces the oxide of silver to give up its oxygen too, so that metallic silver is produced.

NITROGEN is a colourless, tasteless, odourless gas. Its specific gravity is 0·972; 100 volumes of water dissolve at ordinary temperatures about 1½ volume of the gas; it has not been condensed to the liquid state. Nitrogen occurs in the atmosphere, of which it forms about 79·1 per cent. by volume. Atmospheric air consists essentially of nitrogen and oxygen, with comparatively very small quantities of other gases—carbonic acid, ammonia, and water-vapour. Nitrogen may be prepared from atmospheric air by removing the oxygen; this can be done in various ways; of these we may mention: 1. Passing air through a long tube containing metallic copper, heated to redness; the copper unites with the oxygen, forming cupric oxide, CuO, and the nitrogen passes on. 2. Burning phosphorus (or allowing it slowly to oxidise) in air, the oxygen unites with the phosphorus, forming phosphoric (or phosphorous) acid (see p. 326), which can be removed by water, in which it is soluble.

Nitrogen gas is an eminently inactive substance, and does not readily enter into combination with other elements. In the air, its chief function is to act as a diluent of the oxygen. There are, however, a great many very important compounds of nitrogen which we obtain indirectly from one another. All animals and vegetables contain compounds of nitrogen; and by the decomposition of dead animal and vegetable matters, and from the excreta of animals, other compounds of nitrogen are formed, which in their turn form part of the food of plants. Thus, there is a constant circulation of nitrogen from one state of combination to another, and with this circulation the great mass of free nitrogen in the air has very little connection. We shall here shortly describe the compounds of nitrogen with oxygen and with hydrogen.

Compounds of Nitrogen and Oxygen.—Of these there are five—namely:

Nitric Acid (anhydrous), N_2O_5, forming, with water, hydrated nitric acid or hydric nitrate, H_2O,N_2O_5 or HNO_3; and with bases, nitrates, as K_2O,N_2O_5 or KNO_3, nitrate of potash or potassic nitrate.
Peroxide of Nitrogen, NO_2.
Nitrous Acid (anhydrous), N_2O_3, does not form a stable hydric salt with water, but unites with bases forming nitrites, as K_2O,N_2O_3 or KNO_2, nitrite of potash or potassic nitrite.
Nitric Oxide, NO.
Nitrous Oxide, N_2O.

Nitrates and nitrites occur in the soil. The mode of their formation will be considered under Ammonia. Hydrated nitric acid can be obtained by heating any nitrate (most commonly, nitrate of soda—the cheapest nitrate—is used) with sulphuric acid (see p. 309). All the other oxides of nitrogen are most easily prepared from hydrated nitric acid. Peroxide of nitrogen is a reddish-brown vapour, having an extremely irritating action on the lungs when even a small quantity of it mixed with much air is breathed. It can be condensed to a brown liquid, nearly colourless when cooled to a low temperature. It is formed—1. By the reduction of nitric acid—as when hydrated nitric acid acts on tin, the tin unites with part of the oxygen, forming an oxide; and red fumes are given off, consisting of peroxide of nitrogen. 2. By the decomposition of some nitrates by heat—for instance, nitrate of copper, CuO,N_2O_5, when heated, gives cupric oxide, CuO, which remains behind; while, instead of anhydrous nitric acid being given off, we have peroxide of nitrogen and free oxygen, $CuO,N_2O_5 = CuO + 2NO_2 + O$. 3. By the union of nitric oxide and oxygen. Nitric oxide, NO, when mixed with oxygen, at once combines with it, forming peroxide of nitrogen.

Nitrous acid is produced in various reductions of nitric acid—for instance, when hydrated nitric acid acts on white arsenic, or on starch. It is a reddish-brown vapour, closely resembling peroxide of nitrogen. It can be condensed to a blue liquid. When nitrate of potash, K_2O,N_2O_5 or KNO_3, is strongly heated, it loses oxygen, and yields nitrite of potash, K_2O,N_2O_3 or KNO_2.

Nitric oxide is a colourless, transparent gas, very sparingly soluble in water. It has not been condensed to the liquid state. It is formed by the reduction of nitric acid—for instance, when hydrated nitric acid acts on some metals (copper, lead, mercury, silver), an oxide of the metal is formed, which at once unites with nitric acid to form a nitrate, and nitric oxide gas is given off. Its most remarkable character is its action on oxygen gas. When these two colourless gases are mixed, they instantly combine to form red fumes of peroxide of nitrogen.

Nitrous oxide is a colourless transparent gas, having a sweetish taste. Water, at ordinary temperatures, dissolves about its own volume of the gas. It can be condensed by cold and pressure to the liquid state, and may be frozen to an ice-like solid by very intense cold. This gas supports the combustion of most ordinary combustibles, such as wood, paper, wax, &c. the oxygen combining with the combustible, and the nitrogen becoming free. It cannot, however, support animal life, as the oxygen is too firmly held by the nitrogen to be given up to the red colouring-matter of the blood. At the same time, it is not directly poisonous, and can be breathed for a short time without injury. When so breathed, it produces insensibility, and is now used in minor surgical operations for the same purposes as chloroform or ether. In small quantities, it produces intoxication, whence its popular name, laughing-gas. Its preparation will be described under Ammonia.

The only known substance consisting solely of nitrogen and hydrogen is ammonia. Ammonia is a colourless, transparent gas, having a peculiar pungent odour. Its specific gravity is 0·59. It is very soluble in water, one volume of water absorbing, at ordinary temperatures and pressures, between 600 and 700 volumes of the gas. Solution of ammonia is specifically lighter than water: it gives up the whole of the ammonia when boiled. This solution is what is sold as 'liquor ammoniæ,' or 'spirit of hartshorn.' The gas can be condensed by cold and pressure to a colourless liquid.

Ammonia is composed of 14 parts by weight of nitrogen, and 3 of hydrogen: its formula is NH_3. It unites with the *hydrated* acids or hydric salts to form ammonia salts. Thus, ammonia unites with hydrochloric acid to form the salt known as sal-ammoniac—$NH_3 + HCl = NH_3,HCl$ or NH_4Cl; with nitric acid to form nitrate of ammonia—$NH_3 + HNO_3 = NH_3,HNO_3$ or NH_4NO_3; with sulphuric acid it unites in two proportions to form acid sulphate of ammonia, or bisulphate of ammonia, and normal sulphate of ammonia—$NH_3 + H_2SO_4 = NH_3,H_2SO_4$ or NH_4HSO_4, and $2NH_3 + H_2SO_4 = 2NH_3,H_2SO_4$ or $(NH_4)_2SO_4$. These ammonia salts resemble very closely, in crystalline form and in many chemical characters, the corresponding potash salts; and if we compare the formulæ of the two sets of salts, we see that there is also an analogy in composition:

NH_4Cl;	NH_4NO_3;	NH_4HSO_4;	$(NH_4)_2SO_4$, &c.
KCl;	KNO_3;	$KHSO_4$;	K_2SO_4, &c.

The reader will at once see that wherever we have in a potash salt K (that is, 39 parts of potassium), in the corresponding ammonia salt we have NH_4 (that is, 17 parts of ammonia and 1 of hydrogen). NH_4 is, therefore, a *compound radical* (see p. 313), and stands to K in a relation similar to that of NO_3 to Cl. This compound radical has received the name of ammonium: thus, sal-ammoniac, NH_4Cl, is chloride of ammonium, &c. There are some points where the analogy between potassium and ammonium breaks down. We may compare this analogy to that between a firm or corporation and an individual person. In buying and selling, in borrowing and lending, in suing or in being sued, a corporation or firm resembles an individual; but there are cases where this resemblance totally ceases—those cases, namely, which lead to the dissolution of the firm, or the surrender of the charter of the corporation. So in the case of ammonium and potassium, in a great many double decompositions, the actions of the ammonium salts resemble those of the potassium salts—ammonium (NH_4) in the one case, and potassium (K) in the other, changing place with other metals; but sometimes the ammonium breaks up, and its constituents take each its separate course. It is by a reaction of this kind that pure ammonia is prepared. Anhydrous potash), K_2O, and hydrated or caustic, K_2O,H_2O (or KHO), are compounds of potassium which have no analogues in the ammonium set. There is no $(NH_4)_2O$, and no NH_4HO.* Every chemical change which might be expected to produce either of these bodies really yields ammonia and water—$(NH_4)_2O$ becoming $2NH_3 + H_2O$, and NH_4HO becoming $NH_3 + H_2O$. Thus, when

* The formula NH_4HO and the name hydrated oxide of ammonium are sometimes used, but they do not refer to a definite substance, but merely to ammonia and water acting together.

an ammonia salt—say sal-ammoniac (chloride of ammonium)—is mixed with caustic potash (hydrate of potash), a change takes place, which is represented by the following equation :

$$NH_4Cl + KHO = KCl + NH_3 + H_2O.$$

The K takes the place of the NH_4, but the NH_4 not being able to take the place of the K, breaks up, and instead of NH_4HO, which might have been expected, we have $NH_3 + H_2O$. In preparing ammonia, slaked lime (hydrate of lime) is usually employed instead of caustic potash. The action is quite similar to that given above :

$$2NH_4Cl + CaO,H_2O = CaCl_2 + 2NH_3 + 2H_2O.$$

This operation is conducted in a retort; and the ammonia, if required as a gas, may be dried by passing it through a tube containing fragments of solid caustic potash, which retains the water; or if a solution of the gas (spirits of hartshorn) is wished, it is led into vessels containing water, which dissolves it.

If we attempt to isolate ammonium, it also breaks up, and ammonia and hydrogen are produced. Thus, if sodium amalgam, a compound of sodium and mercury, is covered with a strong solution of sal-ammoniac, the sodium and the ammonium change places, and we obtain chloride of sodium and ammonium amalgam. This, however, rapidly decomposes; hydrogen and ammonia are given off, and mercury remains behind.

The most important source of ammonia and ammoniacal salts is the decomposition of animal and vegetable matters containing nitrogen. Dead animals and vegetables, and animal excreta, yield ammonia in decomposing. When coal (the remains of dead plants) is distilled in the manufacture of gas, a considerable quantity of ammonia is produced, and it is from this source that the ammonia of commerce is chiefly obtained.

The following salts of ammonia deserve notice here. Sulphate, $(NH_4)_2SO_4$, largely used as a manure; sal-ammoniac, NH_4Cl; the nitrate, NH_4NO_3, is specially interesting, on account of the way in which it decomposes when heated, all of the hydrogen uniting with two-thirds of the oxygen to form water, while the nitrogen and the rest of the oxygen form nitrous oxide gas, thus : $NH_4NO_3 = 2H_2O + N_2O$. The nitrite, NH_4NO_2, undergoes a similar decomposition, yielding water and nitrogen gas, $NH_4NO_2 = 2H_2O + N_2$.

It has been stated above that decaying animal and vegetable matters, when these contain, as they generally do, nitrogen, give off ammonia; now, if ammonia, or such ammonia-producing matters are exposed to air in the presence of bases, especially if so exposed in a porous material, such as the soil, the ammonia undergoes oxidation, and in the first place a nitrite is produced, and this nitrite is converted into a nitrate, if the exposure to oxygen is long continued. What nitrite or nitrate is formed depends of course upon the base with which the ammonia was mixed. This is the origin of nitrates in the soil, and thus nitrate of potash is produced in Bengal, where the soil contains potash; nitrate of lime and nitrate of magnesia in this country, where the soil contains these bases. The nitrate of soda, found in extensive layers in Bolivia, appears to have had a different origin. Nitrates and nitrites are not unfrequently found in the water of shallow wells in towns and villages; in such cases, this usually indicates that decaying animal matters, drippings from dunghills, sewage, &c. have percolated through the soil, and found their way, more or less oxidised, into the well.

CARBON occurs free in nature in two perfectly distinct forms : 1. As diamond, a colourless transparent solid, of specific gravity 3·5. It is the hardest substance known; it is found crystallised in forms derived from the cube. When strongly heated in air or oxygen, diamond burns, forming carbonic acid. 2. As graphite, plumbago, or blacklead, a black, opaque solid, with a metallic lustre, crystallised in hexagonal plates. Graphite is seldom found quite pure, generally mixed with from one to five per cent. of iron, silica, and alumina. When strongly heated in air or oxygen, it burns, forming carbonic acid. In combination, carbon is very widely diffused; carbonic acid (CO_2) occurs in atmospheric air in the proportion of about four parts in 10,000. It is poured out in great quantity by volcanos, and from cracks in the earth's surface; many mineral waters contain carbonic acid in solution; it is produced by the combustion and by the slow oxidation (decay) of animal and vegetable substances, all which contain carbon; and forms a large part of the air expired by animals (p. 320). It is also produced in the alcoholic fermentation (see p. 332). Carbonates occur in great quantity in nature; carbonate of lime (marble, limestone, chalk, calcspar), carbonate of lime and magnesia (dolomite, magnesian limestone) being most abundant minerals, and forming the mass of many great mountain chains. Carbonate of iron (p. 329) is one of the most important iron ores. Carbon occurs in nature combined with hydrogen in marsh gas (CH_4), and is an essential constituent of all animal and vegetable tissues. From such tissues carbon may be obtained as *charcoal* by the action of heat. When animal or vegetable substances are heated to redness in such a manner as to exclude air or oxygen from them, the hydrogen and oxygen (and nitrogen and sulphur, if these elements are present) go off with *part* of the carbon as gases or volatile bodies, while the rest of the carbon remains behind as charcoal. This heating or charring may be conducted in either of two ways : 1. The wood, coal, or other substance to be charred, may be set fire to in heaps so arranged that the access of air is limited, only so much being admitted as is necessary to burn a *part* of the combustible, and so furnish heat enough to char the rest. This process is adopted in charcoal-burning in countries where wood is abundant, and in coking-ovens for preparing coke for fuel. 2. By heating the substance to be charred in cylindrical retorts heated by special furnaces outside the retorts; in this process, the gases and volatile matters, instead of being burnt, are led off by pipes from the retorts (see No. 31). Charcoal varies greatly in character according to the substances from which it is prepared; thus, we have wood-charcoal, peat-charcoal, coke (coal-charcoal), bone-charcoal, blood-charcoal, &c. These differ from one another in texture, being more or less dense, more or less porous, &c.; they also contain mixed with them all the mineral matter which may have been present in the substance charred. Nearly every kind of charcoal has a remarkable power of absorbing gases and vapours, and is therefore used for

removing offensive vapours from air; charcoal, especially animal charcoal, also absorbs many colouring-matters, and is accordingly used to decolorise solutions, as in sugar-refining. Charcoal, when heated in air or oxygen, burns, forming carbonic acid.

Lampblack is a form of carbon deposited from the flame of gaseous or volatile compounds of carbon. When compounds of carbon and hydrogen are burnt with a sufficient supply of air or oxygen, the hydrogen is burnt to water, and the carbon to carbonic acid; but if there is not enough oxygen for both, the carbon, or part of it, is deposited as smoke or lampblack. Charcoal and lampblack are 'amorphous;' that is, are not crystalline. We have, then, three distinct forms of the element carbon, two crystalline—diamond and graphite—and one amorphous. These are called 'allotropic' forms of carbon; and carbon is said to be 'dimorphous,' because it occurs in *two* different crystalline forms.

Compounds of Carbon and Oxygen.—Carbonic acid (anhydrous carbonic acid, carbonic anhydride) is composed of carbon and oxygen in the proportion of 3 to 8; its formula is CO_2. It is a colourless transparent gas, and has a pungent taste. Its specific gravity is 1·524. Water dissolves at ordinary temperatures about its own volume of the gas. It can be reduced by cold and pressure to the liquid state, and the liquid can be frozen so as to form a solid. When the gas is produced in a vessel closed at the bottom, such as a brewer's vat or tan-pit (see *Fermentation*, p. 332), or poured from cracks or crevices into a well or mine, it remains—on account of its specific gravity being $1\frac{1}{2}$ time that of air—as a layer at the bottom, only slowly mixing with the air by diffusion (page 306), unless it be disturbed. Loss of life has frequently been caused by persons incautiously descending into such vats or pits, as carbonic acid not only does not support animal life, but is directly injurious. As already mentioned, atmospheric air contains, normally, about 4 parts in 10,000, and this proportion may be considerably increased without serious effects to animal life. Some authors assert, that air which contains one part of carbonic acid in 200 is dangerous; but there is no doubt that when the quantity reaches 2 or 3 per cent. death may be produced. Carbonic acid does not support combustion; a lighted candle is extinguished when plunged into a jar of the gas; it must, however, be remembered that a candle will burn in an atmosphere in which a man could not live, for air containing 2 or 3 per cent. of carbonic acid will support the flame of a candle, but not the life of a man.

Carbonic acid (being an anhydrous acid) unites with bases to form carbonates—as normal carbonate of soda (washing-soda), Na_2O,CO_2 or Na_2CO_3 (this salt crystallises with 10 molecules of water of crystallisation); bicarbonate of soda (baking-soda), Na_2O,CO_2,H_2O,CO_2 or $NaHCO_3$; carbonate of lime (chalk, marble, limestone), CaO,CO_2 or $CaCO_3$. From carbonates we can easily obtain carbonic acid by the action of any strong acid, as hydrochloric acid, and as hydrated carbonic acid does not exist, we obtain by this action anhydrous carbonic acid and water, thus:

$$CaO,CO_2 + 2HCl = CaCl_2 + H_2O + CO_2.$$

Other sources of carbonic acid have already been mentioned.

Carbonic oxide is composed of carbon and oxygen in the proportion 3 : 4—its formula is CO. It is a colourless transparent gas, of specific gravity 0·968, or almost exactly the same as that of nitrogen.* Carbonic oxide is very slightly soluble in water, and has not been liquefied. It may be prepared in various ways; of these we shall mention three. 1. When carbonic acid is passed through a tube containing red-hot iron turnings, the iron takes half of the oxygen from the carbonic acid, and carbonic oxide is produced. 2. When carbonic acid is passed through red-hot charcoal, it takes up carbon—thus $CO_2 + C = 2CO$. This mode of formation may be seen in a common fireplace, in which a clear red fire is burning; the air enters at the bottom of the grate, and its oxygen combines with carbon, forming carbonic acid; this gas passing upwards through the red-hot charcoal or cinders, is converted into carbonic oxide, which burns with a blue flame at the top of the fire. 3. When *oxalic acid* is heated with strong sulphuric acid, it is decomposed into water, carbonic oxide, and carbonic acid, thus:

$$\underset{\text{Oxalic Acid.}}{H_2C_2O_4} = H_2O + CO + CO_2.$$

Carbonic oxide is combustible, burning with a blue flame, and forming carbonic acid. It is an exceedingly poisonous gas, much more so than carbonic acid, and, along with the latter, is the cause of the deaths which have frequently been produced by breathing the air of a room where charcoal has been burnt without a chimney or proper ventilation.

Compounds of Carbon and Hydrogen.—These substances are called 'hydrocarbons,' and form a very large and important class of compounds. When we name as specimens of the class, paraffin oil, solid paraffin, benzine, oil of turpentine, oil of roses, india-rubber, it will be obvious to the reader that it is impossible here to describe the hydrocarbons in detail; some of the more important are treated of in the paper on CHEMISTRY APPLIED TO THE ARTS. We shall here enumerate some of their general characters, and describe two of the simplest hydrocarbons. All hydrocarbons are colourless (when pure), volatile, and combustible; when sufficient oxygen is supplied, they burn to form carbonic acid and water. If the supply of oxygen is insufficient, tarry matters and lamp-black are produced. The luminosity or brightness of the flame depends greatly on the proportion of carbon, the flame being generally brighter the more carbon is contained in the compound.

The two hydrocarbons which we shall here describe are, marsh gas and olefiant gas.

Marsh gas contains carbon and hydrogen in the proportion 3 : 1; its formula is CH_4. Of all known hydrocarbons it contains the largest proportion of hydrogen, and therefore gives the least luminous flame. It is a colourless transparent gas, scarcely soluble in water, and has not been liquefied. Its specific gravity is 0·558. It is the lightest gaseous hydrocarbon, and is often called 'light carburetted hydrogen.' It is produced by the decomposition

* It will be observed that the molecular weight of carbonic oxide is the same as that of nitrogen, $12 + 16 = 2 \times 14$. Their specific gravity should therefore be the same (p. 318). The slight discrepancy is no doubt due to these gases (as is the case with all gases) deviating *slightly*, and not to the same extent, from Boyle's law.

of vegetable matter under water; the gas which bubbles up when the bottom of a pond is disturbed consists of marsh gas mixed with carbonic acid. It also occurs in cavities in coal-seams, and forms the 'fire-damp' of our coal-mines, and is produced by the distillation of many organic substances. It is one of the constituents of coal-gas. It is a combustible gas, and when mixed with the proper proportion of oxygen, forms an explosive mixture. The products of the combination are carbonic acid and water, $CH_4 + 2O_2 = CO_2 + 2H_2O$. From this equation it will be seen that one volume of marsh gas requires two volumes of oxygen for its combustion. As air contains about 20 per cent. of oxygen, one volume of marsh gas requires 10 volumes of air for its complete combustion. The explosions which occur in coal-mines are caused by the ignition of such a mixture, and explosion takes place even when the two gases are not in the exact proportions given above. It has been found by experiment that no explosion takes place when there is less than three volumes, or more than 18 volumes of air, to one of marsh gas. It will be remembered that a red-hot body will cause explosion of a mixture of hydrogen and oxygen—the temperature at which marsh gas takes fire is much higher—contact with a flame or white-hot body being necessary. It is upon this fact that the efficacy of Davy's safety-lamp depends. In this lamp the flame is inclosed in a cylinder of wire-gauze. If such a lamp be placed in an explosive mixture of marsh gas and air, the mixture inside the cylinder, immediately in contact with the flame of the lamp, will burn; but this combustion will not extend to the mixture outside, as the gases, by passing through the meshes of the wire-gauze, are cooled down below the temperature necessary for kindling marsh gas. The enlargement of the flame, due to the marsh gas burning inside the cylinder, is a warning to the miner of the presence of 'fire-damp.'

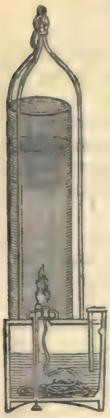

Fig. 2.

Olefiant gas contains carbon and hydrogen in the proportion 6 : 1; its formula is C_2H_4. It is a colourless transparent gas of specific gravity 0·978. It is inflammable, burning with a strongly luminous flame, and producing carbonic acid and water, $C_2H_4 + 3O_2 = 2CO_2 + 2H_2O$. It occurs in coal-gas, and the luminosity of coal-gas is to a great extent due to its presence. It can also be prepared by heating a mixture of four parts of strong sulphuric acid and one of alcohol; the action which takes place is represented by the following equation:

$$\underset{\text{Alcohol.}}{C_2H_6O} = \underset{\text{Water.}}{H_2O} + \underset{\text{Olefiant Gas.}}{C_2H_4}$$

The sulphuric acid in this case acts as a dehydrating or water-removing agent.

CHLORINE has been already spoken of (p. 313) as a simple or elementary *salt-radical*. It occurs in nature in combination with metals, forming metallic chlorides. Of these the most important is chloride of sodium or common salt (NaCl). Common salt is by far the most abundant of the salts dissolved in sea-water, and is obtained from sea-water by spontaneous evaporation in shallow ponds or marshes in the neighbourhood of the sea in warm countries. It also occurs in extensive beds as rock-salt, and in solution in many mineral waters. When acted on by sulphuric acid, it yields sulphate of soda and hydrochloric acid gas ($2NaCl + H_2SO_4 = 2HCl + Na_2SO_4$). Hydrochloric acid gas is a colourless transparent gas, of specific gravity 1·27. It is very soluble in water; at ordinary temperatures, water dissolves about 450 times its volume of the gas. The solution is denser than water, and the gas cannot be wholly expelled by boiling. The solution is generally called hydrochloric acid, or muriatic acid, or spirit of salt. Hydrochloric acid acts upon such metallic oxides as are bases, producing a salt and water; thus, $CaO + 2HCl = CaCl_2 + H_2O$. But if we take an oxide such as peroxide of manganese, which is not a base, and has no corresponding chloride, the action is different, thus: $MnO_2 + 4HCl = MnCl_2 + Cl_2 + 2H_2O$. Instead of obtaining $MnCl_4$, we have $MnCl_2$ *and* Cl_2; that is, free chlorine. It is in this way that chlorine gas is prepared. Chlorine is a greenish yellow gas, of specific gravity 2·45, having a pungent smell. As it is much heavier than air, it may be collected by displacement, the tube from which it issues being led to the bottom of the receiving vessel. The chlorine collects at the bottom of the vessel, and gradually fills it, driving out the air (see fig. 3). It cannot be breathed unless very much diluted with air, and has a very irritating effect on the lining membrane of the air-passages. Water dissolves about twice its volume of chlorine gas. Chlorine unites very readily with hydrogen; a jet of hydrogen kindled in chlorine burns readily, forming hydrochloric acid. A mixture of equal volumes of hydrogen and chlorine can be kept for any length of time in the dark, but explodes violently when exposed to sunlight. In diffused light, the two gases combine more slowly. This tendency of chlorine to combine with hydrogen renders *wet chlorine*, or chlorine along with water, a very powerful oxidising agent; the chlorine attracting the hydrogen of the water, the oxygen of which thus becomes more easily separated, and can therefore readily attack oxidisable substances.

Fig. 3.

It is in this way that chlorine acts as a bleaching and as a disinfecting agent. Many colouring-matters, and many offensive gases and vapours, are oxidisable, and can, by oxidation, be converted into colourless substances, or into inodorous bodies. In these cases, they are destroyed by wet chlorine—the chlorine taking the hydrogen of the water, while the oxygen oxidises the colouring or offensive substances. Chlorine unites with slaked

lime, forming chloride of lime, or bleaching-powder; when sulphuric acid is added to this substance, sulphate of lime is formed, and chlorine is set free.

Chlorine has only a very slight affinity for oxygen, so that the two elements do not directly combine; and their compounds, when indirectly produced, decompose very easily into chlorine and oxygen, the decomposition usually taking place with explosive violence. In these decompositions, heat is given out.

Of these we may mention *Chloric Acid.* Anhydrous chloric acid (Cl_2O_5), corresponding to anhydrous nitric acid (N_2O_5), has not yet been obtained, but many of its salts are well known. Hydrated chloric acid (hydric chlorate, H_2O,Cl_2O_5 or $HClO_3$) is a very explosive and powerfully oxidising liquid. Chlorate of potash (K_2O,Cl_2O_5 or $KClO_3$) is important as a source of oxygen, and as an ingredient in the composition with which some kinds of lucifer-matches are tipped, and in many fireworks.

BROMINE and IODINE are elements closely resembling chlorine in chemical character. They form bromides and iodides with metals, hydrobromic and hydriodic acids with hydrogen, and bromates and iodates corresponding to the chlorates. Their affinity for hydrogen and the metals is in the order chlorine, bromine, iodine; being greatest in the case of chlorine, least in that of iodine. Their affinity for oxygen is in exactly the opposite order; being greatest in the case of iodine, least in that of chlorine.

Bromides occur in small quantity in sea-water and many mineral springs, from the 'mother-liquor' of which (or liquid left after the removal of the less soluble chloride of sodium) bromine is obtained. Compounds of iodine occur in extremely small quantity in sea-water, from which they are removed by sea-weeds. Iodine is obtained from the 'kelp' or ash of such sea-weeds. Bromine is a volatile brown liquid; iodine, a volatile black solid, yielding a beautiful purple vapour when heated.

SULPHUR occurs native in many volcanic districts, most of the sulphur of commerce being obtained from Sicily. It is purified by distillation, and is met with in commerce either as 'flowers of sulphur'—that is, a fine powder produced by rapidly cooling the sulphur-vapour—or as roll-sulphur, cast in cylindrical moulds. When heated, sulphur fuses, at a temperature of about 234° Fahrenheit, forming a mobile liquid of a brownish yellow colour. If this liquid is allowed to cool, it solidifies into an 'allotropic' modification of sulphur. This form of sulphur differs from the usual one: in colour, it is brownish yellow, instead of bright yellow; in specific gravity, it is somewhat lighter than common sulphur; and in crystalline form. When kept, however, it changes back again to the common form. If fused sulphur is heated, it begins to become thick like treacle at a temperature very little above 250° F. The thickness increases as the temperature rises, until, at about 430° F. the vessel containing it can be inverted without any of the sulphur pouring out; about 640° F. it is again more liquid, and can be poured out. If at this stage the sulphur is rapidly cooled by pouring it into water, it is obtained in a plastic form, elastic like india-rubber. This modification, when kept, passes back into the common form of sulphur.

Compounds of Sulphur and Oxygen.—When sulphur is burned in air or oxygen, it unites with oxygen, and forms anhydrous sulphurous acid, a colourless transparent gas, consisting of equal weights of sulphur and oxygen. Its formula is SO_2, its specific gravity is 2·25. It can easily be condensed to a colourless liquid, and dissolves readily in water; one volume of water dissolving about 30 volumes of the gas at ordinary temperatures. The gas has the pungent smell of burning sulphur, and cannot be breathed unless mixed with a large quantity of air. It unites with bases, forming sulphites, such as normal sulphite of soda (Na_2O,SO_2 or Na_2SO_3), acid sulphite of soda (Na_2O,SO_2,H_2O,SO_2 or $NaHSO_3$). Sulphurous acid and the sulphites act as reducing agents (p. 314), taking up oxygen to form sulphuric acid or sulphates. Sulphurous acid acts also as a bleaching agent, rendering certain animal and vegetable colouring-matters colourless, and is used for bleaching straw and woollen goods.

Sulphurous acid is a weak acid, and the sulphites are decomposed by most strong acids.

Anhydrous sulphuric acid (SO_3) is a white crystalline solid, which unites with the production of much heat with water to form hydrated sulphuric acid (H_2O,SO_3 or H_2SO_4). This is a colourless liquid, of specific gravity about 18·4 as compared with water. It is obtained by the oxidation of sulphurous acid. The operation is conducted in large leaden chambers, into which are introduced —1. Sulphurous acid, formed by burning sulphur or iron pyrites (a compound of sulphur and iron); 2. Steam; 3. Nitric acid; and 4. Atmospheric air. The nitric acid oxidises the sulphurous acid to sulphuric acid, which unites with water from the steam—the nitric acid being reduced to nitric oxide (NO) (p. 321); this immediately takes up oxygen from the air, and forms peroxide of nitrogen (NO_2), which again oxidises more sulphurous acid, and is reduced to nitric oxide. By a constant repetition of this process, a small quantity of nitric acid suffices for the oxidation of a large quantity of sulphurous acid. The sulphuric acid thus formed is concentrated by heat, which drives off much of the water, and leaves an acid nearly corresponding to the formula H_2O,SO_3 or H_2SO_4.

Hydrated sulphuric acid has a great attraction for water, and gives out much heat when mixed with it. It is a powerfully corrosive substance, destroying animal and vegetable tissues, and is sometimes used as a caustic in surgery. It is a very strong acid, driving out most other acids from their salts, and is used for preparing hydrochloric, nitric, acetic, and many other acids. With bases it forms sulphates, such as normal sulphate of potash (K_2O,SO_3 or K_2SO_4); acid sulphate of potash (K_2O,SO_3,H_2O,SO_3 or $KHSO_4$); sulphate of lime (CaO,SO_3 or $CaSO_4$), &c. It is often called oil of vitriol, because it can be obtained by distilling green vitriol or ferrous sulphate (FeO,SO_3 or $FeSO_4$). If the green vitriol be dry, anhydrous sulphuric acid is obtained. A mixture or solution of anhydrous sulphuric acid in hydrated sulphuric acid is known as Nordhausen or fuming sulphuric acid; it is used for dissolving indigo.

Sulphur unites with *hydrogen*, forming sulphuretted hydrogen (H_2S); this is a colourless transparent gas, of specific gravity 1·19. It can be condensed by cold and pressure to a colourless liquid. Water dissolves at ordinary temperatures

about three times its volume of the gas. It has an extremely unpleasant smell, like that of rotten eggs, and acts as a poison upon animals and plants. It is inflammable, burning in air or oxygen with a blue flame, and producing water and sulphurous acid gas. It is most conveniently prepared by the action of dilute sulphuric acid on ferrous sulphide ($FeS + H_2SO_4 = H_2S + FeSO_4$). It acts upon many metallic salts, producing a metallic sulphide and a hydrated acid, thus:

CuO,SO_3 +	H_2S =	H_2O,SO_3 +	CuS.
Sulphate of Copper.	Sulphuretted Hydrogen.	Hydrated Sulphuric Acid.	Cupric Sulphide.

All metallic salts are not thus acted on, and this difference of behaviour is taken advantage of in separating the metals from one another.

Sulphur unites with *carbon* when sulphur-vapour is passed over red-hot charcoal, forming bisulphide of carbon (CS_2), a very volatile liquid, used as a solvent of sulphur, phosphorus, and oils and fats. It is very easily set fire to, and burns with a blue flame, forming carbonic acid and sulphurous acid. As will be seen from its formula, it corresponds to carbonic acid (CO_2); and just as carbonic acid unites with basic *oxides* to form carbonates (such as Na_2O,CO_2), so bisulphide of carbon unites with the *sulphides* of positive metals to form *sulpho*-carbonates (such as Na_2S,CS_2).

PHOSPHORUS is an element very widely diffused in nature. Compounds of phosphorus are essential ingredients in every fertile soil, are absorbed by plants, and pass from plants into animal bodies. The animal tissues containing large quantities of phosphorus are the bones, and the nervous tissues, brain, spinal cord, nerves. Phosphorus can be obtained in two 'allotropic' modifications: 1. Common, yellow, or waxy phosphorus—a translucent yellowish solid of specific gravity 2. It fuses at 112° F. and boils at 550° F. It unites slowly with oxygen at ordinary temperatures, and shines in the dark when exposed to air. It is very easily inflammable, taking fire when moderately warmed in the air, so that it is dangerous to handle it, and it ought to be preserved under water. It is extremely poisonous, and serious and even fatal accidents have occurred from children sucking the ends of lucifer-matches containing phosphorus. 2. Red or amorphous phosphorus is produced from common phosphorus by keeping it for a long time at a temperature slightly below its boiling-point. It is a red solid, and differs very much in character from common phosphorus. It is not fusible; it is not readily inflammable; it is not poisonous. When heated to the boiling-point of common phosphorus, it is changed back into the latter, and therefore takes fire if heated to this temperature in the air.

Compounds of Phosphorus and Oxygen.—Phosphorus combines with oxygen in two proportions, forming, first, anhydrous phosphorous acid (P_2O_3), and second, anhydrous phosphoric acid (P_2O_5). We shall here consider only the latter. When phosphorus is set fire to in air or oxygen, it burns with dazzling brilliancy, forming anhydrous phosphoric acid. This is a snow-white solid, which unites with the greatest readiness with water, giving out much heat. It forms with water three distinct hydrates or hydric salts:

$P_2O_5 + H_2O = H_2O,P_2O_5$ .... Hydric *Meta*phosphate.
$P_2O_5 + 2H_2O = 2H_2O,P_2O_5$ .... Hydric *Pyro*phosphate.
$P_2O_5 + 3H_2O = 3H_2O,P_2O_5$ .... Hydric *Ortho*phosphate.

If in these formulæ we put all the oxygen together, we find that the first and third are divisible by two, so that we have the following formulæ:

Hydric Metaphosphate (or Hydrated Metaphosphoric Acid) .... HPO_3.
Hydric Pyrophosphate (or Hydrated Pyrophosphoric Acid) .... $H_4P_2O_7$.
Hydric Orthophosphate (or Hydrated Orthophosphoric Acid, usually called Common Phosphoric Acid) .. H_3PO_4.

Corresponding to each of these hydrates, there are series of salts; thus, we have metaphosphate of lime (CaO,P_2O_5), metaphosphate of soda (Na_2O,P_2O_5), metaphosphate of silver (Ag_2O,P_2O_5), pyrophosphate of lime ($2CaO,P_2O_5$), pyrophosphate of soda ($2Na_2O,P_2O_5$), pyrophosphate of silver ($2Ag_2O,P_2O_5$), orthophosphate (or common phosphate) of lime ($3CaO,P_2O_5$), common phosphate of soda ($2NaO,H_2O,P_2O_5$), common phosphate of silver ($3Ag_2O,P_2O_5$). It will be observed that in common phosphate of soda we have, as in all common, or ortho, phosphates, three equivalents of base to one P_2O_5, but only two of these are anhydrous soda, the other being water; this salt is, therefore, formally, an acid salt; it has not, however, an acid reaction, and the normal salt, $3NaO,P_2O_5$, is an unstable, highly alkaline body. When an orthophosphate, containing, as in this case, basic water, is heated, water is given off, and a pyrophosphate or metaphosphate is left; thus, when common phosphate of soda is heated, water is given off, and pyrophosphate of soda is left: $2Na_2O,H_2O,P_2O_5 = H_2O + 2Na_2O,P_2O_5$ or $2Na_2HPO_4 = H_2O + Na_4P_2O_7$; and when what is called acid phosphate of soda ($Na_2O,2H_2O,P_2O_5$), which is also an orthophosphate, is heated, water is given off, and metaphosphate of soda is left: $Na_2O,2H_2O,P_2O_5 = 2H_2O + Na_2O,P_2O_5$ or $NaH_2PO_4 = H_2O + NaPO_3$.

Common phosphate of lime ($3CaO,P_2O_5$ or $Ca_3(PO_4)_2$) is the most abundant mineral constituent of bones; and 'bone-ash,' the substance left when bones are burned white in an open fire, so as to destroy all the animal matters, consists chiefly of this phosphate. When treated with sulphuric acid and water, a partial decomposition takes place, which is represented by the following equation: $3CaO,P_2O_5 + 2(H_2O,SO_4) = CaO,2H_2O,P_2O_5 + 2(CaO,SO_4)$. The sulphate of lime ($CaO,SO_4$) being sparingly soluble in water, settles for the most part to the bottom of the vessel in which the decomposition is effected, while the acid phosphate of lime (superphosphate) remains in solution. This superphosphate is largely used as a manure. When superphosphate of lime is heated, it loses water, and leaves metaphosphate of lime: $CaO,2H_2O,P_2O_5 = 2H_2O + CaO,P_2O_5$. From metaphosphate of lime, phosphorus is obtained by heating it in earthenware retorts with charcoal. Two-thirds of the anhydrous phosphoric acid (P_2O_5) are decomposed, the charcoal taking the oxygen to form carbonic oxide, and thus setting the phosphorus free, while one-third remains with all the lime as common phosphate of lime: $3(CaO,P_2O_5) + 10C = 10CO + 4P + 3CaO,P_2O_5$.

Phosphuretted hydrogen, PH_3, is a colourless, transparent gas, having a disagreeable smell. It may be formed by heating phosphorus in a strong solution of caustic potash. As thus formed, it is spontaneously inflammable, taking fire at once on coming into contact with air or oxygen. The

gas owes this spontaneous inflammability to the presence of a small quantity of the vapour of another compound of phosphorus and hydrogen (PH_2).

Phosphorus unites with chlorine and also with bromine in two proportions, corresponding to the two oxides—namely, PCl_3; PCl_5 and PBr_3; PBr_5. The terchloride and terbromide are volatile liquids; the pentachloride and pentabromide are crystalline solids; they all undergo decomposition when brought into contact with water, yielding hydrochloric or hydrobromic acid, and phosphorous or phosphoric acids: $2PCl_3 + 6H_2O = 6HCl + 3H_2O,P_2O_3$; $2PCl_5 + 6H_2O = 6HCl + 3H_2O,P_2O_5$.

FLUORINE is an element the compounds of which resemble to a great extent those of chlorine. It occurs in nature combined with metals, forming salts called fluorides. The most important of these are fluorspar (Derbyshire spar) or fluoride of calcium (CaF_2), and cryolite, which is a compound of fluoride of sodium and fluoride of aluminium ($3NaF,AlF_3$). From these fluorides, hydrofluoric acid (HF) can be obtained by the action of sulphuric acid: $CaF_2 + H_2SO_4 = CaSO_4 + 2HF$. Hydrofluoric acid is a very volatile liquid, dissolving readily in water. It acts very corrosively on animal tissues, and produces severe wounds when applied to the skin. Its most striking chemical character is the way in which it acts upon glass (see Silica), and it is used in the arts for the purpose of etching glass.

SILICON, like carbon, can be obtained in three distinct 'allotropic forms:' two of these are crystalline, corresponding to diamond and graphite; and one is amorphous. Silica, the oxide of silicon (SiO_2), corresponds in formula to carbonic acid, and, like it, is an anhydrous acid, uniting with bases to form silicates. It differs, however, very greatly from carbonic acid in physical characters. It occurs in nature crystallised as rock-crystal or quartz, and obscurely crystallised in flint and chalcedony. Opal is an amorphous form of silica, usually containing some water. Silica fuses at a very high temperature. When heated with bases, it unites with them, forming silicates. Some of these silicates are of great importance. Thus, felspar (one of the ingredients of granite) is a compound of silicate of alumina and silicate of soda, potash, or lime; clay is a silicate of alumina; talc is a silicate of magnesia. Glass is formed of a mixture of silicates; of these, one must be the silicate of potash or silicate of soda: in crown-glass and plate-glass, the other is silicate of lime. In flint-glass, and the glass which is cut into ornaments, silicate of lead is present, sometimes in large proportion. Green bottle-glass owes its colour to silicate of iron.

The silicates of the alkalies (when not combined, as in glass, with other silicates) are soluble in water (water-glass), and are decomposed on the addition of an acid. Thus, sulphuric acid acts on silicate of soda, forming sulphate of soda and hydrated silicic acid, which, under some circumstances, remains dissolved in the water, but readily separates as a jelly. Hydrofluoric acid acts on silica and on the silicates, forming water and gaseous fluoride of silicon (SiF_4). On account of this action, hydrofluoric acid is used for etching glass.

BORON also exists in three forms, corresponding to the three forms of carbon and silicon. Its oxide is anhydrous boracic acid, B_2O_3. Its most important compound is borax, or borate of soda ($Na_2O,2B_2O_3$).

SELENIUM and TELLURIUM are comparatively rare elements, forming compounds nearly corresponding to those of sulphur.

METALS.

The general physical and chemical properties of metals have already been described (p. 312). The characters of the more important metals, and the methods used for extracting them from their ores, are described in the article METALS AND METALLURGY. We shall, therefore, here give only a general sketch of the metals and their compounds. The metals may be divided into several groups, the members of each group having many characters in common. We shall name each group after a metal possessing the common characters in a well-marked degree.

1. The *Sodium* group—comprising Sodium, Potassium, Lithium, Rubidium, and Cæsium.

2. The *Calcium* group—comprising Calcium, Strontium, and Barium.

3. The *Iron* group—comprising Magnesium, Zinc, Cadmium, Iron, Manganese, Chromium, Nickel, Cobalt, Aluminium, and Uranium.

4. The *Copper* group, comprising Copper, Mercury, Lead, and Silver.

5. The *Platinum* group, comprising Gold, Platinum, Palladium, and the rare metals found along with platinum.

6. The *Antimony* group, comprising Arsenic, Antimony, Bismuth, Tin, Titanium, Vanadium, Molybdenum, and Tungsten.

By comparing this list with the table at p. 315, it will be seen that we have not here enumerated all the known metals; those omitted are either too imperfectly known to admit of classification, or too rare to be of practical importance.

1. The oxides of the metals of the *Sodium group* are powerful bases, and unite with water to form soluble hydrates, which cannot be decomposed by heat (Na_2O,H_2O; K_2O,H_2O_3 or $NaHO$; KHO). The bases themselves and their hydrates are called 'alkalies.' The carbonates and phosphates of the alkalies are soluble in water. The metals themselves can be obtained by electrolysis of their fused chlorides, or by the reduction of their carbonates by means of charcoal: $Na_2CO_3 + 2C = 2Na + 3CO$. They decompose water at the ordinary temperature, hydrogen being given off, and the hydrated base remaining in solution: $2Na + 2H_2O = Na_2O,H_2O + H_2$.

The most important salts of this group of metals are: Chloride of sodium (common salt) (see p. 324); sulphate of soda (Glauber's salt) (see p. 324); carbonate of soda (Na_2O,CO_2) (washing-soda). This salt is made from sulphate of soda (which is prepared by acting on common salt with sulphuric acid) by heating it with coal and limestone, dissolving out the carbonate of soda thus formed, by means of water, and evaporating the solution. Bicarbonate of soda, baking-soda (Na_2O,CO_2,H_2O,CO_2 or $NaHCO_3$), is prepared by the action of carbonic acid gas on crystallised carbonate of soda. Nitrate of soda (Chili saltpetre), Na_2O,N_2O_5 or $NaNO_3$, occurs in large quantity in Bolivia, and is used for preparing nitric acid, and also as a manure to supply nitrogen

to growing plants. Phosphate of soda (see p. 326); borate of soda (borax) (see p. 327). Chloride of potassium, or muriate of potash (KCl), is found in the salt mines of Stassfurth, near Magdeburg. Carbonate of potash (K_2O,CO_2) is prepared from the ashes of plants. The plants contain various salts of potash, with acids containing carbon, hydrogen, and oxygen (organic acids). These when burnt are converted into water and carbonic acid, which go off into the air, and carbonate of potash, which remains in the ash. The ash is then treated with water, which dissolves the soluble salts, the solution is evaporated, and the less soluble salts crystallise out (see p. 305), leaving the carbonate of potash in the mother-liquor. This is then evaporated to dryness, and the solid substance remaining forms the 'potashes' of commerce, and consists chiefly of carbonate of potash. Nitrate of potash (K_2O,N_2O_5 or KNO_3). Nitre, or saltpetre (see p. 322), is obtained in Bengal from earth containing it, by treating the earth with water, and evaporating the solution. It is also formed from nitrate of lime by the action of chloride of potassium ($CaO,N_2O_5+2KCl=K_2O,N_2O_5+CaCl_2$). It is used for making gunpowder; see CHEMISTRY APPLIED TO THE ARTS.

Lithium, rubidium, and cæsium are comparatively rare metals, generally resembling sodium and potassium.

2. *Calcium group* (or metals of the alkaline earths). The oxides of these metals—Lime (CaO); Strontia (SrO); and Baryta (BaO)—are powerful bases, and unite with water to form hydrates soluble in water. Thus, lime, when treated with water, unites with it, giving out a great deal of heat, and forming 'slaked lime.' The solution of slaked lime in water is called 'lime-water.' The *normal* carbonates and phosphates of this group are insoluble in water. If a current of carbonic acid is passed into lime-water, a white precipitate of carbonate of lime is formed (CaO,CO_2 or $CaCO_3$). This action enables us to test for carbonic acid in air; thus, if a jar of air is shaken up with a definite quantity of lime-water, the proportion of carbonic acid present can be approximately estimated by the degree of milkiness produced. If the current of carbonic acid is continued after all the lime has been converted into carbonate, the milkiness gradually disappears, as carbonate of lime is soluble in water containing carbonic acid, probably on account of the formation of a bicarbonate of lime (CaO,CO_2,H_2O,CO_2). We cannot obtain this bicarbonate in the solid state, because, when the solution is evaporated or boiled, carbonic acid escapes, and carbonate of lime is precipitated. This solubility of carbonate of lime in water containing carbonic acid is of great practical importance. Water filtering through the soil takes up carbonic acid from decaying vegetable matters, and if it then comes in contact with carbonate of lime (limestone, or chalk), it dissolves it. Water thus charged with bicarbonate of lime, deposits carbonate of lime whenever it is exposed to the air: thus, if such water drops from the roof of a cave or from an overhanging rock, each drop before it falls loses some carbonic acid, and deposits some carbonate of lime on the rock: this deposit, increased by every drop which runs over it, gradually forms a dependent mass of carbonate of lime, hanging down from the rock; such a mass is called a 'stalactite.' But the drops do not lose *all* their carbonic acid before falling, and therefore do not deposit *all* their carbonate of lime on the stalactite, so that if they fall upon a rock or upon the floor of the cave, they there, evaporating still more, deposit a further quantity of carbonate of lime; and this second deposit forms a mass, gradually increasing in height, which is called a 'stalagmite.' As the stalactite grows down, and the stalagmite grows up, they sometimes meet, and form a continuous column, which grows in thickness from the deposits formed by the water, which now runs down the surface of the column.

When carbonate of lime is heated, it decomposes into lime and carbonic acid. This is the change effected in the lime-kiln. The lime (CaO) thus obtained is called 'quicklime,' to distinguish it from the hydrate or slaked lime. Common mortar consists of sand, slaked lime, and water. The sand acts merely mechanically to prevent the mortar shrinking; the hardening of the mortar depends on the slow conversion of the hydrate of lime into carbonate by the action of the carbonic acid of the air ($CaO,H_2O+CO_2=CaO,CO_2+H_2O$). Hydraulic mortar, or cement, consists of slaked lime, sand, burnt clay, and water. Here the sand acts also merely mechanically; but the burnt clay (which is frequently introduced by using a limestone containing clay, so that the two are burnt together) contains silica (SiO_2) in a condition such that it can slowly unite with the lime, and form silicate of lime (CaO,SiO_2), and it is upon this union that the hardening or setting of hydraulic mortar or cement depends. Other important salts of lime are: The phosphate (see p. 326); the nitrate (see p. 322). The sulphate ($CaOSO_3$ or $CaSO_4$) occurs *anhydrous* in the mineral anhydrite, also with two molecules of water of halhydration (see p. 316) as selenite or gypsum. When gypsum is heated to about 500° C. it loses all its water, and is converted into 'plaster of Paris.' The setting of plaster of Paris, when mixed with water, depends on the sulphate of lime taking up the water to form again the halhydrated salt ($CaO,SO_3,2H_2O$). Sulphate of lime is very sparingly soluble in water. Water containing lime salts in solution is 'hard;' that is, it requires a greater quantity of soap to form a lather than soft water does (see CHEMISTRY APPLIED TO THE ARTS). The chief lime salts occurring in hard water are the carbonate and the sulphate. The former can be almost entirely removed by boiling, hence the hardness caused by its presence is called removable hardness; that caused by the sulphate is called permanent hardness. The crust which forms in kettles and boilers in which hard water is boiled, consists usually of both carbonate and sulphate of lime.

The compounds of barium and strontium resemble generally those of calcium. Baryta and strontia are more soluble than lime; their sulphates are nearly insoluble in water. The metals barium, strontium, and calcium can be obtained by the electrolysis of their fused chlorides.

3. *Metals of the Iron group.*—Iron forms two basic oxides—namely, protoxide of iron or ferrous oxide (FeO), and sesquioxide, or peroxide, or ferric oxide (Fe_2O_3); each of these forms salts with acids, and these two series of salts are quite different in character from each other. Some metals of the group, like iron, form two basic

oxides (manganese, MnO and Mn_2O_3; chromium, CrO and Cr_2O_3; and Uranium, UO and U_2O_3); some have only the oxide corresponding to ferrous oxide (magnesium, MgO; zinc, ZnO; cadmium, CdO); while aluminium has only the oxide corresponding to ferric oxide, Al_2O_3. Nickel and cobalt form both oxides, NiO and Ni_2O_3,CoO and Co_2O_3; but the peroxide of cobalt has scarcely any basic character, and the peroxide of nickel has none.

Magnesium occurs in nature in the carbonate of magnesia (MgO,CO_2), the mineral magnesite, and associated with carbonate of lime in magnesian limestone, or dolomite; in the sulphate of magnesia (Epsom salts, $MgO,SO_3,7H_2O$), which is found in many mineral waters. Chloride and bromide of magnesium occur in small quantities in sea-water. Steatite and meerschaum are silicates of magnesia. The soluble salts of magnesia have a peculiar bitter taste. The metal magnesium can be obtained by the electrolysis of fused chloride of magnesium, or by the action of sodium on chloride of magnesium ($MgCl_2 + 2Na = 2NaCl + Mg$). It is a bright white metal, of specific gravity 1·75; when heated to redness in air or oxygen, it takes fire, burning with an intensely bright white light, and producing magnesia.

Zinc occurs in nature as zincblende (sulphide of zinc, ZnS), carbonate of zinc (ZnO,CO_2), and silicate of zinc. The method of obtaining it from its ores is described in the article METALS AND METALLURGY. Its oxide (ZnO) is formed when the metal is strongly heated in air or oxygen. Sulphate of zinc (white vitriol) is formed when the oxide is dissolved in sulphuric acid, or when sulphuric acid (hydric sulphate) or cupric sulphate acts on metallic zinc: $Zn + H_2SO_4 = H_2 + ZnSO_4$ or $Zn + CuSO_4 = Cu + ZnSO_4$. It crystallises (like Epsom salts) with seven molecules of water, of which one is water of halhydration, and can be driven off only at a high temperature. Chloride of zinc, $ZnCl_2$, formed by dissolving oxide of zinc or metallic zinc in hydrochloric acid ($ZnO + 2HCl = H_2O + ZnCl_2$ or $Zn + 2HCl = H_2 + ZnCl_2$), is a very soluble salt; it is used in surgery as a caustic, and a strong solution of it is sold under the name 'Burnett's Disinfecting Solution.'

Cadmium usually occurs in nature along with zinc, which it greatly resembles. The sulphide of cadmium (CdS) is yellow, and is used as a pigment.

Iron occurs in nature free as native iron, probably always in the form of meteoric masses which have fallen upon the earth. We know nothing of the origin of these meteoric stones; they appear to have been bodies moving through space, which, coming into the earth's atmosphere, have been attracted to the earth, and so have fallen upon its surface. Iron occurs in combination with oxygen as ferric oxide (red hæmatite, specular iron ore, Fe_2O_3); as hydrated ferric oxide (limonite, goethite, brown hæmatite); as magnetic iron ore, or ferroso-ferric oxide (FeO,F_2O_3). Ferrous carbonate (FeO,CO_2) occurs pure in spathic iron ore, mixed with clay in the clay iron ore, and mixed with coal in the black-band iron-stone; ferrous silicate occurs in many minerals. The most abundant compound of iron and sulphur is iron pyrites (FeS_2). The most important compounds of iron (not treated of in the paper on METALS AND METALLURGY) are: 1. The Ferrous Compounds: Ferrous Sulphide (FeS), formed by the direct union of iron and sulphur heated together, a black, fusible substance, used as a source of sulphuretted hydrogen, which is easily obtained from it by treating it with dilute acids, thus: $FeS + H_2SO_4 = H_2S + FeSO_4$. Ferrous Carbonate; see above. Ferrous Sulphate (green vitriol), formed by the action of dilute sulphuric acid on iron or on ferrous sulphide ($Fe + H_2SO_4 + H_2 + FeSO_4$ or $FeS + H_2SO_4 = H_2S + FeSO_4$), also by the oxidation of iron pyrites in the presence of water ($FeS_2 + H_2O + 7O = FeSO_4 + H_2SO_4$), also by the action of cupric sulphate on metallic iron ($Fe + CuSO_4 = Cu + FeSO_4$); green vitriol crystallises (like Epsom salts and white vitriol) with seven molecules of water, six of which are water of crystallisation, and one water of halhydration. 2. Ferric Compounds: Ferric Oxide (Fe_2O_3) occurs in nature as red hæmatite. Ferric Chloride ($FeCl_3$) is formed by dissolving ferric oxide in hydrochloric acid ($Fe_2O_3 + 6HCl = 3H_2O + 2FeCl_3$), or by oxidising ferrous chloride in the presence of hydrochloric acid ($2FeCl_2 + 2HCl + O = 2FeCl_3 + H_2O$). Ferric chloride is the substance often called muriate of iron, and is used in medicine—a solution of it in weak alcohol is sold as 'steel drops.' The 'rust' of iron is a ferric compound, being a hydrate of ferric oxide, and having nearly the same composition as the mineral *limonite*. Ferric oxide is a comparatively weak base, and (see p. 308) acts also as a weak (anhydrous) acid. So we have compounds of ferric oxide with stronger bases—as with magnesia in magnesic ferrite (MgO,Fe_2O_3); with ferrous oxide in magnetic iron ore (FeO,Fe_2O_3); with oxide of zinc in franklinite, &c. 3. We have a series of salts (of which only a few are known), the Ferrates, as ferrate of potash (K_2O,FeO_3), in which iron appears to play the part of sulphur—K_2O,FeO_3 corresponding to sulphate of potash, K_2O,SO_3.

Manganese.—The most important compounds of manganese are: 1. Peroxide of Manganese MnO_2), which has been already mentioned (p. 324) as used in making chlorine. 2. The Manganous Salts, corresponding to the ferrous salts, as MnO,SO_3; $MnCl_2$; &c. 3. Manganic Salts, which easily lose oxygen, and are transformed into manganous salts (as $Mn_2O_3,3SO_3 + H_2O = 2(MnO,SO_3) + H_2O,SO_3 + O$).

Chromium occurs in nature chiefly as chrome iron ore (FeO,Cr_2O_3), a compound in which chromic oxide (Cr_2O_3) acts as an acid. Its most important compounds are the *chromates*, corresponding to the ferrates or sulphates, as chromate of potash (K_2O,CrO_3), bichromate of potash ($K_2O,2CrO_3$). Chrome yellow is chromate of lead (PbO,CrO_3). Chromic acid, a red crystalline substance (CrO_3), is a powerful oxidising agent, easily giving up half of its oxygen to form chromic oxide (Cr_2O_3).

Nickel and *Cobalt* have already been referred to as forming compounds perfectly analogous to the ferrous salts. Silicate of cobalt is remarkable for its intense blue colour; in the state of fine powder it forms the pigment 'smalt.'

Aluminium.—The most important compounds of this metal are its oxide alumina (Al_2O_3) and the salts of this oxide. Alumina occurs in nature pure as 'corundum;' coloured by small quantities of other oxides, as sapphire, topaz, ruby, and

amethyst. Emery is corundum mixed with ferric oxide. Combined with water, it forms the minerals diaspore and gibbsite. Clay is a silicate of alumina, and is formed in nature by the decomposition of felspar. There are three chief species of felspar—potash felspar, soda felspar, and lime felspar—silicates respectively of alumina and potash, alumina and soda, and alumina and lime. Sulphate of alumina (concentrated alum) is formed by the action of sulphuric acid on clay. Common alum is a double sulphate of alumina and potash ($K_2O,SO_3,Al_2O_3,3SO_3,24H_2O$).

Uranium occurs in the mineral pitchblende, which is essentially an oxide corresponding to magnetic oxide of iron (UO,U_2O_3). This oxide is used for producing an intense and permanent black colour on porcelain. Uranic oxide (U_2O_3) forms a silicate of a yellowish green colour, and is used to give this colour to glass.

4. *Copper Group.*—Copper forms two basic oxides—cuprous oxide, red oxide of copper (Cu_2O), and cupric oxide, black oxide of copper (CuO). There are two corresponding oxides of mercury (Hg_2O and HgO), but silver forms only one *basic* oxide (Ag_2O), peroxide of silver (AgO) not being a base. The only *basic* oxide of lead is that corresponding to cupric oxide—namely, plumbic oxide (PbO).* Copper occurs free, as 'native copper,' in large quantities in North America, particularly in the neighbourhood of Lake Superior; in combination with oxygen, as cuprous oxide (red copper ore), in Siberia, in Cornwall, and in Australia; as cupric oxide (CuO), near Lake Superior; as carbonate (malachite, lazurite); combined with sulphur as 'gray sulphide of copper' (Cu_2S) in Cornwall; along with sulphide of iron as copper pyrites ($CuFeS_2$), the most abundant of all the copper ores, in Cornwall, Devonshire, Sweden, and many parts of the United States; along with sulphide of antimony and sulphide of arsenic as sulphantimonite and sulpharsenite of copper, in the so-called 'fahl ore.'

The most important salts of copper are the cupric salts: Cupric sulphate (CuO, SO_3 or $CuSO_4$), formed by the oxidation of sulphide of copper, or by the action of strong sulphuric acid at a high temperature on metallic copper ($Cu + 2H_2SO_4 = CuSO_4 + 2H_2O + SO_2$). It crystallises as blue vitriol or blue stone with five molecules of water, one of which is water of halhydration (p. 316). Cupric nitrate (CuO,N_2O_5 or $Cu(NO_3)_2$), formed by the action of nitric acid on metallic copper (p. 321), or on cupric oxide ($3Cu+4(H_2O,N_2O_5)= 3(CuO,N_2O_5)+2NO+4H_2O$; $CuO+H_2O,N_2O_5= H_2O + CuO,N_2O_5$), is a blue salt, which, when heated, gives cupric oxide, peroxide of nitrogen, and oxygen ($CuO,N_2O_5 = CuO + 2NO_2 + O$).

Mercury occurs in nature free as native mercury, but much more frequently as cinnabar, the mercuric sulphide (HgS). The most important compounds of mercury are: Mercuric sulphate (HgO,SO_3), formed by the action of strong sulphuric acid at a high temperature on metallic mercury ($Hg + 2H_2SO_4 = HgSO_4+2H_2O+SO_2$); mercuric chloride (corrosive sublimate, $HgCl_2$), formed by heating common salt with mercuric sulphate ($HgO,SO_3+2NaCl=Na_2O,SO_3+HgCl_2$); the corrosive sublimate being volatile, rises in vapour, and is condensed in the cold parts of the apparatus. It is soluble in water, and very poisonous. The mercurous salts are formed by adding metallic mercury to the mercuric salts; thus, calomel (mercurous chloride, $HgCl$) may be formed by heating 271 parts of corrosive sublimate with 200 of mercury ($HgCl_2+Hg=2HgCl$), or by heating mercuric sulphate with metallic mercury and common salt ($HgSO_4+Hg+2NaCl= Na_2SO_4 + 2HgCl$); the calomel is volatile, and sublimes, collecting on the cold parts of the apparatus. It is insoluble in water, and can, therefore, be freed from any corrosive sublimate which may be mixed with it by washing with water. Vermilion is mercuric sulphide.

Lead occurs chiefly as galena (plumbic sulphide, PbS). It forms three oxides: 1. Plumbic oxide (litharge, massicot, PbO). This is produced when lead is strongly heated in air or oxygen. When fused, it forms brown scales (litharge); when prepared at a lower temperature, so that it is not fused, it is a yellow powder (massicot). It is the only basic oxide of lead. 2. Red lead. This oxide is formed when litharge is exposed at a temperature considerably below its fusing-point to the action of air or oxygen; its composition is somewhat variable, but corresponds pretty closely to the formula Pb_3O_4. It may be regarded as a compound of plumbic oxide and the third oxide of lead, peroxide of lead. When treated with nitric acid, it forms plumbic nitrate and peroxide of lead ($2PbO,PbO_2 + 2(H_2O,N_2O_5) = 2(PbO,N_2O_5) + 2H_2O + PbO_2$). White-lead is a compound of carbonate of lead and hydrated oxide of lead. It is formed by exposing metallic lead to air, carbonic acid, water-vapour, and the vapour of vinegar. Sulphate of lead (PbO,SO_3) is insoluble in water; for this reason, persons working in lead are recommended to add a small quantity of sulphuric acid to the water they drink, as the insoluble sulphate is not poisonous. Sulphide of lead is black, and all pigments containing lead are blackened by sulphuretted hydrogen, on account of the formation of the sulphide. Chrome yellow is chromate of lead (PbO,CrO_3).

Silver occurs in nature free as native silver, as chloride in 'horn silver,' as sulphide (Ag_2S) both alone and mixed with other sulphides, most specimens of galena (sulphide of lead) containing some silver, also in fahl ore as sulphantimonite of silver. The most important compounds of silver are: Nitrate of silver (Ag_2O,N_2O_5), formed by the action of nitric acid on silver ($6Ag + 4H_2O,N_2O_5 = 3(Ag_2O,N_2O_5) + 2NO + 4H_2O$). It is soluble in water, and is used in photography, and as a mild caustic (lunar caustic) in surgery. Chloride of silver ($AgCl$) is insoluble in water and acids, soluble in ammonia. British 'standard silver,' of which our silver coins are made, is an alloy of silver and copper, containing in 100 parts, 92·5 of silver and 7·5 of copper. It is harder than pure silver.

5. Of the Platinum group, we need only mention gold and platinum. These metals occur chiefly free, as native gold and native platinum. They are not dissolved by either nitric or hydrochloric acid, but are converted into chlorides ($AuCl_3$ and $PtCl_4$) by the action of chlorine, or of a mixture of nitric and hydrochloric acids (aqua regia). These chlorides unite with the chlorides of the metals of the alkalies, forming double salts, as,

* It is with some hesitation that we place lead in this group; the characters of the lead salts would incline us to group it with calcium, strontium, and barium.

aurochloride of potassium ($KCl,AuCl_3$), aurochloride of sodium ($NaCl,AuCl_3$), platinochloride of potassium ($2KCl,PtCl_4$), platinochloride of sodium ($2NaCl,PtCl_4$). Platinochloride of potassium is sparingly soluble in water, insoluble in a mixture of alcohol and ether; very similar to it is the platinochloride of ammonium ($2NH_4Cl,PtCl_4$). When the latter salt is heated, chloride of ammonium, hydrochloric acid, and nitrogen are given off, and metallic platinum is left as a spongy, porous mass (spongy platinum). British standard gold is an alloy of gold and copper, containing in 12 parts, 11 of gold and 1 of copper.

6. The metals of the Antimony group resemble, in many respects, the non-metallic elements; arsenic, antimony, and bismuth being analogues of phosphorus; while tin has many points of resemblance to silicon. Vanadium, molybdenum, and tungsten are comparatively rare metals.

Arsenic occurs in nature combined with sulphur in realgar (AsS) and orpiment (As_2S_3); with metals, particularly iron, in mispickel and arsenical pyrites (almost all specimens of iron pyrites contain some arsenic, which thus occurs in sulphuric acid prepared from pyrites (see CHEMISTRY APPLIED TO THE ARTS. When arsenical ores are heated in a current of air, the arsenic is converted into 'white arsenic,' or arsenious acid (As_2O_3). Arsenious acid, when heated with nitric acid, is oxidised to form arsenic acid ($3H_2O,As_2O_5$), an acid very closely resembling phosphoric acid ($3H_2O,P_2O_5$). Arsenious and arsenic acids form arsenites and arseniates with bases. Arsenite of copper is the green pigment known as 'Scheele's green.' 'Schweinfurt green' is a compound of arsenite of copper and acetate of copper. All these compounds of arsenic are highly poisonous.

Antimony occurs in nature chiefly as sulphide of antimony (Sb_2S_3). Its most important compounds are: Antimonious oxide (Sb_2O_3), a weak base, forming salts with some acids. Tartar emetic is the double tartrate (see p. 335) of potash and antimony ($K_2O,Sb_2O_3,\bar{T}$, where $\bar{T}$ stands for anhydrous tartaric acid). Chloride of antimony ($SbCl_3$) is formed by the action of strong hydrochloric acid on sulphide of antimony; when poured into water, it forms a white precipitate, 'powder of algaroth,' or oxychloride of antimony ($3SbCl_3 + 3H_2O = 6HCl + Sb_2O_3,SbCl_3$ or $SbCl_3 + H_2O = 2HCl + SbOCl$).

Tin occurs in nature as 'tinstone' or stannic oxide (SnO_2), corresponding to silica (SiO_2). The most important compounds of tin are: Stannous chloride, 'salt of tin,' or 'pink salt' ($SnCl_2$), formed by the action of hydrochloric acid on tin ($Sn + 2HCl = H_2 + SnCl_2$). It is soluble in water, and is used as a mordant in dyeing (see CHEMISTRY APPLIED TO THE ARTS). Stannic chloride ($SnCl_4$), formed by the addition of chlorine to stannous chloride. It is a colourless, volatile liquid. Stannic oxide acts as an anhydrous acid, and forms salts called stannates.

Compounds of the metals with one another are called *alloys*. They resemble metals in their physical characters. We shall mention a few of the most important.

Brass, 64 parts copper and 36 parts zinc; German silver, 51 parts copper, 30·5 parts zinc, and 18·5 parts nickel; bell-metal, 78 parts copper and 22 parts tin; bronze, 80 parts copper, 4 parts zinc, and 16 parts tin; coinage bronze, 95 parts copper, 1 part zinc, and 4 parts tin; aluminium bronze, 90 parts copper and 10 parts aluminium; solder, from 2 parts tin and 1 part lead, to 1 part tin and 2 parts lead; pewter, 4 parts tin and 1 part lead; Britannia metal, pewter with a little copper and antimony; type-metal, 2 parts lead, 1 part tin, and 1 part antimony; standard (or 22 carat) gold contains in 24 parts, 22 of gold and 2 of copper. Alloys containing less gold are used in jewellery—such as 18-carat gold, containing 18 parts gold in 24; 16-carat gold, containing $\frac{16}{24}$ of pure gold; &c.

Standard silver, as already stated, contains 7·5 per cent. of copper.

The alloys of mercury are called amalgams. Tin amalgam is used for silvering looking-glasses. For details respecting the metals, the reader is referred to the article on METALS AND METALLURGY.

ORGANIC CHEMISTRY.

The term 'Organic Chemistry' was first employed to express that department of chemistry which treats of the substances peculiar to animals and vegetables, and the direct derivatives of these substances. As almost all these substances contain carbon, and as almost all compounds of carbon are practically obtained from animal or vegetable products, it is now found more convenient to group all carbon compounds together, and to define organic chemistry as the chemistry of the compounds of carbon. These compounds are so numerous, and many of them so complex, that it is impossible in a sketch like this to do more than shortly describe the relations of a few of them, selected on account of their practical importance.

Some of the simpler carbon compounds—carbonic acid, carbonic oxide, marsh gas, and olefiant gas—have already been described (p. 323), and are therefore omitted here. We shall begin with a large and very important group of compounds known as the 'carbohydrates.' This name implies, not that they contain carbon and water, but that they contain carbon, hydrogen, and oxygen, and that the hydrogen and oxygen are present in them in the same proportion as in water. The most important members of the group are: 1. The sugars; 2. Starch, gum, and inulin; and 3. Cellulose.

1. Sugars are substances, soluble in water, having a sweet taste, and capable of undergoing the peculiar chemical change called the vinous fermentation, which will be described farther on (p. 332). They may be divided into two sets: 1. Those analogous to grape-sugar; and 2. Those analogous to cane-sugar. Honey and the juice of sweet fruits contain principally grape-sugar. These can also be prepared from cane-sugar and its analogues, and from starch, inulin, or cellulose. The formula of grape-sugar is $C_6H_{12}O_6$. Cane-sugar and milk-sugar are the most important sugars of the second set. Cane-sugar is obtained from the juice of the sugar-cane, from the juice of the beetroot, from the sugar-maple, and from the sugar-palms. It occurs mixed with sugars of the first set in most sweet fruits. Milk-sugar is contained in the milk of all mammals, and is obtained by evaporating the whey, and allowing the sugar

to crystallise out. The formula of cane-sugar and milk-sugar is $C_{12}H_{22}O_{11}$. When cane-sugar is boiled with dilute acids, or mixed with water and 'diastase' (a peculiar substance contained in malt), it takes up water, and is converted into *dextrose* and *levulose*, two sugars of the first, or grape-sugar, set: $C_{12}H_{22}O_{11}+H_2O=C_6H_{12}O_6+C_6H_{12}O_6$. Milk-sugar undergoes a similar change.

The two sets of sugar are chiefly distinguished from one another by the readiness with which they undergo chemical change, the second set being the more stable. Thus, in fermentation, cane and milk sugars are first changed into sugars of the grape-sugar set, and then these ferment. Cane-sugar can be obtained in crystals, as in loaf-sugar and sugar-candy; when heated, it fuses, and on cooling, forms a clear, glassy, non-crystalline mass, 'barley-sugar,' which, if long kept, goes back into the crystalline form. More strongly heated, it loses water, and is converted into a dark-brown substance, called caramel, which is largely used for colouring rum and brandy.

2. Starch occurs in many parts of plants, as in the seeds of cereal grains, in the tubers of the potato, in the stems of the sago-palm, &c. When starch is examined under the microscope, it is seen to consist of small rounded granules; these granules vary considerably in size and shape in different plants, so that it is possible, by means of the microscope, to discover the source from which a specimen of starch was derived. Starch is insoluble in cold water; when treated with hot water, the granules swell up, and form a paste, which, when diluted, has all the appearance of a solution. Starch-paste is coloured blue by iodine, and may thus be used as a test for free iodine; similarly, iodine is used as a test for starch. When starch is heated alone, or with a small quantity of acid, it is converted into *dextrine*, a soluble gummy substance, much used in the arts under the name of British gum. Prolonged boiling with dilute acids, and also contact with some animal liquids, convert starch into *dextrose*, a sugar of the grape-sugar set. The same change takes place in the starch contained in seeds during the process of germination. Thus, malt, which is grain in which the process of germination has been arrested, contains, not starch, but dextrine and dextrose derived from starch. Malt also contains a remarkable substance called 'diastase,' which converts starch into dextrine and dextrose.

Inulin resembles starch very much; it occurs in the Jerusalem artichoke, the roots of the dahlia, chicory, &c. It dissolves in hot water, and does not form a jelly like starch. By boiling with dilute acids it is converted into *levulose*, a sugar of the grape-sugar set. Starch, inulin, and dextrine have all the same composition ($C_6H_{10}O_5$).

Gum-arabic is a compound of a base or bases, generally lime, magnesia, and potash, with Arabic acid ($C_6H_{10}O_5$). Gum-senegal, cherry-tree gum, gum-tragacanth, all of which are exudations from trees, have a similar composition.

3. The last carbohydrate of which we shall treat is cellulose. This substance has the same composition as starch, inulin, dextrine, and Arabic acid—namely, $C_6H_{10}O_5$. It occurs in all plants, nearly pure in cotton, wool, and young fibrous cells, such as flax, hemp, &c.; and more or less mixed with resinous and other matters in wood. It is quite insoluble in water. When treated with strong sulphuric acid, it is converted into a jelly, which dries up to a horny mass. If unsized paper, which is almost pure cellulose, is dipped for a few minutes in sulphuric acid diluted with about half its volume of water, then washed and dried, a substance called 'vegetable parchment' is formed, which consists of the fibres of the paper matted together by means of the above-mentioned horny substance. If the jelly is boiled with dilute acid, it is slowly converted into a sugar of the grape-sugar set. Strong nitric acid converts cellulose into gun-cotton. There are several kinds of gun-cotton, the most explosive having the composition $C_6H_7(NO_2)_3O_5$.

FERMENTATION.

If a solution of sugar containing nitrogenous matter is exposed to the air at temperatures between 75° and 95° F. what is called fermentation takes place. There are several kinds of fermentation to which sugar is liable: we shall here consider only two—namely, the vinous or alcoholic, and the lactic. Each kind of fermentation is produced by the growth in the liquid of a special kind of mould or small fungus, which is called a 'ferment;' and fermentation can be prevented by anything which prevents the growth of the fungus: for instance, by keeping away from the liquid the spores or germs from which the fungus springs; by the liquid being either too hot or too cold; by its containing too much sugar; or by the presence of substances which act as poisons to the ferment, and are hence called 'antiseptics.' The fungus or ferment which produces the alcoholic fermentation is called 'yeast;' that which produces the lactic fermentation is probably the mould called *Penicillium glaucum*, the common 'blue mould.' The vinous fermentation proceeds most favourably between 75° and 85° F.; the lactic, between 85° and 95°. In the vinous fermentation, the sugar is changed into alcohol and carbonic acid gas, the latter escaping in bubbles from the surface, and giving rise to an appearance of frothing, whence the name 'fermentation.' Some other substances, 'secondary products of fermentation,' are produced at the same time in small quantity. The chief chemical change may be represented by the equation,

$$\underset{\text{Glucose.}}{C_6H_{12}O_6} = \underset{\text{Alcohol.}}{2C_2H_6O} + \underset{\text{Carbonic Acid.}}{2CO_2}.$$

In the lactic fermentation, the sugar is changed into lactic acid—thus:

$$\underset{\text{Glucose.}}{C_6H_{12}O_6} = \underset{\text{Lactic Acid.}}{2C_3H_6O_3}.$$

The alcoholic fermentation occurs in the making of bread. See CHEMISTRY APPLIED TO THE ARTS. Alcohol is obtained from fermented liquors by distillation (see p. 306). Pure alcohol is a colourless liquid, of specific gravity 0·794, boiling at 173° F. Its composition is indicated by the formula C_2H_6O. It is inflammable, burning with a feebly luminous flame, and producing carbonic acid and water. It is capable of dissolving many substances, and is used as a solvent for resins: an alcoholic solution of shellac is the common 'spirit varnish.'

Alcohol acts upon acids in a manner very similar to that of bases. Thus, with hydrochloric acid,

alcohol yields water and a volatile substance called hydrochloric ether, or chloride of ethyl; just as caustic soda, with hydrochloric acid, yields water and chloride of sodium, $C_2H_6O + HCl = H_2O + C_2H_5Cl$, corresponding to $NaHO + HCl = H_2O + NaCl$; and as caustic soda is regarded as the oxide of hydrogen and sodium, and represented by the graphic formula, Na—O—H, so we may call alcohol the oxide of hydrogen and ethyl, C_2H_5—O—H. The substances produced by the action of acids upon alcohol (which may be looked upon as the *salts* of ethyl) are called 'compound ethers' or 'esters,' and are named after the acid employed in producing them: thus, nitrous acid acts on alcohol to produce nitrous ether; acetic acid, to produce acetic ether; and so on. The analogy between the compounds of ethyl and those of such a metal as sodium can be carried farther; and just as we have anhydrous oxide of sodium, Na_2O or Na—O—Na, so we have anhydrous oxide of ethyl, $(C_2H_5)_2O$ or C_2H_5—O—C_2H_5. This substance is common ether, often, but improperly, called sulphuric ether, because sulphuric acid is used in making it. When alcohol is mixed with sulphuric acid, the first change which takes place is the formation of water and 'sulphovinic acid,' which is the acid sulphate of ethyl, $C_2H_5OH + H_2SO_4 = HOH + C_2H_5HSO_4$. This sulphovinic acid is obviously the analogue of bisulphate of soda, $NaHSO_4$. When sulphovinic acid is heated along with alcohol, ether and sulphuric acid are formed—thus, $C_2H_5OH + C_2H_5HSO_4 = C_2H_5{-}O{-}C_2H_5 + H_2SO_4$. In the ordinary process for making ether, these two actions go on together, so that the sulphovinic acid is decomposed as fast as it is formed, and ether and water distil over together, leaving sulphuric acid behind. A comparatively small quantity of sulphuric acid is thus able to convert a large quantity of alcohol into ether and water.

Common ether is a colourless liquid, of specific gravity 0·723, boiling at 96° F. It is therefore a very volatile substance; and as it evaporates rapidly below its boiling-point, it can be used to produce intense cold. It is also used as a solvent for fats and oils, and as an anæsthetic in surgery.

Acetous Fermentation, Acetic Acid.—If fermented liquors—that is, solutions containing alcohol and nitrogenous substances—are exposed to the air, they gradually become sour, and what is called 'vinegar' is produced. This change is known as the 'acetous fermentation,' and, like other fermentations, depends on the growth of a fungus, *Mycoderma aceti*, the vinegar-plant, or 'mother of vinegar.' The acetous fermentation not only requires the presence and growth of a ferment, but also the presence of air or oxygen, and in this differs essentially from the other two kinds of fermentation which we have been considering. It is, in fact, a process of oxidation taking place under the influence of the ferment. In the 'quick process' for making vinegar, weak alcohol is made to trickle through casks containing wood-shavings, and pierced with holes for the admission of air. The shavings become coated with *mycoderma*, and the oxidation of the alcohol proceeds very rapidly. Alcohol can also be oxidised by various oxidising agents, and we can thus trace the process more minutely than is possible in the case of the acetous fermentation. When alcohol is heated with a mixture of sulphuric acid and solution of bichromate of potash (or what comes to the same thing, sulphuric acid and chromic acid), the alcohol loses hydrogen, and the chromic acid loses oxygen; these combine to form water, and the chromic acid is reduced to chromic oxide, which, with the sulphuric acid, forms chromic sulphate. The alcohol, by the loss of hydrogen, is converted into a very volatile liquid, called aldehyd (*al*cohol *dehyd*rogenatum—that is, alcohol from which hydrogen has been removed), having the composition indicated by the formula C_2H_4O—that is, $C_2H_6O - H_2$. Aldehyd is very easily oxidised, readily taking up another atom of oxygen, and forming acetic acid, $C_2H_4O_2$. Besides the oxidation of alcohol, there are various ways in which acetic acid can be produced; of these, the most practically important is the distillation of wood. As has been already stated (p. 332), wood consists principally of cellulose. When it is heated to redness in a retort, closed so as to exclude air, and provided with a tube, by which the gaseous and volatile products can be led to a cooling and condensing apparatus, a great many different substances are formed. They may be grouped thus: 1. The charcoal which remains in the retort; 2. Uncondensable gases which pass through the condenser; and 3. Volatile substances, which flow as liquids from the condenser. Of these we may again distinguish the *tar*, which contains the substances insoluble, or sparingly soluble in water, and a watery liquid floating upon the tar, and consisting chiefly of water, acetic acid, and a light inflammable liquid called pyroxylic spirit. These may be separated from one another by converting the acetic acid into an acetate by the addition of a base (soda, lime, or oxide of lead) distilling off the pyroxylic spirit; and, if the acetic acid is required as such, decomposing the acetate by means of sulphuric acid, and distilling. Pure acetic acid is a colourless liquid, with a pure sour taste and pungent odour; at 32° F. it freezes, and forms a colourless crystalline mass, which does not fuse till the temperature is raised to about 60° F. The specific gravity of the liquid is 1·063. It boils at 246° F. Its composition is represented by the formula $C_2H_4O_2$. The strongest vinegar of commerce contains about 5 per cent. of pure acetic acid. The most important acetates are: Acetate of soda, acetate of lead (sugar of lead), basic acetate of lead (Goulard's solution), acetate of copper, basic acetate of copper (verdigris), acetate of alumina, and ferric acetate; the last two are used as mordants in dyeing and calico-printing.

ALCOHOLS AND THEIR DERIVATIVES.

Many substances have a chemical character similar to that of common alcohol—that is to say, they form compound ethers when treated with acids, lose two atoms of hydrogen to form bodies analogous to aldehyd, which, again, easily take up oxygen, and are converted into acids corresponding to acetic acid. Thus, there is a substance contained in pyroxylic spirit called 'methylic alcohol,' which has the formula CH_4O (or CH_3—O—H). With hydrochloric acid, it forms water and CH_3Cl, chloride of methyl; when oxidised, it is converted into CH_2O, its aldehyd; and this, again, into CH_2O_2, formic acid. Formic acid is interesting as the acid contained in the bodies of red ants, and in the stinging fluid of the common

nettle. To take another example, common fousel oil (see p. 306) consists mainly of an oily liquid, to which the name 'amylic alcohol' has been given. This substance has the composition $C_5H_{12}O$ (or $C_5H_{11}—O—H$); it yields water and a compound ether when treated with an acid, for instance:

$$\underset{\text{Amylic Alcohol.}}{C_5H_{11}—O—H} + \underset{\text{Hydrochloric Acid.}}{HCl} = \underset{\text{Water.}}{H—O—H} + \underset{\text{Chloride of Amyl.}}{C_5H_{11}Cl.}$$

When oxidised by means of a mixture of sulphuric acid and bichromate of potash, it is converted by the loss of two atoms of hydrogen into $C_5H_{10}O$, which is easily oxidised to valerianic acid, $C_5H_{10}O_2$, an acid also obtained from the plant 'valerian,' whence its name.

Polyatomic Alcohols and their Derivatives.—Chloride of methyl, which is the hydrochloric ether of methylic alcohol, can also be obtained by the action of chlorine upon marsh gas ($CH_4 + Cl_2 = CH_3Cl + HCl$); and similarly, the chloride of ethyl, the chloride of amyl, &c. can be obtained by the action of chlorine upon the corresponding hydrocarbons, C_2H_6; C_5H_{12}; &c. We have thus a relation between the class of alcohols which we have just been considering, and compounds of carbon, hydrogen, and *one* atom of chlorine. Now there are other classes of alcohols which stand in a similar relation to certain compounds of carbon and hydrogen with *two or more* atoms of chlorine. It will be sufficient for our present purpose to give a few examples of such alcohols. Olefiant gas (see p. 324) unites with its own volume of chlorine gas to form a colourless volatile liquid, sparingly soluble in water, called chloride of ethylene, or 'oil of Dutch chemists,' because it was discovered by four Dutch chemists. This substance has the formula $C_2H_4Cl_2$, and is formed by the union of C_2H_4 and Cl_2. It has many points of analogy with such a metallic chloride as chloride of lead, $PbCl_2$, just as chloride of ethyl resembles in many respects chloride of sodium, NaCl. Thus, if chloride of lead is treated with acetate of silver, we get chloride of silver and acetate of lead; and similarly, chloride of ethylene with acetate of silver gives us chloride of silver and acetate of ethylene; and by acting on acetate of ethylene with caustic potash, we obtain acetate of potash and hydrated oxide of ethylene; just as acetate of lead and caustic potash yield acetate of potash and hydrated oxide of lead. Hydrated oxide of lead is $H—O—Pb—O—H$, and hydrated oxide of ethylene is $H—O—C_2H_4—O—H$. Here ethylene (C_2H_4) is a dyad radical, and its hydrated oxide (which, from its sweet taste, has been called glycol) is a diatomic alcohol. Glycol forms compound ethers with acids, and just as in the case of lead we have normal and basic salts, so from glycol we can obtain normal and basic ethers; $C_2H_4Cl_2$ or $Cl—C_2H_4—Cl$, and $H—O—C_2H_4—Cl$ may be given as examples. When oxidised, glycol yields, among other products, its aldehyd, 'glyoxal' ($C_2H_2O_2 = C_2H_6O_2 — 2H_2$), which is easily oxidised to form oxalic acid, $C_2H_2O_4$. Oxalic acid is a white crystalline solid, readily soluble in water. As crystallised from its aqueous solution, it contains two molecules of water of crystallisation. It has an intensely sour taste, and is very poisonous. It is produced in the oxidation of very many organic substances; thus, when sugar is boiled with nitric acid, much oxalic acid is formed. It is now usually prepared by heating sawdust (impure cellulose) with caustic potash—hydrogen is given off, and oxalate of potash ($C_2K_2O_4$) formed; from this, oxalic acid can be obtained. Oxalic acid is a dibasic acid (see p. 317). Its most important salts are: Acid oxalate (binoxalate) of potash, or 'salt of sorrel,' C_2HKO_4, which occurs in the juice of various kinds of sorrel; oxalate of lime (C_2CaO_4).

Glycerine, a substance of great importance, the preparation of which will be described presently, is an example of a triatomic alcohol. Its formula is

$$C_3H_8O_3 \text{ or } C_3H_5\begin{cases}—O—H\\—O—H\\—O—H\end{cases}$$

Here the radical C_3H_5 is triad, like bismuth in $Bi(OH)_3$. Accordingly, glycerine forms with acids compound ethers, of which there are three series, which we may represent by the examples $C_3H_5Cl_3$, $C_3H_5Cl_2(OH)$, and $C_3H_5Cl(OH)_2$. Erythromannite, a sweet substance obtained from certain lichens, is an example of a tetratomic alcohol ($C_4H_{10}O_4$ or $C_4H_6(OH)_4$); and mannite, a sweet crystalline substance found along with sugar in the manna, or sweet exudation from the ash-tree, is an example of a hexatomic alcohol. The formula of mannite is $C_6H_{14}O_6$ (or $C_6H_8(OH)_6$), and differs from that of grape-sugar by containing two atoms of hydrogen more; and grape-sugar (especially levulose, p. 332) can be converted into mannite by treating it with nascent hydrogen.

FATS AND OILS.

Soap.—If pure acetic acid and glycerine be mixed together and heated, the product will be found to be different according to the temperature and the proportion in which the two substances are mixed. If the temperature does not rise above 212° F. the reaction takes place in accordance with the equation:

$$\underset{\text{Glycerine.}}{C_3H_5\begin{cases}OH\\OH\\OH\end{cases}} + \underset{\text{Acetic Acid.}}{H—C_2H_3O_2} = \underset{\text{Water.}}{H—O—H} + \underset{\text{Monoacetine.}}{C_3H_5\begin{cases}C_2H_3O_2.\\OH.\\OH.\end{cases}}$$

If sufficient acetic acid is present, and the temperature is raised to 480° F. a more complete action of exactly the same kind takes place, thus:

$$\underset{\text{Glycerine.}}{C_3H_5\begin{cases}OH\\OH\\OH\end{cases}} + \underset{\text{Acetic Acid.}}{\begin{matrix}H—C_2H_3O_2\\H—C_2H_3O_2\\H—C_2H_3O_2\end{matrix}} = \underset{\text{Water.}}{\begin{matrix}H—O—H\\H—O—H\\H—O—H\end{matrix}} + \underset{\text{Triacetine.}}{C_3H_5\begin{cases}C_2H_3O_2.\\C_2H_3O_2.\\C_2H_3O_2.\end{cases}}$$

When the conditions are intermediate, diacetine $\left(C_3H_5\begin{cases}C_2H_3O_2\\C_2H_3O_2\\OH\end{cases}\right)$ is formed.

Monoacetine and diacetine are *basic* compound ethers of glycerine; while triacetine is a *normal* compound ether. Now, the fats and fixed or greasy oils, which are found in such abundance in

many seeds, and in the cellular tissue of animals, are all *normal compound ethers of glycerine*, constituted like triacetine; such compounds are called 'glycerides.' As triacetine is formed by the union of glycerine and acetic acid and the simultaneous separation of water, so we can reverse the process, and by heating triacetine with a large quantity of superheated steam, add water to it, and obtain glycerine and acetic acid. The fats and oils treated in the same way yield glycerine and one or more 'fatty or oily acids.' A similar decomposition takes place, but much more readily, when the fat or oil is treated with caustic potash or caustic soda. In this case, of course, we obtain, not the acid, but its potash or soda salt, and as the potash and soda salts of the fatty and oily acids are *soaps*, this process is called 'saponification,' or soap-making; and a fat or oil is said to be 'saponified' when it is treated with a caustic alkali. In order to separate the soap thus produced from the glycerine formed at the same time, common salt is added to the liquid, when the soap, being insoluble in brine, separates as a curdy solid, leaving the glycerine dissolved. 'Hard soap' has soda, 'soft soap' potash, as base.

The most important 'glycerides' are stearine, palmitine, oleine, and linoleine, which are normal compound ethers of glycerine and stearic, palmitic, oleic, and linoleic acids, respectively. Stearine and palmitine are white solids, melting at 160° F. and 142° F. respectively. Oleine and linoleine are liquids. The ordinary fats, such as suet, lard, tallow, &c. are mixtures of stearine, palmitine, and oleine in various proportions; the harder and less fusible containing most stearine; the softer and more fusible containing most oleine. Olive-oil contains palmitine and oleine; almond-oil, oleine with a small quantity of palmitine. Linoleine occurs in linseed-oil, poppy-oil, hemp-seed oil, and other 'drying oils;' when exposed to the air, it absorbs oxygen, and is converted into a solid varnish. Castor-oil consists almost entirely of ricinoleine, the glyceride of ricinoleic acid. The composition of these fatty and oily acids is given in the following table:

Palmitic Acid	$C_{16}H_{32}O_2$.
Stearic Acid	$C_{18}H_{36}O_2$.
Oleic Acid	$C_{18}H_{34}O_2$.
Linoleic Acid	$C_{16}H_{28}O_2$.
Ricinoleic Acid	$C_{18}H_{34}O_3$.

ORGANIC ACIDS.

We have already mentioned a considerable number of organic acids—namely, acetic, lactic, formic, valerianic, oxalic, stearic, palmitic, oleic, linoleic, and ricinoleic. We shall here name, and very shortly describe a few more.

Succinic Acid, $C_4H_6O_4$, a dibasic acid, obtained by the distillation of amber, by the oxidation of fatty acids, and by the reduction of malic and of tartaric acids.

Malic Acid, $C_4H_6O_5$, a dibasic acid, obtained from the juice of sour apples, currants, rowan-berries, rhubarb, &c.

Tartaric Acid, $C_4H_6O_6$, a dibasic acid. Acid tartrate of potash, $C_4H_5KO_6$, occurs in the juice of the grape. This salt is somewhat sparingly soluble in water, and still less soluble in dilute alcohol; it is therefore deposited as a crystalline crust when the grape-juice is fermented. This crust, which contains, besides bitartrate of potash, tartrate of lime, and colouring-matter, is called tartar or argol. Purified by recrystallisation, it is known as cream of tartar. Tartaric acid is obtained from it by first converting it into tartrate of lime, and decomposing this by sulphuric acid. Tartar emetic is prepared by dissolving antimonious oxide (Sb_2O_3) in a solution of cream of tartar.

Citric Acid, $C_6H_8O_7$, a tribasic acid, occurs in the juice of the orange, lemon, citron, and, along with malic acid, in the currant, gooseberry, raspberry, and many other fruits. It is prepared by neutralising the acid juice with lime, and decomposing the citrate of lime by means of sulphuric acid.

When citric acid is heated, it loses water, and is converted into *aconitic acid*, $C_6H_6O_6$, a tribasic acid, also obtained from the aconite plant, whence its name.

Benzoic Acid, $C_7H_6O_2$, a monobasic acid, is contained in gum-benzoin, and is obtained from it by sublimation. Oil of bitter almonds is a mixture of prussic acid and benzoic aldehyd (C_7H_6O). Benzoic acid when distilled with lime yields *benzol*, C_6H_6; thus, $C_7H_6O_2 + CaO,H_2O = C_6H_6 + CaO,CO_2 + H_2O$.

Gallic Acid, $C_7H_6O_5$, a monobasic acid obtained by the fermentation of the tannin of nut-galls. It produces, when mixed with solutions of ferric salts, a deep blue-black precipitate, which is the basis of ordinary writing ink. With ferrous salts, it produces a white precipitate, which becomes black, owing to oxidation, when exposed to the air.

Tannin or *Tannic Acid*.—This name is applied to a number of substances occurring in nut-galls, oak-bark, catechu, kino, cinchona bark, &c. and having the property of forming an insoluble compound with gelatine.

Uric Acid, $C_5H_4N_4O_3$, a dibasic acid, occurs as urate of soda, and urate of ammonia in the excrements of birds and reptiles, in small quantity in the urine of other animals, in some urinary calculi, and in the 'chalk-stones' which form in the joints of gouty persons. Urate of ammonia forms a large part of guano.

Prussic Acid or *Hydrocyanic Acid*.—If nitrogen gas is passed through a heated mixture of charcoal and caustic potash, carbonic oxide, hydrogen, and a substance having the composition KCN, are formed, thus:

$$2KHO + 4C + N_2 = 2KCN + 2CO + H_2.$$

The potassium in this compound may be replaced by other metals, thus: $KCN + AgNO_3 = AgCN + KNO_3$, and $KCN + HCl = HCN + KCl$. There is thus a series of compounds in which the group CN acts as a monad salt-radical—plays, in fact, the part of Cl. This radical is called cyanogen, and its compounds, cyanides. HCN is hydrocyanic (or prussic) acid; KCN, cyanide of potassium; and so on. Almost all cyanogen compounds are prepared from the substance known as 'yellow prussiate of potash,' or 'ferrocyanide of potassium.' This salt has the composition $4KCN,Fe(CN)_2$, and may be regarded as a compound of cyanide of potassium and ferrous cyanide. It is formed by fusing animal refuse containing nitrogen (such as dried blood, parings of horn, hide, &c.) along with caustic potash and iron, exhausting the mass with water in the presence of air, and concentrating the clear solution, when the

salt crystallises out in large tabular crystals containing two molecules of water of crystallisation. In the fusion, cyanide of potassium is formed by the union of the nitrogen and carbon of the animal matter with the potassium of the potash; and the cyanide of potassium, by the action of water, oxygen, and iron, is converted into the ferrocyanide, thus: $6KCN + Fe + H_2O + O = 2KHO + 4KCN,Fe(CN)_2$. Ferrocyanide of potassium, when treated with dilute sulphuric acid, yields hydrocyanic acid, which, being volatile, can be distilled off from the residue, consisting of sulphate of potash and a substance called 'Everitt's salt.'

Prussic acid is an extremely poisonous substance, and this character belongs also to most of the cyanides. The ferrocyanides are, however, exceptions. By the action of chlorine, ferrocyanide of potassium is converted into ferricyanide of potassium or red prussiate of potash, $4KCN,Fe(CN)_2 + Cl = 3KCN,Fe(CN)_3 + KCl$. The most important cyanides are: Cyanide of potassium, KCN; cyanide of silver, $AgCN$; mercuric cyanide, $Hg(CN)_2$, formed by dissolving mercuric oxide in aqueous hydrocyanic acid, and crystallising. Ferrocyanide and ferricyanide of potassium. Ferric ferrocyanide (Prussian blue) and ferrous ferricyanide (Turnbull's blue). Mercuric cyanide, when heated, decomposes into metallic mercury and cyanogen. Part of the cyanogen passes off as cyanogen gas, $(CN)_2$ or C_2N_2, part remains as brown solid of the same composition, known as paracyanogen. Just as chlorine, when passed into a cold solution of caustic potash, gives chloride of potassium, and hypochlorite of potash, KCl and $KClO$, so cyanogen, under the same conditions, gives cyanide of potassium, KCN, and cyanate of potash, $KCNO$. Cyanate of potash can also be formed by the oxidation of cyanide of potassium by means of red oxide of lead or black oxide of manganese.

ORGANIC BASES.

It has already been pointed out that the alcohols have a great resemblance in their mode of action upon acids to hydrated bases (p. 333); but there are other organic compounds which are much more completely analogous to the bases of inorganic chemistry, forming, with acids, salts, which are usually crystalline, and which undergo double decomposition exactly as the salts of metallic oxides do. Many of these organic bases, or alkaloids, as they are called, are soluble in water, and have an alkaline reaction. Some of them can be formed artificially, and some occur as salts in the juices of various plants. Thus, in opium, the dried juice of the unripe heads of the white poppy (*Papaver somniferum*), there occur salts of morphia, codeia, narcotine, thebaine, papaverine, narceine, and some other less completely investigated alkaloids. The juice of the deadly nightshade (*Atropa belladonna*) contains a salt of the alkaloid atropia. Nux-vomica contains salts of strychnia and brucia; cinchona bark, salts of quina and cinchona; henbane (*Hyoscyamus niger*) contains a salt of hyoscyamine; tobacco (*Nicotiana tabacum*) contains a salt of nicotine; hemlock (*Conium maculatum*), a salt of conia; and so on. In most cases, the plant owes its special action on the animal system, as a poison or drug, to the alkaloid or alkaloids contained in it, so that it is possible to substitute a salt of the alkaloid as a medicine for the extract or tincture of the plant, with the advantage of having a substance of constant composition and action, instead of a mixture which sometimes contains more, sometimes less, of the alkaloid which is its really active ingredient.

For detailed accounts of these vegetable alkaloids, we must refer the reader to the larger handbooks of chemistry. They all contain nitrogen, and may be regarded as ammonia in which the hydrogen has been replaced by organic radicals; thus, trimethylamine, a base which occurs in herring-brine, is $N(CH_3)_3$, corresponding to ammonia, NH_3. The other natural bases have a similar, though, in most cases, a much more complicated constitution.

VOLATILE OR ESSENTIAL OILS

are obtained from many plants by distillation with water, the oil coming over with the water, and collecting in the receiver, partly dissolved in the water, partly floating upon its surface. The watery solution has the odour of the oil. In this way, oil (or *attar*) of roses and rose-water, oil of lavender and lavender water, &c. are prepared. Many of these oils, so different in odour, have the same composition as oil of turpentine—namely, C_5H_8. Of these we may name—oil of lemons, of bergamot, of juniper, of thyme, of parsley. Others contain various volatile substances. Thus, oil of bitter almonds is a mixture of benzoic aldehyd (C_7H_6O) and prussic acid; oil of meadow-sweet is salicylic aldehyd ($C_7H_6O_2$); oil of mustard, C_4H_5NS.

ALBUMINOUS OR PROTEIN COMPOUNDS.

The white of egg consists chiefly of a watery solution of a substance called *albumine;* a similar substance occurs in the serum of blood and in dropsical fluids. *Fibrine* occurs in the clot of blood; *caseine* is that constituent of milk which is curdled by rennet or by the addition of an acid to the milk. These substances have many properties in common, and have nearly the same composition. We now know a considerable number of such bodies. They form essential constituents of animal organisms, and also occur in plants. They are *produced* in the plant from simpler substances. In the animal system they are never formed, but only undergo transformation. They are thus necessary ingredients in the food of animals (see HUMAN PHYSIOLOGY). They exist both in the soluble and in the insoluble condition, and are easily changed from the one to the other. Thus, albumine occurs in solution in white of egg, but when the egg is boiled, the albumen becomes insoluble. Caseine is in solution in milk, but when the milk is curdled, the caseine is rendered insoluble. By the process of digestion in the stomach, insoluble albuminous substances are rendered soluble, and capable of being absorbed. These albuminous substances have an extremely complex composition, and chemists are not yet able to give *formulæ* for them. Analysis gives the following results:

Carbon	52·7	to	54·5	per cent.
Hydrogen	6·9	"	7·3	"
Nitrogen	15·4	"	16·5	"
Oxygen	20·9	"	23·5	"
Sulphur	0·8	"	1·6	"

CHEMISTRY APPLIED TO THE ARTS.

ALMOST every branch of manufacture involves to a greater or less extent chemical principles, so that a complete treatise on chemical technology should contain an account of nearly every manufacturing process, and a discussion of the chemical actions taking place in each. It is obvious that nothing of this kind can be attempted here. We shall confine ourselves to a statement of the chemical principles involved in a few of the more important chemical manufactures, excluding, of course, those to which separate papers are devoted in this series, or which have been sufficiently explained in the article CHEMISTRY.

It is scarcely possible to adopt anything like a systematic arrangement of this subject, but we shall endeavour to keep, as far as possible, allied manufactures together, and to proceed from the less to the more complex. The reader is expected to possess an elementary knowledge of chemistry, such as might be acquired by the study of the paper on CHEMISTRY.

We shall first consider the preparation of sulphuric acid, as that is the starting-point of a large number of chemical manufactures.

Anhydrous sulphuric acid (SO_3) can be prepared by heating certain sulphates. Thus, if bisulphate of soda (H_2O,SO_3,Na_2O,SO_3 or $HNaSO_4$) is heated, it loses water, and is converted into what is called anhydrous bisulphate of soda (Na_2O,SO_3,SO_3). When this substance is very strongly heated, it gives off anhydrous sulphuric acid, and normal sulphate of soda is left. The ferric sulphates are decomposed by heat into ferric oxide and anhydrous sulphuric acid. Thus, $Fe_2O_3,3SO_3 = Fe_2O_3 + 3SO_3$; and a similar decomposition takes place with basic ferric sulphates. Thus, $Fe_2O_3,2SO_3 = Fe_2O_3 + 2SO_3$. It is upon this latter decomposition that the preparation of 'Nordhausen' or 'Saxon' sulphuric acid depends.

Green vitriol or ferrous sulphate has the composition $FeSO_4,7H_2O$ or $FeO,SO_3,7H_2O$; when exposed to heat and air, it absorbs oxygen, and is converted into basic ferric sulphate; thus, $2(FeO,SO_3) + O = Fe_2O_3,2SO_3$, the water of crystallisation being given off. If the oxidation and drying were complete, on distilling the product nothing would be given off but anhydrous sulphuric acid. But in practice this is not so; some water is always left, so that some hydrated sulphuric acid (H_2O,SO_3 or H_2SO_4) is formed, and some ferrous sulphate (FeO,SO_3) is always left unoxidised, which undergoes the following decomposition: $2(FeO,SO_3) = Fe_2O_3 + SO_3 + SO_2$, half of the SO_3 losing oxygen, so as to convert $2FeO$ into Fe_2O_3. The result, therefore, is, that ferric oxide (Fe_2O_3) is left behind, and sulphurous acid (SO_2), anhydrous sulphuric acid (SO_3), and hydrated sulphuric acid (H_2O,SO_3 or H_2SO_4) pass over. The latter unite to form 'fuming' or 'Nordhausen' sulphuric acid ($H_2O,2SO_3$ or $H_2S_2O_7$). The distillation is performed in earthenware retorts, arranged in rows in a furnace, and earthenware jars are used as receivers. This mode of preparing sulphuric acid from 'green vitriol' gave rise to the name 'oil of vitriol,' now generally given to hydrated sulphuric acid.

But by far the largest part of the sulphuric acid of commerce is prepared from sulphurous acid.

The sulphurous acid is made either by burning sulphur ($S + O_2 = SO_2$), or, more commonly, by burning iron pyrites (FeS_2). When this mineral is heated in presence of air, it burns, giving out a great deal of heat, and forms ferric oxide and sulphurous acid; thus, $2FeS_2 + 7O = Fe_2O_3 + 2SO_2$. The sulphurous acid gas, prepared in either way, is led by a wide pipe into a series of large chambers lined with lead, into which nitric acid, atmospheric air, and steam, are also conducted. The action which takes place is represented by the following equations:

$$(1.)\ 3SO_2 + H_2O,N_2O_5 + 2H_2O = 3(H_2O,SO_3) + 2NO.$$

The sulphuric acid (H_2O,SO_3) falls down as a fine rain to the bottom of the chamber, while the nitric oxide (NO) (see CHEMISTRY) immediately unites with oxygen from the air to form peroxide of nitrogen, thus:

$$(2.)\ NO + O = NO_2.$$

The peroxide of nitrogen then acts on sulphuric acid and water, thus:

$$(3.)\ NO_2 + H_2O + SO_2 = NO + H_2O,SO_3.$$

The sulphuric acid thus formed falls to the floor of the chamber, and the nitric acid (NO) unites with oxygen from the air, as in (2). If atmospheric air is admitted in sufficient quantity, the actions (2) and (3) go on continuously, a limited quantity of oxide of nitrogen being able to convert an unlimited quantity of sulphurous acid and water into sulphuric acid; the nitrogen oscillating between two states of oxidation, NO and NO_2, the latter giving oxygen to the sulphurous acid, and the former taking oxygen from the air. The gas in the chambers, therefore, becomes poorer in sulphurous acid and oxygen as it proceeds onwards, until at last it contains no sulphurous acid, and consists almost entirely of nitrogen from the atmospheric air and of peroxide of nitrogen. As will be presently seen, the gas leaving the chambers should contain no nitric oxide, and to insure this, there should be a little oxygen. It is obvious that if the peroxide of nitrogen can be extracted from the effluent gas, it may be used over again to effect the oxidation of a new quantity of sulphurous acid. This extraction is effected in the following way: Peroxide of nitrogen is soluble in *strong*, but not in *dilute* sulphuric acid. The effluent gas is, therefore, sent up a tower, or wide chimney, which is packed with fragments of coke. Down this tower a stream of strong sulphuric acid is poured, trickling through the coke. The gas is thus freed from the peroxide

of nitrogen, and only atmospheric nitrogen, with any excess of oxygen which may be present, escapes at the top of the tower. As nitric oxide is not soluble in sulphuric acid, it would also escape, and thus be lost, if it were not all converted into peroxide of nitrogen before leaving the last chamber. The solution of peroxide of nitrogen is conducted back to the first chamber, where the actions (3) (2) are again commenced. It will be seen that, theoretically, a given quantity of nitric acid should be able to convert an unlimited quantity of sulphurous acid, water, and oxygen, into sulphuric acid. In practice, however, this is not the case, and it is necessary to supply new nitric acid from time to time to compensate for loss. This loss occurs (not to speak of accidental leakage) from two causes: 1. Part of the nitric oxide, even in the presence of excess of oxygen, is reduced to nitrous oxide (N_2O), which, not being directly oxidisable, takes no further part in the action, and escapes with the nitrogen from the top of the tower. 2. The sulphuric acid on the floor of the chamber, although not strong enough to dissolve peroxide of nitrogen, dissolves some *nitric acid*, which is removed with it from the chamber. The admission of steam to the chambers must be so regulated, that the sulphuric acid on the floor has the specific gravity 1·5, which corresponds to 60 per cent. of hydrated sulphuric acid (H_2O,SO_3), and 40 per cent. water. If the acid is stronger than this, the oxidation does not take place regularly; and if it is weaker, it dissolves sulphurous acid. The 'chamber acid' is concentrated by heating it in glass or platinum vessels, until it has a specific gravity 1·83, corresponding to about 92 per cent. of hydrated sulphuric acid. The concentration can be carried on up to specific gravity 1·75 in lead vessels; acid stronger than this acts rapidly on lead at high temperatures.

Sulphuric acid thus prepared contains various impurities: 1. Sulphate of lead, derived from a slight action on the lead of the chambers, or on the lead-pan used for concentration; sulphate of lead, being insoluble in dilute sulphuric acid, is precipitated as a white powder when sulphuric acid containing it is mixed with water. 2. Nitric acid. 3. Arsenic, derived from the iron pyrites, which always contains traces of arsenic. Sulphuric acid prepared from *sulphur* does not contain arsenic.

MANUFACTURE OF SODA.

Carbonate of soda occurs naturally in Hungary, North Africa, and Mexico. It is found either as a crystalline crust, left by the evaporation of the water of lakes containing the salt in solution, or mixed with earth. In the latter case, the earth is exhausted with water, and the solution evaporated. The North African soda, from Egypt and Fezzan, has been long known under the names 'natron' and 'trona.' It is the substance mentioned in the Bible (Proverbs xxv. 20; Jeremiah ii. 22) as nitre: the reader will see, on referring to the passages, that the meaning becomes at once clear if we read 'washing-soda,' instead of 'nitre.'

Another long-known source of soda is the ash of certain plants. Just as most land-plants contain organic salts of potash, which, when the plants are burnt, are converted into carbonate of potash, which can be extracted from the ash—so sea-weeds and some plants growing on the sea-shore contain organic salts of soda, and in precisely the same way their ashes yield carbonate of soda. 'Barilla' is the crude carbonate of soda obtained in Spain from the ash of the sea-side plant, *Salsola soda;* and in France, 'salicor' and 'blanquette' are similarly obtained from the ashes of *Salicornia annua* and other shore-plants. 'Kelp,' the ash of various sea-weeds gathered and burnt on the northern and western shores of Scotland and Ireland, also contains carbonate of soda, but is chiefly prepared on account of the iodides contained in it (see CHEMISTRY).

But by far the greater part of the soda of commerce is prepared from common salt (chloride of sodium), by what is called, from its inventor, 'Leblanc's process.'

The salt is first heated with sulphuric acid, and thus converted into sulphate of soda; the hydrochloric acid evolved being condensed in coke towers, down which a stream of water flows:

$$NaCl + H_2SO_4 = HCl + NaHSO_4 \text{ and}$$
$$NaCl + NaHSO_4 = HCl + Na_2SO_4.$$

(See CHEMISTRY.) The sulphate of soda, known as 'salt-cake,' is then mixed with coal and limestone in the proportion of about 2 parts salt-cake, 2 limestone, and rather more than 1 coal. The mixture is heated in a reverberatory furnace, and thoroughly stirred with an iron instrument. After about an hour's heating, it is removed, and allowed to cool. In this state it is called 'black ball.' The precise course of the chemical change is not yet certainly ascertained, but the final result is, that the 'black ball' consists chiefly of carbonate of soda and a compound of lime with sulphide of calcium ($3CaS,CaO$), along with some caustic soda and charcoal. By treatment with water, the carbonate of soda and caustic soda are dissolved, while the oxysulphide of calcium and the charcoal are left behind. The clear solution is then evaporated, and the dried residue is known in commerce as 'soda-ash.'

'Soda crystals,' or 'washing-soda,' is prepared from soda-ash by dissolving it in hot water, and allowing the solution to crystallise, when nearly pure carbonate of soda crystallises out with 10 molecules of water of crystallisation ($Na_2O,CO_2,10H_2O$ or $Na_2CO_3,10H_2O$), almost all the impurities remaining in the mother-liquor (see CHEMISTRY). 'Bicarbonate of soda,' or 'baking-soda,' is prepared by treating soda crystals with carbonic acid gas.

The residue left, on dissolving out the carbonate of soda from the 'black ball,' consisting chiefly of oxysulphide of calcium (the compound of lime and sulphide of calcium), is called 'soda-waste,' and has long been a source of great annoyance to soda manufacturers and their neighbours. It accumulates in vast mounds round the works, and gives off sulphuretted hydrogen whenever acid liquids come in contact with it.

There are now various methods in use by which the sulphur is recovered from the waste, so that it can be used again in the manufacture of sulphuric acid.

These methods are in principle the same, and consist in the oxidation of the waste by means of atmospheric oxygen, and in the precipitation of

the sulphur from the solution of the oxidised waste by means of hydrochloric acid.

Caustic Soda is formed from soda-ash by dissolving it in water, and adding slaked lime, when carbonate of lime falls as an insoluble white powder, leaving caustic soda in solution. This solution is either used as such, or boiled down to a solid mass. The action is:

$$Na_2O,CO_2 + CaO,H_2O = Na_2O,H_2O + CaO,CO_2 \text{ or}$$
$$\underset{\text{Carbonate of Soda.}}{Na_2CO_3} + \underset{\text{Slaked Lime.}}{CaH_2O_2} = \underset{\text{Caustic Soda.}}{2NaHO} + \underset{\text{Carbonate of Lime.}}{CaCO_3}.$$

Caustic soda is also often prepared direct from the 'black ball,' which, for this purpose, is made from a mixture containing a larger quantity of coal than is used for preparing soda-ash.

Bleaching-powder.—Slaked lime readily absorbs chlorine gas, forming a substance called 'chloride of lime,' or bleaching-powder. This substance may be regarded as a mixture, or compound of chloride of calcium ($CaCl_2$), hypochlorite of lime (CaO,Cl_2O or $CaCl_2O_2$), and slaked lime (CaO,H_2O). Exposed to the air, it gives off hypochlorous acid, the hypochlorite of lime being decomposed by the carbonic acid of the air. When treated with sulphuric acid, sulphate of lime is formed; and if only so much acid is added as is required to neutralise the slaked lime, and decompose the hypochlorite, hypochlorous acid is given off; but if a larger quantity of acid is added, the chloride of calcium is also decomposed, and the hydrochloric acid produced in this decomposition acts on the hypochlorous acid, and produces chlorine:

$$2HCl + Cl_2O = H_2O + 2Cl_2.$$

Other strong acids act in the same way.

BLEACHING.

The bleaching of vegetable or animal fibre, yarn, or cloth, consists in the destruction or removal of the colouring-matter naturally accompanying the fibre, so as to leave the latter white. Along with this, we may conveniently consider the discharging—that is, removal or destruction of colouring-matter artificially added to the fibre. In bleaching vegetable fibres, or the yarn or cloth made from them, two distinct things have to be attended to—first, the removal of fatty or oily matters, either originally present, or introduced in the processes of spinning or weaving; and second, the destruction of those colouring-matters which are not removed along with the oil. The removal of the oil is effected by boiling with alkalies—by which a soap is formed (see p. 349), which is washed out with water. This washing removes along with the soap the dirt which the oil kept fixed to the fibre. There still, however, remains a yellowish colouring-matter, which must be destroyed if the cloth is to be rendered quite white. This may be done either by the old process of grass-bleaching, in which the cloth is spread in a moist state upon grass, and exposed for several days to the action of the air, or by means of wet chlorine or hypochlorous acid. In either case, the colouring-matter is destroyed by *oxidation*. In grass-bleaching it is probable that the oxidation of the colouring-matter is caused by the *ozone* (see CHEMISTRY) that is present in the air.

In order to understand how chlorine along with water can act as an oxidising agent, we must recollect that chlorine and hydrogen readily enter into combination to form hydrochloric acid. If a solution of chlorine gas in water is exposed to light, the chlorine slowly displaces the oxygen—hydrochloric acid is formed, and oxygen is set free. Now, this decomposition of water takes place only slowly, and only when the mixture is exposed to bright light, *if no oxidisable substance is present.* But very many oxidisable substances, even such as are not easily oxidised by means of free oxygen, assist the chlorine to decompose the water; so that, the constituents of the water being, so to speak, pulled in opposite directions, the chlorine takes the hydrogen, forming hydrochloric acid, and the oxidisable substance is oxidised. It is in this way the chlorine bleaches, and it will be at once seen that water is essential in the process. This can easily be shewn by placing a piece of cloth, dyed with a vegetable colour—turkey-red, for instance—in a jar of chlorine gas; if part of the cloth be wet with water, and part left dry, it will be found that, in a few minutes, the wet parts have become white, while the dry parts remain red. Hypochlorous acid acts also as a bleaching agent, by oxidising the colouring-matter, $Cl_2O + H_2O$ becoming $2HCl + O_2$—the oxygen not being given off as gas, but acting upon the colouring-matter. Most vegetable colouring-matters are converted by such oxidation into colourless substances; or, at all events, are rendered soluble in water, so that they can be washed away.

In practice, cotton cloth, after having been boiled in alkaline solutions, and washed, is soaked in a very dilute solution of bleaching-powder, and then 'soured'—that is, passed through water containing a small quantity of acid (sulphuric or hydrochloric). The acid, acting on the bleaching-powder, produces chlorine, which bleaches the cloth in the way explained above. The excess of chlorine, or hypochlorous acid, must be got rid of, as, if left long in contact with the cloth, it injures the fibre. This is done by means of washing with water, or by treating the cloth with what is technically called an 'antichlor'—that is, some substance which will convert the chlorine into a harmless compound. Sulphite of soda and hyposulphite of soda are the substances mostly used for this purpose. They are oxidised by the moist chlorine, the chlorine becoming hydrochloric acid, which can be neutralised by an alkali and washed out.

Chlorine and hypochlorous acid are not only used to bleach cloth or vegetable fibre, but also to discharge colours with which the cloth has been dyed. If this discharging is confined to definite parts of the cloth, a white pattern can be produced on a coloured ground. This is effected by printing the pattern on the cloth with a mixture of tartaric or citric acid and gum. The cloth is then passed through a dilute solution of bleaching-powder, when the acid sets free chlorine upon the parts printed; and by the oxidising action explained above, the colour is discharged from these parts.

Animal fibres (silk, wool) cannot be bleached by means of chlorine, as that substance exerts a destructive action upon them. The only materials used in bleaching wool and silk are water, soap, carbonate of soda, and sulphurous acid.

COLOURING-MATTERS.

The object of dyeing is to give a fast colour to animal or vegetable fibres or fabrics made from them. It differs from painting or mere staining in that the colour is fast—that is, so fixed to or in the fibre that it cannot be washed off or out by water or soap. In painting, on the contrary, the colouring-matter is mechanically spread upon the object to be painted. As, however, many colouring-matters are used both in dyeing and in painting, we shall first give a description of the most important colouring-matters, without reference to their special use.

Colouring-matters, among which, for convenience, we have included white paints, may be most conveniently divided into Inorganic and Organic.

Of the Inorganic, the most important are :
